Abstract

We propose a novel algorithm for the solution of mean-payoff games that merges together two seemingly unrelated concepts introduced in the context of parity games, small progress measures and quasi dominions. We show that the integration of the two notions can be highly beneficial and significantly speeds up convergence to the problem solution. Experiments show that the resulting algorithm performs orders of magnitude better than the asymptotically-best solution algorithm currently known, without sacrificing on the worst-case complexity.

1. Introduction

In this article we consider the problem of solving mean-payoff games, namely infinite-duration perfect-information two-player games played on weighted directed graphs, each of whose vertexes is controlled by one of the two players. The game starts at an arbitrary vertex and, during its evolution, each player can take moves at the vertexes it controls, by choosing one of the outgoing edges. The moves selected by the two players induce an infinite sequence of vertexes, called play. The payoff of any prefix of a play is the sum of the weights of its edges. A play is winning if it satisfies the game objective, called mean-payoff objective, which requires that the limit of the mean payoff, taken over the prefixes lengths, never falls below a given threshold \( \nu \).

Mean-payoff games have been first introduced and studied by Ehrenfeucht and Mycielski in [20], who showed that positional strategies suffice to obtain the optimal value. A slightly generalized version was also considered by Gurvich et al. in [24]. Positional determinacy entails that the decision problem for these games lies in \textsc{NPTIME} \cap \textsc{CoNPTIME} [34], and it was later shown to belong to \textsc{UPTIME} \cap \textsc{CoUPTIME} [25], being \textsc{UPTIME} the class of unambiguous non-deterministic polynomial time. This result gives the problem a rather peculiar complexity status, shared by very few other problems, such as integer factorization [22], [1] and parity games [25]. Despite various attempts [7], [19], [24], [30], [34], no polynomial-time algorithm for the mean-payoff game problems is known so far.

A different formulation of the game objective allows to define another class of quantitative games, known as energy games. The energy objective requires that, given an initial value \( c \), called credit, the sum of \( c \) and the payoff of every prefix of the play never falls below 0. These games, however, are tightly connected to mean-payoff games, as the two type of games have been proved to be log-space equivalent [11]. They are also related to other more complex forms of quantitative games. In particular, unambiguous polynomial-time reductions [25] exist from these games to discounted payoff [34] and simple stochastic games [18].

Recently, a fair amount of work in formal verification has been directed to consider, besides correctness properties of computational systems, also quantitative specifications, in order to express performance measures and resource requirements, such as quality of service, bandwidth and power consumption and, more generally, bounded resources. Mean-payoff and energy games also have important practical applications in system verification and synthesis. In [14] the authors show how quantitative aspects, interpreted as penalties and rewards associated to the system choices, allow for expressing optimality
requirements encoded as mean-payoff objectives for the automatic synthesis of systems that also satisfy parity objectives. With similar application contexts in mind, [9] and [8] further contribute to that effort, by providing complexity results and practical solutions for the verification and automatic synthesis of reactive systems from quantitative specifications expressed in linear time temporal logic extended with mean-payoff and energy objectives. Further applications to temporal networks have been studied in [16] and [15]. Consequently, efficient algorithms to solve mean-payoff games become essential ingredients to tackle these problems in practice.

Several algorithms have been devised in the past for the solution of the decision problem for mean-payoff games, which asks whether there exists a strategy for one of the players that grants the mean-payoff objective. The very first deterministic algorithm was proposed in [34], where it is shown that the problem can be solved with \( O(n^3 \cdot m \cdot W) \) arithmetic operations, with \( n \) and \( m \) the number of positions and moves, respectively, and \( W \) the maximal absolute weight in the game. A strategy improvement approach, based on iteratively adjusting a randomly chosen initial strategy for one player until a winning strategy is obtained, is presented in [31], which has an exponential upper bound. The algorithm by Lifshits and Pavlov [29], which runs in time \( O(n \cdot m \cdot 2^n \cdot \log W) \), computes the “potential” of each game position, which corresponds to the initial credit that the player needs in order to win the game from that position. Algorithms based on the solution of linear feasibility problems over the tropical semiring have been also provided in [2]–[4]. The best known deterministic algorithm to date, which requires \( O(n \cdot m \cdot W) \) arithmetic operations, was proposed by Brim et al. [13]. They adapt to energy and mean-payoff games the notion of progress measures [28], as applied to parity games in [26]. The approach was further developed in [17] to obtain the same complexity bound for the optimal strategy synthesis problem. A strategy-improvement refinement of this technique has been introduced in [12]. Finally, Bjork et al. [6] proposed a randomized strategy-improvement based algorithm running in time \( \min\{O(n^2 \cdot m \cdot W), 2^{O(\sqrt{n} \log n)}\} \).

Our contribution is a novel mean-payoff progress measure approach that enriches such measures with the notion of quasi dominions, originally introduced in [5] for parity games. These are sets of positions with the property that as long as the opponent chooses to play to remain in the set, it loses the game for sure, hence its best choice is always to try to escape. A quasi dominion from where is not possible escaping is a winning set for the other player. Progress measure approaches, such as the one of [13], typically focus on finding the best choices of the opponent and little information is gathered on the other player. In this sense, they are intrinsically asymmetric. Enriching the approach with quasi dominions can be viewed as a way to also encode the best choices of the player, information that can be exploited to speed up convergence significantly. The main difficulty here is that suitable lift operators in the new setting do not enjoy monotonicity. Such a property makes proving completeness of classic progress measure approaches almost straightforward, as monotonic operators do admit a least fixpoint. Instead, the lift operator we propose is only inflationary (specifically, non-decreasing) and, while still admitting fixpoints [10], [33], need not have a least one. Hence, providing a complete solution algorithm proves more challenging. The advantages, however, are significant. On the one hand, the new algorithm still enjoys the same worst-case complexity of the best known algorithm for the problem proposed in [13]. On the other hand, we show that there exist families of games on which the classic approach requires a number of operations that can be made arbitrarily larger than the one required by the new approach. Experimental results also witness the fact that this phenomenon is by no means isolated, as the new algorithm performs orders of magnitude better than the algorithm developed in [13].

2. Mean-Payoff Games

A two-player turn-based arena is a tuple \( \mathcal{A} = (P_{S\oplus}, P_{S\ominus}, M_v) \), with \( P_{S\oplus} \cap P_{S\ominus} = \emptyset \) and \( P_S \triangleq P_{S\oplus} \cup P_{S\ominus} \), such that \( (P_S, M_v) \) is a finite directed graph without sinks. \( P_{S\oplus} \) (resp., \( P_{S\ominus} \)) is the set of
positions of player \( \oplus \) (resp., \( \square \)) and \( Mv \subseteq \text{Ps} \times \text{Ps} \) is a left-total relation describing all possible moves. A path in \( V \subseteq \text{Ps} \) is a finite or infinite sequence \( \pi \in \text{Pth} \) of positions in \( V \) compatible with the move relation, i.e., \( (\pi_i, \pi_{i+1}) \in Mv \), for all \( i \in [0,|\pi| - 1] \). A positional strategy for player \( \alpha \in \{\oplus, \square\} \) on \( V \subseteq \text{Ps} \) is a function \( \sigma_\alpha \in \text{Str}_\alpha(V) \subseteq (V \cap P_{\text{sa}}) \rightarrow \text{Ps} \), mapping each \( \alpha \)-position \( v \) in the domain of \( \sigma_\alpha \) to position \( \sigma_\alpha(v) \) compatible with the move relation, i.e., \( (v, \sigma_\alpha(v)) \in Mv \). With \( \text{Str}_\alpha(V) \) we denote the set of all \( \alpha \)-strategies on \( V \), while \( \text{Str}_\alpha \) denotes \( \bigcup_{V \subseteq \text{Ps}} \text{Str}_\alpha(V) \). A play in \( V \subseteq \text{Ps} \) from a position \( v \in V \) w.r.t. a pair of strategies \( (\sigma_\oplus, \sigma_\square) \in \text{Str}_\oplus(V) \times \text{Str}_\square(V) \), called \( ((\sigma_\oplus, \sigma_\square), v) \)-play, is a path \( \pi \in \text{Pth}(V) \) such that \( \pi_0 = v \) and, for all \( i \in [0,|\pi| - 1] \), if \( \pi_i \in \text{Ps}_\oplus \) then \( \pi_{i+1} = \sigma_\oplus(\pi_i) \) else \( \pi_{i+1} = \sigma_\square(\pi_i) \). The play function \( \text{play} : (\text{Str}_\oplus(V) \times \text{Str}_\square(V)) \times V \rightarrow \text{Pth}(V) \) returns, for each position \( v \in V \) and pair of strategies \( (\sigma_\oplus, \sigma_\square) \in \text{Str}_\oplus(V) \times \text{Str}_\square(V) \), the maximal \( ((\sigma_\oplus, \sigma_\square), v) \)-play \( (\sigma_\oplus, \sigma_\square), v \). If a pair \( (\sigma_\oplus, \sigma_\square) \in \text{Str}_\oplus(V) \times \text{Str}_\square(V) \) induces a finite play starting from position \( v \in V \), then \( \text{play}((\sigma_\oplus, \sigma_\square), v) \) identifies the maximal prefix of that play that is contained in \( V \).

A mean-payoff game (MPG for short) is a tuple \( \mathcal{G} = (A, \text{Wg}, \text{wg}) \), where \( A \) is an arena, \( \text{Wg} \subseteq Z \) is a finite set of integer weights, and \( \text{wg} : \text{Ps} \rightarrow \text{Wg} \) is a weight function assigning a weight to each position. \( \text{Ps}^+ \) (resp., \( \text{Ps}^- \)) denotes the set of position-positive weights (resp., non-position-positive weights). For convenience, we shall refer to non-positive weights as negative weights. Notice that this definition of MPG is equivalent to the classic formulation in which the weights label the moves, instead. The weight function naturally extends to paths, by setting \( \text{wg}(\pi) \triangleq \sum_{i=0}^{|\pi|-1} \text{wg}(\pi_i) \). The goal of player \( \oplus \) (resp., \( \square \)) is to maximize (resp., minimize) \( \nu(\pi) \triangleq \lim_{i \rightarrow \infty} \frac{1}{i} \cdot \text{wg}(\pi_{\leq i}) \), where \( \pi_{\leq i} \) is the prefix up to index \( i \). Given a threshold \( \nu \), a set of positions \( V \subseteq \text{Ps} \) is a \( \oplus \)-dominion, if there exists a \( \oplus \)-strategy \( \sigma_\oplus \in \text{Str}_\oplus(V) \) such that, for all \( \square \)-strategies \( \sigma_\square \in \text{Str}_\square(V) \) and positions \( v \in V \), the induced play \( \pi = \text{play}((\sigma_\oplus, \sigma_\square), v) \) satisfies \( \nu(\pi) > \nu \). The pair of winning regions \( (W_{\text{in} \oplus}, W_{\text{in} \square}) \) forms a \( \nu \)-mean partition. Assuming \( \nu \) integer, the \( \nu \)-mean partition problem is equivalent to the \( 0 \)-mean partition one, as we can subtract \( \nu \) to the weights of all the positions. As a consequence, the MPG decision problem can be equivalently restated as deciding whether player \( \oplus \) (resp., \( \square \)) has a strategy to enforce \( \lim_{i \rightarrow \infty} \frac{1}{i} \cdot \text{wg}(\pi_{\leq i}) > 0 \) (resp., \( \lim_{i \rightarrow \infty} \frac{1}{i} \cdot \text{wg}(\pi_{\leq i}) \leq 0 \)), for all the resulting plays \( \pi \).

3. Solving Mean-Payoff Games via Progress Measures

The abstract notion of progress measure [28] has been introduced as a way to encode global properties on paths of a graph by means of simpler local properties of adjacent vertexes. In the context of MPG, the graph property of interest, called mean-payoff property, requires that the mean payoff of every infinite path in the graph be non-positive. More precisely, in game theoretic terms, a mean-payoff progress measure witnesses the existence of strategy \( \sigma_\square \) for player \( \square \) such that each path in the graph induced by fixing that strategy on the arena satisfies the desired property. A mean-payoff progress measure associates with each vertex of the underlying graph a value, called measures, taken from the set of extended natural numbers \( \mathbb{N}_\infty \triangleq \mathbb{N} \cup \{\infty\} \), endowed with an ordering relation \( \leq \) and an addition operation \( + \), which extend the standard ordering and addition over the naturals in the usual way. Measures are associated with positions in the game and the measure of a position \( v \) can intuitively be interpreted as an estimate of the payoff that player \( \oplus \) can enforce on the plays starting in \( v \). In this sense, they measure “how far” \( v \) is from satisfying the mean-payoff property, with the maximal measure \( \infty \) denoting failure of the property for \( v \). More precisely, the \( \square \)-strategy induced by a progress measure ensures that measures do not increase along the paths of the induced graph. This, in turn, ensures that every path eventually gets trapped in a non-positive-weight cycle, thereby witnessing a win for player \( \square \). To obtain a progress measure, one starts from some suitable association of position of the game with measures. The local information encoded by these measures is then propagated back along the edges of the underlying graph so as to associate with each position the information gathered along plays of some finite length starting from that position. The propagation process is performed according to the following
intuition. The measures of positions adjacent to \( v \) are propagated back to \( v \) only if those measures push \( v \) further away from the property. This propagation is achieved by means of a measure stretch operation \( + \), which adds, when appropriate, the weight of an adjacent position to the measure of a given position. This is established by comparing the measure of \( v \) with those of its adjacent positions, since, for each position \( v \), the mean-payoff property is defined in terms of the sum of the weights encountered along the plays from that position. The process ends when no position can be pushed further away from the property and each position is not dominated by any, respectively one, of its adjacents, depending on whether that position belongs to player \( \oplus \) or to player \( \square \), respectively. The positions that did not reach measure \( \infty \) are those from which player \( \square \) can win game and the set of measures currently associated with such positions forms a mean-payoff progress measure for the game.

To make the above intuitions precise, we introduce the notion of measure function, progress measure, and an algorithm for computing progress measures correctly. It is worth noticing that the progress-measure based approach as described in [13], called SEPM from now on, can be easily recast equivalently in the form below. A measure function \( \mu: \text{Ps} \to \mathbb{N}_\infty \) maps each position \( v \) in the game to a suitable measure \( \mu(v) \). The order \( \preceq \) of the measures naturally induces a pointwise partial order \( \sqsubseteq \) on the measure functions defined in the usual way, namely, for any two measure functions \( \mu_1 \) and \( \mu_2 \), we write \( \eta_1 \sqsubseteq \eta_2 \) if \( \mu_1(v) \leq \mu_2(v) \), for all positions \( v \). The set of measure functions over a measure space, together with the induced ordering \( \sqsubseteq \), forms a measure-function space.

**Definition 1** (Measure-Function Space). The measure-function space is the partial order \( \mathcal{F} \triangleq (\text{MF}, \sqsubseteq) \) whose components are defined as reported in the following:

1. \( \text{MF} \triangleq \text{Ps} \to \mathbb{N}_\infty \) is the set of all functions \( \mu \in \text{MF} \), called measure functions, mapping each position \( v \in \text{Ps} \) to a measure \( \mu(v) \in \mathbb{N}_\infty \);
2. for all \( \mu_1, \mu_2 \in \text{MF} \), it holds that \( \mu_1 \sqsubseteq \mu_2 \) if \( \mu_1(v) \leq \mu_2(v) \), for all positions \( v \in \text{Ps} \).

The \( \oplus \)-notation (resp., \( \square \)-notation) of a measure function \( \mu \in \text{MF} \) is the set \( \|\mu\|_{\oplus} \triangleq \mu^{-1}(\infty) \) (resp., \( \|\mu\|_{\square} \triangleq \mu^{-1}(\infty) \)) of all positions having maximal (resp., non-maximal) measure associated within \( \mu \).

Assuming that a given position \( v \) has an adjacent with measure \( \eta \), a measure update of \( \eta \) w.r.t. \( v \) is obtained by the stretch operator \( +: \mathbb{N}_\infty \times \text{Ps} \to \mathbb{N}_\infty \), defined as

\[ \eta + v \triangleq \max\{0, \eta + \text{wg}(v)\}, \]

which corresponds to the payoff estimate that the given position will obtain by choosing to follow the move leading to the prescribed adjacent.

A mean-payoff progress measure is such that the measure associated with each game position \( v \) needs not be increased further in order to beat the actual payoff of the plays starting from \( v \). In particular, it can be defined by taking into account the opposite attitude of the two players in the game. While the player \( \oplus \) tries to push toward higher measures, the player \( \square \) will try to keep the measures as low as possible. A measure function in which the payoff of each \( \oplus \)-position (resp., \( \square \)-position) \( v \) is not dominated by the payoff of all (resp., some of) its adjacents augmented with the weight of \( v \) itself meets the requirements.

**Definition 2** (Progress Measure). A measure function \( \mu \in \text{MF} \) is a progress measure if the following two conditions hold true, for all positions \( v \in \text{Ps} \):

1. \( \mu(u) + v \leq \mu(v) \), for all adjacents \( u \in \text{Mv}(v) \) of \( v \), if \( v \in \text{Ps}_{\oplus} \);
2. \( \mu(u) + v \leq \mu(v) \), for some adjacent \( u \in \text{Mv}(v) \) of \( v \), if \( v \in \text{Ps}_{\square} \).

The following theorem states the fundamental property of progress measures, namely, that every position associated with a non-maximal value is won by player \( \square \).

**Theorem 1** (Progress Measure). Let \( \mu \in \text{MF} \) be a progress measure. Then, \( \|\mu\|_{\square} \subseteq W_{\text{N}_{\square}} \).
In order to obtain a progress measure from a given measure function, one can iteratively adjust the current measure values in such a way to force the progress condition above among adjacent positions. To this end, we define the lift operator \( \text{lift}: \text{MF} \rightarrow \text{MF} \) as follows:

\[
\text{lift}(\mu)(v) \triangleq \begin{cases} 
\max\{\mu(w) + v : w \in Mv(v)\}, & \text{if } v \in P_{S \oplus}; \\
\min\{\mu(w) + v : w \in Mv(v)\}, & \text{otherwise}.
\end{cases}
\]

Note that the lift operator is clearly monotone and, therefore, admits a least fixpoint. A mean-payoff progress measure can, then, be obtained by repeatedly applying this operator until a fixpoint is reached, starting from the minimal measure function \( \mu_0 \triangleq \{ v \in P \mapsto 0 \} \) that assigns measure 0 to all the positions in the game. The following solver operator applied to \( \mu_0 \) computes the desired solution:

\[
\text{sol} \triangleq \text{lfp } \mu \cdot \text{lift}(\mu): \text{MF} \rightarrow \text{MF}.
\]

Observe that the measures generated by the procedure outlined above have a fairly natural interpretation. Each positive measure, indeed, under-approximates the weight that player \( \oplus \) can enforce along finite prefixes of the plays from the corresponding positions. This follows from the fact that, while player \( \oplus \) maximizes its measures along the outgoing moves, player \( \ominus \) minimizes them. In this sense, each positive measure witnesses the existence of a positively-weighted finite prefix of a play that player \( \oplus \) can enforce. Let \( S \triangleq \sum\{w_g(v) \in \mathbb{N} : v \in P_{S} \land w_g(v) > 0\} \) be the sum of all the positive weights in the game. Clearly, the maximal payoff of a simple play in the underlying graph cannot exceed \( S \). Therefore, a measure greater than \( S \) witnesses the existence of a cycle whose payoff diverges to infinity and is won, thus, by player \( \oplus \). Hence, any measure strictly greater than \( S \) can be substituted with the value \( \infty \). This observation established the termination of the algorithm and is instrumental to its completeness proof. Indeed, at the fixpoint, the measures actually coincide with the highest payoff player \( \oplus \) is able to guarantee. Soundness and completeness of the above procedure have been established in \cite{13}, where the authors also show that, despite the algorithm requiring \( O(n \cdot S) = O(n^2 \cdot W) \) lift operations in the worst-case, with \( n \) the number of positions and \( W \) the maximal positive weight in the game, the overall cost of these lift operations is \( O(S \cdot m \cdot \log S) = O(n \cdot m \cdot W \cdot \log(n \cdot W)) \), with \( m \) the number of moves and \( O(\log S) \) the cost of each arithmetic operation necessary to compute the stretch of the measures.

4. Solving Mean-Payoff Games via Quasi Dominions

Let us consider the simple example game depicted in Figure 1, where the shape of each position indicates the owner, circles for player \( \oplus \) and square for its opponent \( \ominus \), and, in each label of the form \( \ell/w \), the letter \( w \) corresponds to the associated weight, where we assume \( k > 1 \). Starting from the smallest measure function \( \mu_0 = \{ a, b, c, d \mapsto 0 \} \), the first application of the lift operator returns \( \mu_1 = \{ a \mapsto \text{lfp } \mu \cdot \text{lift}(\mu_0) \} \). After that step, the following iterations of the fixpoint alternatively updates positions \( c \) and \( d \), since the other ones already satisfy the progress condition. Being \( c \in P_{S \oplus} \), the lift operator chooses for it the measure computed along the move \( (c, d) \), thus obtaining \( \mu_2(c) = \text{lift}(\mu_1)(c) = \mu_1(d) = 1 \). Subsequently, \( d \) is updated to \( \mu_3(d) = \text{lift}(\mu_2)(d) = \mu_2(c) + 1 = 2 \). A progress measure is obtained after exactly \( 2k + 1 \) iterations, when the measure of \( c \) reaches value \( k \) and \( d \) value \( k + 1 \). Note, however, that the choice of the move \((c, d)\) is clearly a losing strategy for player \( \ominus \), as remaining in the highlighted region would make the payoff from position \( c \) diverge. Therefore, the only reasonable choice for player \( \ominus \) is to exit from that region by taking the move leading to position \( a \). An operator able to diagnose this phenomenon early on could immediately discard the move \((c, d)\) and jump directly to the correct payoff obtained by choosing the move to position \( a \). As we shall see, such an operator might lose the monotonicity property and recovering the completeness of the resulting approach will prove more involved.
In the rest of this article we shall devise a progress operator that does precisely that. To this end, we start by providing a notion of quasi dominion, originally introduced for parity games in [5], which can be exploited in the context of MPGs.

**Definition 3 (Quasi Dominion).** An arbitrary set of positions $Q \subseteq \mathcal{P}$ is a quasi $\oplus$-dominion if there exists a $\oplus$-strategy $\sigma_{\oplus} \in \text{Str}_{\oplus}(Q)$, called $\oplus$-witness for $Q$, such that, for all $\square$-strategies $\sigma_{\square} \in \text{Str}_{\square}(Q)$ and positions $v \in Q$, the induced play $\pi = \text{play}(\sigma_{\oplus}, \sigma_{\square}, v)$, called $(\sigma_{\oplus}, v)$-play in $Q$, satisfies $\text{wg}(\pi) > 0$. If the condition $\text{wg}(\pi) > 0$ holds only for infinite plays $\pi$, then $Q$ is called weak quasi $\oplus$-dominion.

Essentially, a quasi $\oplus$-dominion consists in a set $Q$ of positions starting from which player $\oplus$ can force plays in $Q$ of positive weight. Analogously, any infinite play that player $\oplus$ can force in a weak quasi $\oplus$-dominion has positive weight. Clearly, any quasi $\oplus$-dominion is also a weak quasi $\oplus$-dominion. Moreover, the latter are closed under subsets, while the former are not. It is an immediate consequence of the definition above that all infinite plays induced by the $\oplus$-witness, if any, necessarily have infinite weight and, thus, are winning for player $\oplus$. Indeed, every such a play $\pi$ is regular, i.e. it can be decomposed into a prefix $\pi'$ and a simple cycle $(\pi'')^\omega$, i.e. $\pi = \pi'((\pi'')^\omega)^\omega$, since the strategies we are considering are memoryless. Now, $\text{wg}((\pi'')^\omega) > 0$, so, $\text{wg}(\pi') > 0$, which implies $\text{wg}((\pi'')^\omega) = \infty$. Hence, $\text{wg}(\pi) = \infty$.

**Proposition 1.** Let $Q$ be a weak quasi $\oplus$-dominion with $\sigma_{\oplus} \in \text{Str}_{\oplus}(Q)$ one of its $\oplus$-witnesses and $Q^* \subseteq Q$. Then, for all $\square$-strategies $\sigma_{\square} \in \text{Str}_{\square}(Q^*)$ and positions $v \in Q^*$ the following holds: if the $(\sigma_{\oplus}|Q^*, v)$-play $\pi = \text{play}(\sigma_{\oplus}|Q^*, \sigma_{\square}, v)$ is infinite, then $\text{wg}(\pi) = \infty$.

From Proposition 1 it directly follows that, if a weak quasi $\oplus$-dominion $Q$ is closed w.r.t. its $\oplus$-witness, namely all the induced plays are infinite, then it is a $\ominus$-dominion, hence is contained in $W_{\ominus}$.

Consider again the example of Figure 1. The set of position $Q \triangleq \{a, c, d\}$ forms a quasi $\oplus$-dominion whose $\ominus$-witness is the only possible $\oplus$-strategy mapping position $d$ to $c$. Indeed, any infinite play remaining in $Q$ forever and compatible with that strategy (e.g., the play from position $c$ when player $\square$ chooses the move from $c$ leading to $d$ or the one from $a$ to itself or the one from $a$ to $d$) grants an infinite payoff. Any finite compatible play, instead, ends in position $a$ (e.g., the play from $c$ when player $\square$ chooses the move from $c$ to $a$ and then one from $a$ to $b$) giving a payoff of at least $k > 0$. On the other hand, $Q^* \triangleq \{c, d\}$ is only a weak quasi $\oplus$-dominion, as player $\square$ can force a play of weight 0 from position $c$, by choosing the exiting move $(c, a)$. However, the internal move $(c, d)$ would lead to an infinite play in $Q^*$ of infinite weight.

The crucial observation here is that the best choice for player $\square$ in any position of a (weak) quasi $\oplus$-dominion is to exit from it as soon as it can, while the best choice for player $\ominus$ is to remain inside it as long as possible. The idea of the algorithm we propose in this section is to precisely exploit the information provided by the quasi dominions in the following way. Consider the example above. In position $a$ player $\square$ must choose to exit from $Q = \{a, c, d\}$, by taking the move $(a, b)$, without changing its measure, which would correspond to its weight $k$. On the other hand, the best choice for player $\square$ in position $c$ is to exit from the weak quasi-dominion $Q^* = \{c, d\}$, by choosing the move $(c, a)$ and lifting its measure from 0 to $k$. Note that this contrasts with the minimal measure-increase policy for player $\square$ employed in [13], which would keep choosing to leave $c$ in the quasi-dominion by following the move to $d$, which gives the minimal increase in measure of value 1. Once $c$ is out of the quasi-dominion, though, the only possible move for player $\ominus$ is to follow $c$, taking measure $k + 1$. The resulting measure function is a progress measure and the solution has, thus, been reached.

In order to make this intuitive idea precise, we need to be able to identify quasi dominions first. Interestingly enough, the measure functions $\mu$ defined in the previous section do allow to identify a quasi dominion, namely the set of positions $\mu^{-1}(\{0\})$ having positive measure. Indeed, as observed at the end of that section, a positive measure witnesses the existence of a positively-weighted finite play that player $\oplus$ can enforce from that position onward, which is precisely the requirement of Definition 3. In the example...
of Figure \( \text{\(\beth\)} \) \( \mu^{-1}(0) = \emptyset \) and \( \mu^{-1}(0) = \{a, c, d\} \) are both quasi dominions, the first one \textit{w.r.t.} the empty \( \oplus \)-witness and the second one \textit{w.r.t.} the \( \oplus \)-witness \( \sigma_\emptyset(d) = c \).

We shall keep the quasi-dominion information in pairs \((\mu, \sigma)\), called quasi-dominion representations (QDR, for short), composed of a measure function \( \mu \) and a \( \oplus \)-strategy \( \sigma \), which corresponds to one of the \( \oplus \)-witnesses of the set of positions with positive measure in \( \mu \). The connection between these two components is formalized in the definition below that also provides the partial order over which the new algorithm operates.

**Definition 4** (QDR Space). The quasi-dominion-representation space is the partial order \( Q \triangleq (\text{QDR}, \sqsubseteq) \), whose components are defined as prescribed in the following:

1. \( \text{QDR} \subseteq \text{MF} \times \text{Str} \) is the set of all pairs \( \varrho \triangleq (\mu_\varrho, \sigma_\varrho) \in \text{QDR} \), called quasi-dominion-representations, composed of a measure function \( \mu_\varrho \in \text{MF} \) and a \( \oplus \)-strategy \( \sigma_\varrho \in \text{Str}(Q(\varrho)) \), where \( Q(\varrho) \triangleq \mu^{-1}(0) \), for which the following four conditions hold:
   a) \( Q(\varrho) \) is a quasi \( \oplus \)-dominion enjoying \( \sigma_\varrho \) as a \( \oplus \)-witness;
   b) \( \|\mu_\varrho\|_{\square} \) is a \( \oplus \)-dominion;
   c) \( \mu_\varrho(v) \leq \mu_\varrho(\sigma_\varrho(v)) + v \), for all \( \oplus \)-positions \( v \in Q(\varrho) \cap P_{\square} \);
   d) \( \mu_\varrho(v) \leq \mu_\varrho(u) + v \), for all \( \sqsubseteq \)-positions \( v \in Q(\varrho) \cap P_{\sqsubseteq} \) and adjacents \( u \in M(v) \);

2. for all \( \varrho_1, \varrho_2 \in \text{QDR} \), it holds that \( \varrho_1 \sqsubseteq \varrho_2 \) if \( \mu_\varrho_1 \subseteq \mu_\varrho_2 \), and \( \sigma_\varrho_1(v) = \sigma_\varrho_2(v) \), for all \( \oplus \)-positions \( v \in Q(\varrho_1) \cap P_{\square} \) with \( \mu_{\varrho_1}(v) = \mu_{\varrho_2}(v) \).

The \( \alpha \)-denotation \( \|\varrho\|_\alpha \) of a QDR \( \varrho \), with \( \alpha \in \{\oplus, \sqsubseteq\} \), is the \( \alpha \)-denotation \( \|\mu_\varrho\|_\alpha \) of its measure function.

Condition [\( I_\emptyset \)] is obvious. Condition [\( I_\square \)] instead, requires that every position with infinite measure is indeed won by player \( \oplus \) and is crucial to guarantee the completeness of the algorithm. Finally, Conditions [\( I_{\emptyset} \)] and [\( I_\square \)] ensure that every positive measure under approximates the actual weight of some finite play within the induced quasi dominion. This is formally captured by the following proposition, which can be easily proved by induction on the length of the play.

**Proposition 2.** Let \( \varrho \) be a QDR and \( v \) a finite path starting at position \( u \in P_{\square} \) and terminating in position \( u \in P_{\square} \) compatible with the \( \oplus \)-strategy \( \sigma_\varrho \). Then, \( \mu_\varrho(v) \leq w_g(v\pi) + \mu_\varrho(u) \).

It is immediate to see that every MPG admits a non-trivial QDR space, since the pair \((\mu_\emptyset, \sigma_\emptyset)\), with \( \mu_\emptyset \) the smallest measure function and \( \sigma_\emptyset \) the empty strategy, trivially satisfies all the required conditions.

**Proposition 3.** Every MPG has a non-empty QDR space associated with it.

The solution procedure we propose, called QDPM from now on, can intuitively be broken down as an alternation of two phases. The first one tries to lift the measures of positions outside the quasi dominion \( Q(\varrho) \) in order to extend it, while the second one lifts the positions inside \( Q(\varrho) \) that can be forced to exit from it by player \( \square \). The algorithm terminates when no new position can be absorbed within the quasi dominion and no measure needs to be lifted to allow the \( \square \)-winning positions to exit from it, when possible. To this end, we define a controlled lift operator lift: \( \text{QDR} \times 2^{P_{\square}} \times 2^{P_{\square}} \rightarrow \text{QDR} \) that works on QDRs and takes two additional parameters, a source and a target set of positions. The intended meaning is that we want to restrict the application of the lift operation to the positions in the source set \( S \), while using only the moves leading to the target set \( T \). The different nature of the two types of lifting operations is reflected in the actual values of the source and target parameters.

\[
\text{lift}(\varrho, S, T) \triangleq \varrho^*, \quad \text{where}
\]

\[
\mu_\varrho^*(v) \triangleq \begin{cases} 
\max\{\mu_\varrho(u) + v : u \in M(v) \cap T\}, & \text{if } v \in S \cap P_{\square}; \\
\min\{\mu_\varrho(u) + v : u \in M(v) \cap T\}, & \text{if } v \in S \cap P_{\sqsubseteq}; \\
\mu_\varrho(v), & \text{otherwise};
\end{cases}
\]
and, for all $\oplus$-positions $v \in Q(\varrho) \cap P_{\oplus}$,

$$\sigma_{\varrho}(v) \in \arg\max_{u \in Mv(v) \cap T} \mu_{\varrho}(u) + v,$$

if $\mu_{\varrho}(v) \neq \mu_{\varrho}(v)$, and $\sigma_{\varrho}(v) = \sigma_{\varrho}(v)$, otherwise.

Except for the restriction on the outgoing moves considered, which are those leading to the targets in $T$, the lift operator acts on the measure component of a QDR very much like the original lift operator does. In order to ensure that the result is still a QDR, however, the lift operator must also update the $\oplus$-witness of the quasi dominion. This is required to guarantee that Conditions (1) and (2) of Definition (4) are preserved. If the measure of a $\oplus$-position $v$ is not affected by the lift, the $\oplus$-witness must not change for that position. On the other hand, if the application of the lift operation increases the measure, then the $\oplus$-witness on $v$ needs to be updated to any move $(v, u)$ that grants measure $\mu_{\varrho}(v)$ to $v$. In principle, more than one such move may exist and any one of them can serve the purpose as witness.

The solution algorithm can then be expressed as the inflationary fixpoint (10), (33) of the composition of the two phases mentioned above, defined by the progress operators $\text{prg}_{\text{prg}}$ and $\text{prg}_{+}$.

$$\text{sol} \triangleq \text{ifp}_{\text{prg}}. \text{prg}_{+}(\text{prg}_{\text{prg}}): \text{QDR} \rightarrow \text{QDR}.$$  

The first phase is computed by the operator $\text{prg}_{\text{prg}}: \text{QDR} \rightarrow \text{QDR}$, defined as follows:

$$\text{prg}_{\text{prg}}(\varrho) \triangleq \sup\{\varrho, \text{lift}(\varrho, Q(\varrho), P_{\varrho})\}.$$  

This operator is responsible for enforcing the progress condition on the positions outside the quasi dominion $Q(\varrho)$ that do not satisfy the inequalities between the measures along a move leading to $Q(\varrho)$ itself. It does that by applying the lift operator with $Q(\varrho)$ as source and no restrictions on the moves. Those position that acquire a positive measure in this phase contribute to enlarging the current quasi dominion. Observe that the strategy component of the QDR is updated so that it is a $\oplus$-witness of the new quasi dominion. To guarantee that measures never decrease, the supremum w.r.t. the QDR-space ordering is taken as result.

**Lemma 1.** Let $\varrho \in \text{QDR}$ be a fixpoint of $\text{prg}_{\text{prg}}$. Then, $\mu_{\varrho}$ is a progress measure over $\overline{Q(\varrho)}$.

The second phase, instead, implements the mechanism intuitively described above, while analyzing the simple example of Figure (1). This is achieved by the operator $\text{prg}_{+}$ reported in Algorithm (2). The procedure iteratively examines the current quasi dominion by lifting the measures of the positions that must exit from it. Specifically, it processes $Q(\varrho)$ layer by layer, starting from the outer layer of positions that must escape from. The process ends when a, possibly empty, closed weak quasi dominion is obtained. Recall that all the positions in a closed weak quasi dominion are necessarily winning for player $\oplus$, due to Proposition (2). We distinguish two sets of positions in $Q(\varrho)$. Those that already satisfy the progress condition and those that do not. The measures of first ones already witness an escape route from $Q(\varrho)$. The other ones, instead, are those whose current choice is to remain inside it. For instance, when considering the measure function $\mu_2$ in the example of Figure (1) position $a$ belongs to the first set, while positions $c$ and $d$ to the second one, since the choice of $c$ is to follow the internal move $(c, d)$.

Since the only positions that change measure are those in the second set, only such positions need to be examined. To identify them, which form a weak quasi dominion $\Delta(\varrho)$ strictly contained in $Q(\varrho)$, we proceed as follows. First, we collect the set $\text{npp}(\varrho)$ of positions in $Q(\varrho)$ that do not satisfy the progress condition, called the non-progress positions. Then, we compute the set of positions that will have no choice other than reaching $\text{npp}(\varrho)$. The non-progress positions are computed as follows.

$$\text{npp}(\varrho) \triangleq \{v \in Q(\varrho) \cap P_{\text{prg}} : \exists u \in Mv(v) . \mu_{\varrho}(v) < \mu_{\varrho}(u) + v\}$$

$$\cup \{v \in Q(\varrho) \cap P_{\text{prg}} : \forall u \in Mv(v) . \mu_{\varrho}(v) < \mu_{\varrho}(u) + v\}.$$
The remaining positions in $\Delta(q)$ are collected as the inflationary fixpoint of the following operator.

$$\text{pre}(q, Q) \triangleq Q \cup \{v \in Q(q) \cap P_{\Box} : \sigma_q(v) \in Q\}$$

$$\cup \{v \in Q(q) \cap P_{\Box} : \forall u \in M(v) \setminus Q, \mu_q(v) < \mu_q(u) + v\}.$$  

The final result is

$$\Delta(q) \triangleq (\text{ifp } Q \cdot \text{pre}(q, Q))(\text{npp}(q))$$

Intuitively, $\Delta(q)$ contains all the $\oplus$-positions that are forced to reach npp($q$) via the quasi-dominion $\oplus$-witness and all the $\Box$-positions that can only avoid reaching npp($q$) by strictly increasing their measure, which player $\Box$ wants obviously to prevent.

It is important to observe that, from a functional view-point, the progress operator $\text{prg}_+$ would work just as well if applied to the entire quasi dominion $Q(q)$, since it would simply leave unchanged the measure of those positions that already satisfy the progress condition. However, it is crucial that only the positions in $\Delta(q)$ are processed in order to achieve the best asymptotic complexity bound known to date. We shall reiterate on this point later on.

At each iteration of the while-loop of Algorithm 1 let $Q$ denote the current (weak) quasi dominion, initially set to $\Delta(q)$ (Line 1). It first identifies the positions in $Q$ that can immediately escape from it (Line 2). Those are (i) all the $\Box$-position with a move leading outside of $Q$ and (ii) the $\oplus$-positions $v$ whose $\oplus$-witness $\sigma_q(v)$ forces $v$ to exit from $Q$, namely $\sigma_q(v) \not\in Q$, and that cannot strictly increase their measure by choosing to remain in $Q$. While the condition for $\Box$-position is obvious, the one for $\oplus$-positions require some explanation. The crucial observation here is that, while player $\oplus$ does indeed prefer to remain in the quasi dominion, it can only do so while ensuring that by changing strategy it does not enable infinite plays within $Q$ that are winning for the adversary. In other words, the new $\oplus$-strategy must still be a $\oplus$-witness for $Q$ and this can only be ensured if the new choice strictly increases its measure. The operator $\text{esc}: QDR \times 2^{Ps} \rightarrow 2^{Ps}$ formalizes the idea:

$$\text{esc}(q, Q) \triangleq \{v \in Q \cap P_{\Box} : M(v) \setminus Q \neq \emptyset\}$$

$$\cup \{v \in Q \cap P_{\Box} : \sigma_q(v) \not\in Q \land \forall u \in M(v) \cap Q, \mu_q(u) + v \leq \mu_q(v)\}.$$  

Consider, for instance, the example in Figure 2 and a QDR $q$ such that $\mu_q = \{a \mapsto 3; b \mapsto 2; c, d, f \mapsto 1; e \mapsto 0\}$ and $\sigma_q = \{b \mapsto a; f \mapsto d\}$. In this case, we have $Q_e = \{a, b, c, d, f\}$ and $\Delta(q) = \{c, d, f\}$, since $c$ is the only non-progress positions, $d$ is forced to follow $c$ in order to avoid the measure increase required to reach $b$, and $f$ is forced by the $\oplus$-witness to reach $d$. Now, consider the situation where the current weak quasi dominion is $Q = \{c, f\}$, i.e., after $d$ has escaped from $\Delta(q)$. The escape set of $Q$ is $\{c, f\}$. To see why the $\oplus$-position $f$ is escaping, observe that $\mu_q(f) + f = 1 = \mu_q(f)$ and that, indeed, should player $\oplus$ choose to change its strategy and take the move $(f, f)$ to remain in $Q$, it would obtain an infinite play with payoff 0, thus violating the definition of weak quasi dominion.

Before proceeding, we want to stress an easy consequence of the definition of the notion of escape set and Conditions 1C and 1D of Definition 4, i.e., that every escape position of the quasi dominion $Q(q)$ can only assume its weight as possible measure inside a QDR $q$, as reported is the following proposition. This observation, together with Proposition 2, precisely ensures that the measure of a position $v \in Q(q)$ is an under approximation of the weight of all finite plays leaving $Q(q)$.
Proposition 4. Let \( \varrho \) be a QDR. Then, \( \mu_\varrho(v) = \text{wg}(v) > 0 \), for all \( v \in \text{esc}(\varrho, Q(\varrho)) \).

Now, going back to the analysis of the algorithm, if the escape set is non-empty, we need to select the escape positions that need to be lifted in order to satisfy the progress condition. The main difficulty is to do so in such a way that the resulting measure function still satisfies Condition [1d] of Definition 4 for all the \( \square \)-positions with positive measure. The problem occurs when a \( \square \)-position can exit either immediately or passing through a path leading to another position in the escape set. Consider again the example above, where \( Q = \Delta(\varrho) = \{ c, d, f \} \). If position \( d \) immediately escapes from \( Q \) using the move \((d, b)\), it would change its measure to \( \mu'(d) = \mu(b) + d = 2 > \mu(d) = 1 \). Now, position \( c \) has two ways to escape, either directly with move \((c, a)\) or by reaching the other escape position \( d \) passing through \( f \). The first choice would set its measure to \( \mu(a) + c = 4 \). The resulting measure function, however, would not satisfy Condition [1d] of Definition 4 as the new measure of \( c \) would be greater than \( \mu'(d) + c = 2 \), preventing to obtain a QDR. Similarly, if position \( d \) escapes from \( Q \) passing through \( c \) via the move \((c, a)\), we would have \( \mu''(d) = \mu''(c) + d = (\mu(a) + c) + d = 4 > 2 = \mu(b) + d \), still violating Condition [1d]. Therefore, in this specific case, the only possible way to escape is to reach \( b \).

The solution to this problem is simply to lift in the current iteration only those positions that obtain the lowest possible measure increase, hence position \( d \) in the example, leaving the lift of \( c \) to some subsequent iteration of the algorithm that would choose the correct escape route via \( d \). To do so, we first compute the minimal measure increase, called the best-escape forfeit, that each position in the escape set would obtain by exiting the quasi dominion immediately. The positions with the lowest possible forfeit, called best-escape positions, can all be lifted at the same time. The intuition is that the measure of all the positions that escape from a (weak) quasi dominion will necessarily be increased of at least the minimal best-escape forfeit. This observation is at the core of the proof of Theorem 2 (see the appendix) ensuring that the desired properties of QDRs are preserved by the operator \( \text{prg}_+ \). The set of best-escape positions is computed by the operator \( \text{bep}: \text{QDR} \times 2^{P_s} \to 2^{P_s} \) as follows:

\[
\text{bep}(\varrho, Q) \triangleq \arg\min_{v \in \text{esc}(\varrho, Q)} \text{bep}(\mu_\varrho, Q, v),
\]

where the operator \( \text{bep}: \text{MF} \times 2^{P_s} \times P_s \to N_\infty \) computes, for each position \( v \) in a quasi dominion \( Q \), its best-escape forfeit:

\[
\text{bep}(\mu, Q, v) \triangleq \begin{cases} 
\max\{\mu(u) + v - \mu(v) : u \in M_v(v) \setminus Q\}, & \text{if } v \in P_{S\varrho}; \\
\min\{\mu(u) + v - \mu(v) : u \in M_v(v) \setminus Q\}, & \text{otherwise}.
\end{cases}
\]

In our example, \( \text{bep}(\mu, Q, c) = \mu(a) + c - \mu(c) = 4 - 1 = 3 \), while \( \text{bep}(\mu, Q, d) = \mu(b) + d - \mu(d) = 2 - 1 = 1 \). Therefore, \( \text{bep}(\varrho, Q) = \{d\} \).

Once the set \( E \) of best-escape positions is identified (Line 3 of the algorithm), the procedure simply lifts them restricting the possible moves to those leading outside the current quasi dominion (Line 4). Those positions are, then, removed from the set (Line 5), thus obtaining a smaller weak quasi dominion ready for the next iteration.

The algorithm terminates when the (possibly empty) current quasi dominion \( Q \) is closed. By virtue of Proposition 1 all those positions belong to \( W_{1\varrho} \) and their measure is set to \( \infty \) by means of the operator \( \text{win}: \text{QDR} \times 2^{P_s} \to \text{QDR} \) (Line 6), which also computes the winning \( \oplus \)-strategy on those positions:

\[
\text{win}(\varrho, Q) \triangleq \varrho^*, \text{ where } \mu_\varrho^* \triangleq \mu_\varrho[Q \mapsto \infty]
\]

and, for all \( \oplus \)-positions \( v \in Q(\varrho^*) \cap P_{S\varrho} \),

\[
\sigma_\varrho^*(v) \in \arg\max_{u \in M(v) \cap Q} \mu_\varrho(u) + v, \text{ if } \sigma_\varrho(v) \not\in Q \text{ and } \sigma_\varrho^*(v) = \sigma_\varrho(v), \text{ otherwise}.
\]
Observe that, since we know that every $\oplus$-position $v \in Q \cap Ps_\boxdot$, whose current $\oplus$-witness leads outside $Q$, is not an escape position, any move $(v, u)$ within $Q$ that grants the maximal stretch $\mu_\varnothing(u) + v$ strictly increases its measure and, therefore, is a possible choice for a $\oplus$-witness of the $\oplus$-dominion $Q$.

At this point, it should be quite evident that the progress operator $\text{prg}_+$ is responsible of enforcing the progress condition on the positions inside the quasi dominion $Q(\varnothing)$, thus, the following necessarily holds.

**Lemma 2.** Let $\varnothing \in \text{QDR}$ be a fixpoint of $\text{prg}_+$. Then, $\mu_\varnothing$ is a progress measure over $Q(\varnothing)$.

![Fig. 3: Yet another MPG.](image)

We now exemplify the lack of monotonicity of the progress operator $\text{prg}_+$. To do so, consider the game of Figure 3 and the following two QDRs $\varnothing_1$ and $\varnothing_2$ defined via their components: $\mu_{\varnothing_1} = \{a \mapsto 3; b \mapsto 0; c \mapsto 2; d, e \mapsto 1\}$ and $\sigma_{\varnothing_1} = \{e \mapsto d\}; \mu_{\varnothing_2} = \{a \mapsto 3; b \mapsto 0; c, e \mapsto 2; d \mapsto 1\}$ and $\sigma_{\varnothing_2} = \{e \mapsto c\}$. Obviously, $\varnothing_1 \subseteq \varnothing_2$. However, $\varnothing^*_1 \triangleq \text{prg}_+(\varnothing_1) \not\subseteq \varnothing^*_2 \triangleq \text{prg}_+(\varnothing_2)$. Indeed, $\mu_{\varnothing^*_1} = \{a \mapsto 3; b \mapsto 0; c \mapsto 2; d, e \mapsto 4\}$, while $\mu_{\varnothing^*_2} = \{a \mapsto 3; b \mapsto 0; c, e \mapsto 2; d \mapsto 4\}$, which implies that $\varnothing^*_1 \subset \varnothing^*_2$. Moreover, $\varnothing^*_2$ is already a progress measure, while $\varnothing^*_2$ requires another application of $\text{prg}_+$ in order to solve the game, since $\varnothing^*_1 = \text{prg}_+(\varnothing^*_2)$.

In order to prove the correctness of the proposed algorithm, we first need to ensure that any quasi-dominion space $Q$ is indeed closed under the operators $\text{prg}_0$ and $\text{prg}_+$. This is established by the following theorem, which states that the operators are total functions on that space.

**Theorem 2** (Totality). The progress operators $\text{prg}_0$ and $\text{prg}_+$ are total inflationary functions.

Since both operators are inflationary, so is their composition, which admits fixpoint. Therefore, the operator $\text{sol}$ is well defined. Moreover, following the same considerations discussed at the end of Section 3, it can be proved the fixpoint is obtained after at most $n \cdot (S + 1)$ iterations. Let $\text{if}_k \mathcal{X} \cdot F(\mathcal{X})$ denote the $k$-th iteration of an inflationary operator $F$. Then, we have the following theorem.

**Theorem 3** (Termination). The solver operator $\text{sol} \triangleq \text{if}_0 \varnothing \cdot \text{prg}_+(\text{prg}_0(\varnothing))$ is a well-defined total function. Moreover, for every $\varnothing \in \text{QDR}$ it holds that $\text{sol}(\varnothing) = (\text{if}_k \varnothing \cdot \text{prg}_+(\text{prg}_0(\varnothing^*)))(\varnothing)$, for some index $k \leq n \cdot (S + 1)$, where $n$ is the number of positions in the MPG and $S \triangleq \sum \{w(\varnothing) \in \mathbb{N} : \varnothing \in Ps \land w(\varnothing) > 0\}$ the total sum of its positive weights.

Consider, as a final example, the game depicted in Figure 4, with $k > 2$, where the numbers denote the weights of the positions of the game, in the picture labeled (0), and the measures assigned by the procedure, in the remaining ones. Each picture also features the $\oplus$-witness strategy in dashed red and the best counter $\boxdot$-strategy in dashed red for the current quasi dominion. Moreover, solid colored moves are moves along which the measure strictly increases. Below each picture, we also indicate the phase, $\text{prg}_0$ or $\text{prg}_+$, that produces the displayed result. The computation starts from the initial QDR $\varnothing_0 = (\mu_0, \sigma_0)$, assigning measure 0 to all the positions of the game with the associated empty strategy. The first iteration applies $\text{prg}_0$ to $\varnothing_0$, which lifts positions a, f, and g to their respective weights, leading to $\varnothing_1$ as shown in Picture (1). At this point, $Q(\varnothing_1) = \{a, f, g\}$ but $\Delta(\varnothing_1)$ is empty, as all those positions already satisfy the progress condition, thus, $\text{prg}_+$ does nothing. In the next iteration, $\text{prg}_0$ applied to $\varnothing_1$ results in the lifting of positions c and d, as reported in Picture (2). Position c is a $\oplus$-position and the lift operator chooses $(c, f)$ as its strategy. The resulting quasi-dominion is $Q(\varnothing_2) = \{c, d, f, g\}$ and $\Delta(\varnothing_2) = \{d, g\}$, with g the only escape position that is also non-progress. The measure of g is lifted to $\mu_2(c) + g = 4$. Finally, it is the turn of position d to be lifted to $\mu_2(g) + d = 3$. Figure (3) shows the resulting QDR $\varnothing_3$. The final iteration first applies $\text{prg}_0$ to $\varnothing_3$ (Picture (4)), lifting position b to measure 1 via the move (b, c). This change of measure triggers another application of $\text{prg}_+$, as position f is now non-progress. The resulting QDR $\varnothing_4$ is such that $Q(\varnothing_4) = \{a, b, c, d, f, g\}$ and $\Delta(\varnothing_4) = \{b, c, d, f, g\}$. The only escape position is b, which is lifted directly to measure $k - 1$. In the remaining set $\{c, d, f, g\}$,
the only escape position is \( f \), which is lifted to measure \( k + 1 \). The resulting weak quasi dominion \( \{c, d, g\} \), however, is closed, since \( \mu_{\phi_5}(c) = 2 < \mu_{\phi_5}(d) + c = 3 \). Therefore, player \( \oplus \) changes strategy and chooses the move \( (c, d) \). Since no escape positions remain, the set \( \{c, d, g\} \) is winning for player \( \oplus \) and the win operator lifts all their measures to \( \infty \), leading to \( \phi_5 \) in Picture (5). The measure function \( \mu_5 \) is now a progress measure and the algorithm terminates. The total number of single measure updates for QDPM to reach the fixpoint on the example of Figure 4 is 13, regardless of the value of the maximal weight \( k \) in the game assigned to position \( a \).

On the other hand, it can easily be proved that SEPM requires \( 3k + 8 \) applications of its lift operator to compute a progress measure, for a total of \( 5k + 9 \) measure updates. Indeed, the first two evaluations of lift, starting from \( \mu_0 \), lead to \( \mu_2 = \{a \mapsto k; b, e \mapsto 0; c, f, g \mapsto 2; d \mapsto 1\} \), as in Picture (2), and require 5 measure lifts. Then, the algorithm iteratively increases the measures of \( b, g, d, f, \) and \( c \) by applying \( 3(k - 1) \) times the lift operator, for a total of \( 5(k - 1) \) measure lifts: \( \mu_{3i} = \mu_{3i-1}[b \mapsto i; g \mapsto i + 3] \), \( \mu_{3i+1} = \mu_{3i}[d, f \mapsto i + 2] \), and \( \mu_{3i+2} = \mu_{3i+1}[c \mapsto i + 2] \), for all \( i \in [1, k - 1] \). At this point, \( b \) and \( f \) have obtained measures \( k - 1 \) and \( k + 1 \), respectively, which suffice to satisfy the progress relation along the moves \( (f, b) \) and \( (b, a) \). However, the \( \square \)-position \( g \) does not satisfy such a relation along its unique move \( (g, c) \), since \( \mu_{3k-1}(g) = k + 2 < \mu_{3k-1}(c) + g = (k + 1) + 2 = k + 3 \). Therefore, other six applications of lift are needed before \( g \) can exceed the bound \( S = \text{wg}(a) + \text{wg}(f) + \text{wg}(g) = k + 4 \). Each one of them modifies the measure of one position only, for a total of 6 lifts: \( \mu_{3(k+i)} = \mu_{3(k+i)-1}[g \mapsto k + 3 + i] \), \( \mu_{3(k+i)+1} = \mu_{3(k+i)}[d \mapsto k + 2 + i] \), and \( \mu_{3(k+i)+2} = \mu_{3(k+i)+1}[c \mapsto k + 2 + i] \), for \( i \in \{0, 1\} \). At this point, we have \( \mu_{3k+6} = \mu_{3k+5}[g \mapsto \infty] \), \( \mu_{3k+7} = \mu_{3k+6}[d \mapsto \infty] \), and, finally, \( \mu_{3k+8} = \mu_{3k+7}[c \mapsto \infty] \), which contribute with the remaining 3 lifts. From this observation, the next result immediately follows.

**Theorem 4 (Efficiency).** An infinite family of MPGs \( \{\mathcal{G}_k\}_k \) exists on which QDPM requires a constant number of measure updates, while SEPM requires \( O(k) \) such updates.

From Theorem 4 together with Lemmas 1 and 2, it follows that the solution provided by the algorithm is indeed a progress measure, hence establishing soundness.

**Theorem 5 (Soundness).** \( \|\text{sol}(\rho)\|_\square \subseteq W_{\mu_\square} \), for every \( \rho \in \text{QDR} \).

On the other hand, Theorem 4 together with Condition 1b of Definition 4 ensures that all the positions with infinite measure are winning for player \( \oplus \), hence the algorithm is also complete.

**Theorem 6 (Completeness).** \( \|\text{sol}(\rho)\|_\square \subseteq W_{\mu_\oplus} \), for every \( \rho \in \text{QDR} \).

The following lemma ensures that each execution of the operator \( \text{prg}_+ \) strictly increases the measure.
of all the positions in $\Delta(\varrho)$.

**Lemma 3.** Let $\varrho^* \triangleq \text{prg}_+(\varrho)$, for some $\varrho \in \text{QDR}$. Then, $\mu_{\varrho^*}(v) > \mu_{\varrho}(v)$, for all positions $v \in \Delta(\varrho)$.

Recall that each position can at most be lifted $S + 1 = O(n \cdot W)$ times and, by the previous lemma, the complexity of sol only depends on the cumulative cost of such lift operations. We can express, then, the total cost as the sum, over the set of positions in the game, of the cost of all the lift operations performed on that positions. Each such operation can be computed in time linear in the number of incoming and outgoing moves of the corresponding lifted position $v$, namely $O(|Mv(v)| + |Mv^{-1}(v)|) \cdot \log S$, with $O(\log S)$ the cost of each arithmetic operation involved. Summing all up, the actual asymptotic complexity of the procedure can, therefore, be expressed as $O(n \cdot m \cdot W \cdot \log(n \cdot W))$.

**Theorem 7** (Complexity). QDPM requires time $O(n \cdot m \cdot W \cdot \log(n \cdot W))$ to solve an MPG with $n$ positions, $m$ moves, and maximal positive weight $W$.

### 5. Experimental Evaluation

In order to assess the effectiveness of the proposed approach, we implemented both QDPM and SEPM [13], the most efficient known solution to the problem and the more closely related one to QDPM, in C++ within OINK [32]. OINK has been developed as a framework to compare parity game solvers. However, extending the framework to deal with MPGs is not difficult. The form of the arenas of the two types of games essentially coincide, the only relevant difference being that MPGs allow negative numbers to label game positions. We ran the two solvers against randomly generated MPGs of various sizes.

Figure 5 compares the solution time, expressed in seconds, of the two algorithms on 4000 games, each with 5000 positions and randomly assigned weights in the range $[-15000, 15000]$. The scale of both axes is logarithmic. The experiments are divided in 4 clusters, each containing 1000 games. The benchmarks in different clusters differ in the maximal number $m$ of outgoing moves per position, with $m \in \{10, 20, 40, 80\}$. These experiments clearly show that QDPM substantially outperforms SEPM. Most often, the gap between the two algorithms is between two and three orders of magnitude, as indicated by the dashed diagonal lines. It also shows that SEPM is particularly sensitive to the density of the underlying graph, as its performance degrades significantly as the number of moves increases. The maximal solution time was 8940 sec. for SEPM and 0.5 sec. for QDPM.

Figure 6, instead, compares the two algorithms fixing the maximal out-degree of the underlying graphs to 2, in the left-hand picture, and to 40, in the right-hand one, while increasing the number of positions from $10^3$ to $10^5$ along the x-axis. Each picture displays the performance results on 2800 games. Each point shows the total time to solve 100 randomly generated games with that given number of positions, which increases by 1000 up to size $2 \cdot 10^5$ and by 10000, thereafter. In both pictures the scale is logarithmic. For the experiments in the right-hand picture we had to set a timeout for SEPM to 45 minutes per game, which was hit most of the times on the bigger ones.

Once again, the QDPM significantly outperforms SEPM on both kinds of benchmarks, with a gap of more than an order of magnitude on the first ones, and a gap of more than three orders of magnitude on

---

1. The experiments were carried out on a 64-bit 3.9GHz quad-core machine, with INTEL i5-6600K processor and 8GB of RAM, running UBUNTU 18.04.
the second ones. The results also confirm that the performance gap grows considerably as the number of moves per position increases.

We are not aware of actual concrete benchmarks for MPGs. However, exploiting the standard encoding of parity games into mean-payoff games [25], we can compare the behavior of SEPM and QDPM on concrete verification problems encoded as parity games. For completeness, Table 1 reports some experiments on such problems.

The table reports the execution times, expressed in seconds, required by the two algorithms to solve instances of two classic verification problems: the Elevator Verification and the Language Inclusion problems. These two benchmarks are included in the PGSolver [23] toolkit and are often used as benchmarks for parity games solvers. The first benchmark is a verification under fairness constraints of a simple model of an elevator, while the second one encodes the language inclusion problem between a non-deterministic Büchi automaton and a deterministic one. The results on various instances of those problems confirm that QDPM significantly outperforms the classic progress measure approach. Note also that the translation into MPGs, which encodes priorities as weights whose absolute value is exponential in the values of the priorities, leads to games with weights of high magnitude. Hence, the results in Table 1 provide further evidence that QDPM is far less dependent on the absolute value of the weights. They also show that QDPM can be very effective for the solution of real-world qualitative verification problems. It is worth noting, though, that the translation from parity to MPGs gives rise to weights that are exponentially distant from each other [25]. As a consequence, the resulting benchmarks are not necessarily representative of MPGs, being a very restricted subclass. Nonetheless, they provide evidence of the applicability of the approach in practical scenarios.

6. Concluding Remarks

We proposed a novel solution algorithm for the decision problem of MPGs that integrates progress measures and quasi dominions. We argue that the integration of these two concepts may offer significant speed up in convergence to the solution, at no additional computational cost. This is evidenced by the existence of a family of games on which the combined approach can perform arbitrarily better than a classic progress measure based solution. Experimental results also show that the introduction of quasi dominions can often reduce solution times up to three order of magnitude, suggesting that the approach
may be very effective in practical applications as well. We believe that the integration approach we devised is general enough to be applied to other types of games. In particular, the application of quasi dominions in conjunction with progress measure based approaches, such as those of [27] and [21], may lead to practically efficient quasi polynomial algorithms for parity games and their quantitative extensions.

Appendix A.
Proofs

In this appendix, we collect some supplementary material, providing three further lemmas (Lemmas 4, 5 and 6), and the proofs of the theorems and lemmas introduced in Sections 3 and 4.

Theorem 1 (Progress Measure). Let $\mu \in MF$ be a progress measure. Then, $\|\mu\|_\square \subseteq W^\square_n$.

Proof. Consider a $\Box$-strategy $\pi_\square \in \text{Str}_\square$ for which all measures $\mu(v)$ of positions $v \in \|\mu\|_\square \cap P_\square$ are a progress at $w$ w.r.t. the measures $\mu(\sigma_\square(v))$ of their adjacents $\sigma_\square(v)$, formally, $\mu(\sigma_\square(v)) + v \leq \mu(v)$. The existence of such a strategy is ensured by the fact that $\mu$ is a progress measure. Indeed, by Condition 2 of Definition 2 there necessarily exists an adjacent $u^* \in Mv(v)$ of $v$ such that $\mu(u^*) + v \leq \mu(v)$. Now, it can be shown that $\pi_\square$ is a winning strategy for player $\square$ from all the positions in $\|\mu\|_\square$, which implies that $\|\mu\|_\square \subseteq W^\square_n$. To do this, let us consider a $\oplus$-strategy $\pi_\oplus \in \text{Str}_\oplus$ and the associated play $\pi = \text{play}(\pi_\square, \pi_\oplus, v)$ starting at a position $v \in \|\mu\|_\square$. Assume, by contradiction, that $\pi$ is won by player $\oplus$. Since the game $\square$ is finite, $\pi$ must contain a finite simple cycle, and so a finite simple path, with strictly positive total weight sum. In other words, there exist two natural numbers $h \in \mathbb{N}$ and $k \in \mathbb{N}_+$ such that $(\pi)_h = (\pi)_{h+k}$ and $\text{wg}(\rho) = \sum_{i=h}^{h+k-1} \text{wg}((\pi)_i) > 0$, where $\rho = (\pi)_h < h+k$ is the simple path named above. Now, recall that, $((\pi)_i, (\pi)_{i+1}) \in Mv$, for all indexes $i \in \mathbb{N}$. Thus, by both conditions of Definition 2 and the notion of play, we have that

$$\mu((\pi)_{i+1}) + (\pi)_i \leq \mu((\pi)_i).$$

Via a trivial induction, it is immediate to see that $\mu((\pi)_i) \leq S$, where $S = \sum \{\text{wg}(v) \in \mathbb{N} : v \in P_\square \cap \text{wg}(v) > 0\} < \infty$, for all $i \in \mathbb{N}$, since $\mu((\pi)_0) = \mu(v) \neq \infty$, being $v \in \|\mu\|_\square$. As a consequence, due to the definition of the measure stretch operator, it holds that

$$\mu((\pi)_{i+1}) + \text{wg}((\pi)_i) \leq \mu((\pi)_i) \leq S.$$

Hence, by summing together all the inequalities having indexes $i \in \mathbb{N}$ with $h \leq i < h + k$, we obtain

$$\sum_{i=h+1}^{h+k} \text{pf}_\mu((\pi)_i) + \sum_{i=h}^{h+k-1} \text{wg}((\pi)_i) \leq \sum_{i=h}^{h+k-1} \text{pf}_\mu((\pi)_i) < \infty,$$

which simplifies in $\text{wg}(\rho) = \sum_{i=h}^{h+k-1} \text{wg}((\pi)_i) \leq 0$, since $\text{pf}_\mu((\pi)_{h+k}) = \text{pf}_\mu((\pi)_h)$. However, this contradicts the above assumption $\text{wg}(\rho) > 0$. Therefore, $\pi_\square$ is a winning strategy for player $\square$ on $\|\mu\|_\square$ as required by the theorem statement.

In the following, for a finite path $\pi$ of an MPG, we denote by $\text{fst}(\pi)$ and $\text{lst}(\pi)$ the first and last positions of $\pi$, respectively.

Lemma 4. Let $\varrho \in \text{QDR}$ and $\sigma^* \in \text{Str}_\oplus(\text{Q}(\varrho))$ a $\oplus$-strategy such that, if $\sigma^*(v) \neq \sigma_\varrho(v)$, then $\mu_\varrho(v) < \mu_\varrho(\sigma^*(v)) + v$, for all positions $v \in Q(\varrho) \cap \text{Ps}_\varrho$. Then, $\sigma^*$ is a $\oplus$-witness for $Q(\varrho)$.

Proof. The proof proceed by induction on the number $i \triangleq |D|$ of the positions in $D = \{v \in \text{Ps}_\varrho : \sigma^*(v) \neq \sigma_\varrho(v)\}$ on which the two strategies $\sigma^*$ and $\sigma_\varrho$ differ. The base case $i = 0$ is immediate, since $\varrho$ is a QDR. Therefore, assume $i > 0$, let $v \in D$, and consider the strategy $\tilde{\sigma} \in \text{Str}_\oplus(\text{Q}(\varrho))$ such that $\tilde{\sigma}(v) = \sigma_\varrho(v)$ and $\tilde{\sigma}(u) = \sigma^*(u)$, for all positions $u \in Q(\varrho) \cap \text{Ps}_\varrho$ with $u \neq v$. By the inductive hypothesis, we have that $\tilde{\sigma}$ is a $\oplus$-witness for the quasi dominion $Q(\varrho)$. Now, consider an arbitrary path $\pi$ compatible with the $\oplus$-strategy $\sigma^*$. If $\pi$ does not meet $v$, it is necessarily compatible with the $\oplus$-strategy $\tilde{\sigma}$, thus, $\text{wg}(\pi) > 0$. If $\pi$ meets $v$ once, then it can be decomposed as $\pi' v \pi''$, where $\pi'$ and $\pi''$ are paths not meeting $v$, where only the first can be possibly empty. On the one hand, if $\pi''$ is infinite,
by Proposition 1 we have $\text{wg}(\pi'') = \infty$ and, so, $\text{wg}(\pi) = \text{wg}(\pi'\pi'') = \infty$. On the other hand, if $\pi''$ is finite, then, by Propositions 2 and 3 we have that $0 < \mu_\sigma(fst(\pi'')) \leq \text{wg}(\pi') + \mu_\sigma(lst(\pi'')) = \text{wg}(\pi') + \mu_\sigma(v)$ and $\mu_\sigma(fst(\pi'')) \leq \text{wg}(\pi'')$, since both $\pi'$ and $\pi''$ are compatible with $\tilde{\sigma}$. Moreover, $\mu_\sigma(v) < \mu_\sigma(\sigma^*(v)) + v = \mu_\sigma(fst(\pi'')) + v = \mu_\sigma(fst(\pi'')) + \text{wg}(v)$. Now, by putting all things together, we have $0 < \mu_\sigma(fst(\pi')) \leq \text{wg}(\pi') + \mu_\sigma(v) = \text{wg}(\pi') + \mu_\sigma(fst(\pi'')) + \text{wg}(v) \leq \text{wg}(\pi'') + \text{wg}(v) + \text{wg}(\pi'') = \text{wg}(\pi''v\pi'')$, i.e., $\text{wg}(\pi) > 0$. Finally, consider the case where $\pi$ meets $v$ more than once and, so, infinitely many times, due to the regularity of the path, which is in its turn due to the memoryless strategies. Then, $\pi$ can be written as $\pi'(v\pi'' \omega) = \pi'v(\pi''v\omega)$, where $\pi'$ and $\pi''$ are possibly empty paths not meeting $v$. First observe that the finite path $\pi'v\pi''$ is compatible with $\tilde{\sigma}$, thus, by Proposition 2 we have that $\mu_\sigma(fst(\pi''v)) \leq \text{wg}(\pi'') + \mu_\sigma(\pi')$. Moreover, $\mu_\sigma(v) < \mu_\sigma(fst(\pi''v)) + \text{wg}(v)$, as already shown above. Hence, $\mu_\sigma(v) < \mu_\sigma(fst(\pi''v)) + \text{wg}(\pi''v) + \text{wg}(v) + \mu_\sigma(v) = \text{wg}(\pi''v) + \mu_\sigma(v)$, which implies $\text{wg}(\pi''v) > 0$. As a consequence, $\text{wg}((\pi''v)\omega) = \infty$ and, so, $\text{wg}(\pi) = \text{wg}(\pi'v(\pi''v\omega)) > 0$. Summing up, $\sigma^*$ is a $\oplus$-witness for the quasi dominion $Q(\sigma)$ as required by the lemma statement. \hfill $\square$

**Theorem 2** (Totality). The progress operators $\text{prg}_0$ and $\text{prg}_+$ are total inflationary functions.

**Proof.** The proof proceeds by showing that, for each $\sigma \in \text{QDR}$, the elements $\text{prg}_0(\sigma)$ and $\text{prg}_+(\sigma)$ are QDR too. We also prove that $\sigma \subseteq \text{prg}_0(\sigma)$ and $\sigma \subseteq \text{prg}_+(\sigma)$. The two operators are analyzed separately.

- **[prg$_0$.]** Let $\sigma^* \triangleq \text{prg}_0(\sigma) = \text{sup} \{ \sigma, \text{lift}(\sigma, Q(\sigma), Ps) \} \subseteq \sigma$. It is obvious, so, that $\text{prg}_0$ is inflationary. Consider now a position $v \in Q(\sigma^*)$. Recall that $\mu_{\sigma^*}(v) > 0$. If $v \in Q(\sigma)$, by definition of the lift operator, it holds that $\mu_{\sigma^*}(v) = \mu_\sigma(v)$ and $\sigma_{\sigma^*}(v) = \sigma_\sigma(v)$, thus the appropriate condition between Conditions 1c and 1d of Definition 4 is verified, since $\sigma \in \text{QDR}$. Thus, assume $v \in Q(\sigma)$. If $v \in Ps_\sigma$, we have that $\mu_{\sigma^*}(v) = \text{max} \{ \mu_\sigma(u) + v : u \in Mv(\sigma) \} = \mu_\sigma(\sigma_{\sigma^*}(v)) + v = \mu_{\sigma^*}(\sigma_{\sigma^*}(v)) + v$, since $\sigma_{\sigma^*}(v) \in Q(\sigma)$. As a consequence, Condition 1c is satisfied. If $v \in Ps_{\sigma^*}$, instead, we have that $\mu_{\sigma^*}(v) = \text{min} \{ \mu_\sigma(u) + v : u \in Mv(\sigma) \}$, which implies $\mu_{\sigma^*}(v) \leq \mu_\sigma(u) + v = \mu_{\sigma^*}(u) + v$, for all adjacent $u \in Mv(\sigma)$, as required by Condition 1d. To complete the proof that $\text{prg}_0$ is a total function from QDR to itself, we need to show that $\sigma^*$ satisfies Conditions 1b and 1a too. It is immediate to see that $\|\mu_{\sigma}||_\oplus \leq \|\mu_{\sigma^*}||_\oplus$. Since $\sigma$ is a QDR, $\|\mu_{\sigma^*}||_\oplus$ is a $\oplus$-dominion. Moreover, for all positions $v \in \|\mu_{\sigma^*}||_\oplus \setminus \|\mu_{\sigma}||_\oplus$, it holds that $\sigma_{\sigma^*}(v) \in \|\mu_{\sigma}||_\oplus$, if $v \in Ps_\sigma$, and $Mv(\sigma) \subseteq \|\mu_{\sigma}||_\oplus$, otherwise. Therefore, $\|\mu_{\sigma^*}||_\oplus$ is necessarily a $\oplus$-dominion, so Condition 1b is verified. Finally, let us focus on Condition 1a and consider a $(\sigma_{\sigma^*}, v)$-play $\nu \pi$. If, on the one hand, $\pi$ is infinite and does not meet $v$, thanks to Proposition 1 we have $\text{wg}(\pi) = \infty$, thus $\text{wg}(v\pi) = \infty$ and, so, $\text{wg}(\nu\pi) > 0$. If $\pi$ is finite, instead, it holds that $\text{lst}(\pi) \in \text{esc} (\sigma, Q(\sigma))$ and, so, $\mu_\sigma(\text{lst}(\pi)) = \text{wg}(\text{lst}(\pi))$, due to Proposition 2. Now, by Proposition 2 we have that $\mu_\sigma(fst(\pi)) \leq \mu_\sigma(\text{lst}(\pi)) + \text{wg}(\pi_{\ell-1}) = \text{wg}(\text{lst}(\pi)) + \text{wg}(\pi_{\ell-1}) = \text{wg}(\pi)$, where $\ell \in \mathbb{N}$ is the length of $\pi$. Moreover, $0 < \mu_\sigma(v) \leq \mu_\sigma(fst(\pi)) + v = \mu_\sigma(fst(\pi)) + \text{wg}(\pi) + \text{wg}(\sigma)$, thanks to the previously proved Conditions 1c and 1d. Hence, $0 < \mu_{\sigma^*}(v) \leq \mu_{\sigma^*}(fst(\pi)) + \text{wg}(\sigma) \leq \text{wg}(\pi) + \text{wg}(\pi) = \text{wg}(\nu\pi)$, as required by the definition of quasi $\oplus$-dominion. Finally, if $\pi$ is infinite and does meet $v$, it can be decomposed as $(v\pi')\omega$, where $\pi$ is a non-empty finite path that does not meet $v$. Then, by exploiting the same reasoning done above for the case where $\pi$ is finite, we have that $\text{wg}(v\pi') > 0$, which implies $\text{wg}(\nu\pi) = \text{wg}((v\pi')\omega) = \infty$.

- **[prg$_+$.]** Let $\sigma^* \triangleq \text{prg}_+(\sigma)$ and consider the two infinite monotone sequences $Q_0 \supseteq Q_1 \supseteq \ldots$ and $\sigma_0 \subseteq \sigma_1 \subseteq \ldots$ defined as follows: $Q_0 \triangleq \Delta(\sigma)$ and $\sigma_0 \triangleq \sigma$; $Q_{i+1} \triangleq Q_i \setminus E_i$ and $\sigma_{i+1} \triangleq \text{lift}(\sigma_i, E_i, \sigma_i)$, where $E_i \triangleq \text{bep}(\sigma_i, Q_i) \subseteq \text{esc}(\sigma_i, Q_i)$, for all $i \in \mathbb{N}$. Since $|Q_0| < \infty$, there necessarily exists an index $k \in \mathbb{N}$ such that $Q_{k+1} = Q_k$, $\sigma_{k+1} = \sigma_k$. Moreover, observe that $\sigma^* = \text{win}(\sigma_k, Q_k)$. We first prove, by induction on the index $i \in \mathbb{N}$ of the sequences, that every $\sigma_i$ satisfies Conditions 1a and 1c of Definition 4. Finally, we show that $\sigma^*$ is a QDR.

The base case $i = 0$ is trivial, since $\sigma_0 = \sigma$ is a QDR. Now, let us consider the inductive case $i > 0$. Since the lift operator only modifies the measure of positions belonging to $E_{i-1} \subseteq Q_{i-1} \subseteq \Delta(\sigma) \subseteq$
Q(ψ), it immediately follows that Q(ψ_i) = Q(ψ_{i-1}) = Q(ψ). Moreover, if σ^e_0(v) ≠ σ^e_{i-1}(v), we have that μ_ψ_{i-1}(v) < μ_ψ_i(v) = μ_ψ_i(σ^e_i(v)) = μ_ψ_{i-1}(σ^e_i(v)), for all positions v ∈ Q(ψ_i) ∩ P_ψ, where the latter equality is due to the fact that σ^e_i(v) ∈ E_{i-1}. Thus, by Lemma 4, it holds that σ^e_i is a ⊕-witness for Q(ψ_i), i.e., Condition 1a is verified. Also, Condition 1c directly follows from the definition of the ⊕-strategy inside the lift operator.

At this point, we can conclude the proof by showing that ψ^* is a QDR. Indeed, by Lemma 4, σ^e_n is a ⊕-witness for Q(ψ_n) = Q(ψ), so, Condition 1a is satisfied. Similarly to the inductive analysis developed above, Condition 1c directly follows from the definition of the ⊕-strategy inside the win function. Moreover, the set Q_k is a closed subset of Q(ψ_k), since E_k = ∅, and, so, esc(ψ_k, Q_k) = ∅. Therefore, Q_k ⊆ W_n, by Proposition 1. In addition, all positions in ∥µ_ψ_k∥_Q \ (∥µ_ψ∥_Q \ Q_k) necessarily reach (∥µ_ψ∥_Q \ Q_k) ⊆ W_n. As a consequence, Condition 1b is verified as well.

It remains to prove Condition 1d. To do so, let f_i = min_{v ∈ esc(ψ_i, Q_i)} bef(µ_ψ_i, Q_i, v). We now first show that the sequence of natural numbers f_0, f_1, . . . is monotone, i.e., f_i ≤ f_{i+1}. Suppose by contradiction that f_i > f_{i+1}, for some index i ∈ N. Then, there necessarily exists a position v ∈ esc(ψ_{i+1}, Q_{i+1}) \ esc(ψ_i, Q_i) with v ∈ E_{i+1} such that f_{i+1} = bef(µ_ψ_{i+1}, Q_{i+1}, v) < f_i. We proceed by a case analysis on the owner of the position v.

- [v ∈ P_ψ]. By definition of the best-escape forfeit function, we have that f_{i+1} = max{µ_ψ_{i+1}(u) + v - µ_ψ_{i+1}(v) : u ∈ Mv(v) \ Q_{i+1}} ≥ µ_ψ_{i+1}(σ_ψ_i(v)) + v - µ_ψ_{i+1}(v), since σ_ψ_i(v) ∈ E_i and, so, σ_ψ_i(v) ∉ Q_{i+1}. Therefore, the following equalities and inequalities hold, which lead to the contradiction f_i ≤ f_{i+1} < f_i:

\[
\begin{align*}
f_{i+1} & \geq \mu_\psi_{i+1}(\sigma_\psi_i(v)) + v - \mu_\psi_{i+1}(v) \\
& = \mu_\psi_{i+1}(\sigma_\psi_i(v)) + wg(v) - \mu_\psi_{i+1}(v) \\
& = \mu_\psi_i(\sigma_\psi_i(v)) + f_i + wg(v) - \mu_\psi_i(v) \\
& = \mu_\psi_i(\sigma_\psi_i(v)) + v - \mu_\psi_i(v) + f_i \\
& \geq f_i.
\end{align*}
\]

Notice that the first and last equality are due to the definition of the measure stretch operator. The second one is derived from the fact that σ_ψ_i(v) ∈ E_i, while the third one from v ∈ E_{i+1}, which implies µ_ψ_{i+1}(v) = µ_ψ_i(v). Finally, the last inequality follows from Condition 1c applied to ψ_i, i.e., µ_ψ_i(v) ≤ µ_ψ_i(σ_ψ_i(v)) + v.

- [v ∈ P_ψ]. Again by definition of the best-escape forfeit function, we have that f_{i+1} = min{µ_ψ_{i+1}(u) + v - µ_ψ_{i+1}(v) : u ∈ Mv(v) \ Q_{i+1}}. In addition, Mv(v) \ Q_{i+1} ⊆ E_i Therefore, the following equalities hold:

\[
\begin{align*}
f_{i+1} & = \min\{\mu_\psi_{i+1}(u) + v - \mu_\psi_{i+1}(v) : u \in Mv(v) \setminus Q_{i+1}\} \\
& = \min\{\mu_\psi_{i+1}(u) + wg(v) - \mu_\psi_{i+1}(v) : u \in Mv(v) \setminus Q_{i+1}\} \\
& = \min\{\mu_\psi_i(u) + f_i + wg(v) - \mu_\psi_i(v) : u \in Mv(v) \setminus Q_{i+1}\} \\
& = \min\{\mu_\psi_i(u) + v - \mu_\psi_i(v) + f_i : u \in Mv(v) \setminus Q_{i+1}\} \\
& \geq f_i.
\end{align*}
\]

Notice that the second and last equality are due to the definition of the measure stretch operator. The third one is derived from the fact that u ∈ Mv(v) \ Q_{i+1} ⊆ E_i, while the fourth one from v ∈ E_{i+1}, which implies µ_ψ_{i+1}(v) = µ_ψ_i(v). Finally, the last inequality follows from
Condition $[1]$ applied to $g$, i.e., $\mu_{g_i}(v) = \mu_g(v) \leq \mu_{g_i}(u) + v \leq \mu_{g_i}(u) + v$, for all adjacents $u \in Mv(v)$.

Now suppose by contradiction that Condition $[1]$ does not hold for $g^*$. Then, there exist a $\square$-position $v \in Q(g^*) \cap P_{\square}$ and one of its adjacents $u \in Mv(v)$ such that $\mu_{g^*}(u) + v < \mu_{g^*}(v)$. Due to the process used to compute $g^*$, there are indexes $i, j \in [0, k]$ such that $\mu_{g^*}(u) = \mu_{g_i}(u) + f_i$ and $\mu_{g^*}(v) = \mu_{g_i+1}(v) = \mu_{g_i}(v) + f_j$.

Now, by Condition $[1]$ applied to $g$, we have $\mu_{g_i}(v) \leq \mu_{g}(u) + v$, which implies that $0 \leq \mu_{g_i}(u) + v - \mu_{g_i}(v) < f_j - f_i$ and, consequently, both $i < j$ and $u \not\in Q_j$.

However,

$$f_j - f_i = \min\{\mu_{g_i}(z) + v - \mu_{g_i}(v) : z \in Mv(v) \setminus Q_j\} - f_i$$

$$\leq \mu_{g_i}(u) + v - \mu_{g_i}(v) - f_i$$

$$= \mu_{g_i}(u) + v - \mu_{g_i}(v) - f_i$$

$$= \mu_{g_i+1}(u) + v - \mu_{g_i}(v) - f_i$$

$$= (\mu_{g}(u) + f_i) + v - \mu_{g_i}(v) - f_i$$

$$= \mu_{g}(u) + v - \mu_{g_i}(v),$$

leading to the contradiction $\mu_{g_i}(u) + v - \mu_{g_i}(v) < f_j - f_i \leq \mu_{g_i}(u) + v - \mu_{g_i}(v)$. Notice that the first equality is due to the definition of the best-escape forfeit function. The second and third ones, instead, follows from the fact that $v$ and $u$ changed their values at iterations $j + 1$ and $i + 1$, respectively.

Finally, the fourth equality derives from the operation of lift and best-escape forfeit computed on $u$.

\[\square\]

**Lemma 5.** Let $g^* \triangleq prg_+(g)$, for some $g \in QDR$, and $S \triangleq \sum\{wg(v) \in \mathbb{N} : v \in Ps \land wg(v) > 0\}$. Then, for all positions $v \in Q(g^*)$ with $g^*(v) \neq \infty$, it holds that $g^*(v) \leq S$.

**Proof.** Suppose by contradiction that there exists a position $v \in Q(g^*)$ with $g^*(v) \neq \infty$, but $g^*(v) > S$. If $v \in Q(g) \setminus \Delta(g)$, then $g^*(v) = g(v)$. Moreover, there exists a finite path $\pi$ compatible with the $\oplus$-strategy $\sigma$ and entirely contained in $Q(g) \setminus \Delta(g)$, which starts in $v$ and ends in $esc(\sigma, Q(g))$, i.e., $\text{fst}(\pi) = v$ and $\text{lst}(\pi) \in esc(\sigma, Q(g))$. By Propositions $[2]$ and $[4]$ we have that $S < \mu_{g}(v) \leq wg(\pi) \leq S^*$, with $S^* \triangleq \sum\{wg(v) \in \mathbb{N} : v \in Q(g) \setminus \Delta(g) \land wg(v) > 0\}$, where the last inequality is obviously due to the fact that there are no repeated positions in $\pi$, being it finite. However, $S^* \leq S$, which means that a contradiction has been reached with $v \in Q(g) \setminus \Delta(g)$. Thus, assume $v \in \Delta(g)$ and consider the two infinite monotone sequences $Q_0 \supset Q_1 \supset \ldots$ and $Q_0 \subseteq Q_1 \subseteq \ldots$ defined as in the proof of Theorem $[2]$. $Q_0 \triangleq \Delta(g)$ and $Q_i \triangleq \Delta(g \upharpoonright E_i)$ and $Q_{i+1} = \text{lift}(Q_i, E_i, Q_i)$, where $E_i \triangleq \text{bev}(Q_i, Q_i) \subseteq esc(Q_i, Q_i)$, for all $i \in \mathbb{N}$. Also, let $S_0 \leq S_1 \leq \ldots \leq \top$ be the sequence of natural numbers defined as $S_i \triangleq \sum\{wg(v) \in \mathbb{N} : v \in Q(g) \setminus Q_i \land wg(v) > 0\}$. Since $g^*(v) \neq \infty$, there exists an index $k$ such that $v \in E_k$ with $\text{bev}(Q_k, Q_k, v) < \infty$. Therefore, to prove the thesis, it suffices to show that $\mu_{g_i}(z) \leq S_i$, for all positions $z \in Q_i$ and index $i \in [0, k]$. The base case $i = 0$ follows by applying the same reasoning previously done for the case $v \in Q(g) \setminus \Delta(g)$ and by noticing that $S_0 = S^*$. Now, let $i > 0$. By definition of the lift operator, there exists at least one adjacent $x$ of $z$ such that $\mu_{g_i+1}(z) = \mu_{g_i}(x) + z$. By the inductive hypothesis, $\mu_{g_i}(x) \leq S_i$. Thus, $\mu_{g_i+1}(z) \leq S_i + wg(z) \leq S_{i+1}$, since $wg(z) \not\in S_i$. \[\square\]

**Theorem 3** (Totality). The solver operator $\text{sol} \triangleq \text{if} \cdot prg_+(prg_+(g))$ is a well-defined total function. Moreover, for every $g \in QDR$ it holds that $\text{sol}(g) = (\text{if} \cdot prg_+(prg_+(g^*)))(g)$, for some index $k \leq n \times (S+1)$, where $n$ is the number of positions in the MPG and $S \triangleq \sum\{wg(v) \in \mathbb{N} : v \in Ps \land wg(v) > 0\}$ the total sum of its positive weights.

**Proof.** Consider the sequence $g_0, g_1, \ldots$ recursively defined as follows: $g_0 \triangleq (\text{if} \cdot g^* \cdot prg_+(prg_+(g^*))(g) = g$ and $g_{i+1} \triangleq (\text{if} \cdot g^* \cdot prg_+(prg_+(g^*))(g) = prg_+(prg_+(g_i))$, for all $i \in \mathbb{N}$. By induction on the index
Lemma 5. We have that $\varrho_i(v) \leq S$, for all positions $v \in \mathbb{Q}(q_i)$ with $\varrho_i(v) \neq \infty$ and index $i > 0$. Now, there are at most $n \cdot (S + 1)$ such QDRs, thus, there necessarily exists an index $k \leq n \cdot (S + 1)$ such that $\varrho_{k+1} = \varrho_k$, which implies $\text{sol}(\varrho) = (\text{ifp } \varrho^* \cdot \text{lift}(\varrho^*))(\varrho) = \varrho_k$. Hence, the thesis immediately follows.

Lemma 6. Let $\varrho^* \triangleq \text{sol}(\varrho)$ be the result of the solver operator applied to an arbitrary $\varrho \in \text{QDR}$. Then, $\varrho^*$ is a fixpoint of the progress operators, i.e., $\varrho^* = \text{prg}_0(\varrho^*) = \text{prg}_+(\varrho^*)$.

Proof. By definition of inflationary fixpoint, $\varrho^*$ is a fixpoint of the composition of the two progress operators, i.e., $\varrho^* = \text{prg}_+(\text{prg}_0(\varrho^*))$, which are inflationary functions, due to Theorem 2. As a consequence, we have that $\varrho^* = \text{prg}_+(\text{prg}_0(\varrho^*)) \supseteq \text{prg}_0(\varrho^*) \supseteq \varrho^*$. Thus, $\text{prg}_0(\varrho^*) = \varrho^*$ and, so, $\text{prg}_+(\varrho^*) = \varrho^*$.

Lemma 1. Let $\varrho \in \text{QDR}$ be a fixpoint of $\text{prg}_0$. Then, $\mu_\varrho$ is a progress measure over $\overline{\text{Q}(\varrho)}$.

Proof. By definition of the progress operator $\text{prg}_0$, we have that $\varrho = \text{prg}_0(\varrho) = \sup\{\varrho, \text{lift}(\varrho, \overline{\text{Q}(\varrho)}, \text{Ps})\}$, from which we derive $\varrho^* = \text{prg}_+(\text{prg}_0(\varrho^*))$, which are inflationary functions, due to Theorem 2. As a consequence, we have that $\varrho^* = \text{prg}_+(\text{prg}_0(\varrho^*)) \supseteq \text{prg}_0(\varrho^*) \supseteq \varrho^*$. Thus, $\text{prg}_0(\varrho^*) = \varrho^*$ and, so, $\text{prg}_+(\varrho^*) = \varrho^*$.

Lemma 2. Let $\varrho \in \text{QDR}$ be a fixpoint of $\text{prg}_+$. Then, $\mu_\varrho$ is a progress measure over $\overline{\text{Q}(\varrho)}$.

Proof. Let us consider the infinite monotone sequence of position sets $\mathbb{Q}_0 \supseteq \mathbb{Q}_1 \supseteq \ldots$ defined as follows:

\[ Q_0 \triangleq \Delta(\varrho); \ Q_{i+1} \triangleq \mathbb{Q}_i \setminus E_i, \text{ where } E_i \triangleq \text{bepl}(\varrho, \mathbb{Q}_i), \text{ for all } i \in \mathbb{N}. \]

Since $|Q_0| < \infty$, there necessarily exists an index $k \in \mathbb{N}$ such that $Q_{k+1} = Q_k$. By definition of the progress operator $\text{prg}_+$ and the equality $\varrho = \text{prg}_+(\varrho)$, we have that $\varrho = \text{lift}(\varrho, E_i, \overline{Q_i})$, for all $i \in [0, k]$, and $\varrho = \text{win}(\varrho, Q_k)$. Now, consider an arbitrary position $v \in \mathbb{Q}(\varrho)$. If $v \notin \Delta(\varrho)$, due to the definition of the set $\Delta(\varrho)$, the position $v$ satisfies by definition of the appropriate condition of Definition 2 on $\overline{\text{Q}(\varrho)}$. Therefore, let us assume $v \in \Delta(\varrho)$. Then, it is obvious that either $v \in Q_k$ or there is a unique index $i \in [0, k]$ such that $v \in Q_i \setminus Q_{i+1}$, i.e., $v \in E_i$. In the first case, we have $\mu_\varrho(v) = \infty$, due to the definition of the function win. Therefore, $v$ is a progress position. In the other case, the proof proceeds by a case analysis on the owner of the position $v$ itself.

- [v \in \mathbb{P}(\varrho_0)]. First observe that bepl($\varrho_0$, $Q_i$) $\subseteq$ esc($\varrho_0$, $Q_i$). Thus, due to the definition of the function esc, we have that $\mu_\varrho(u) + v \leq \mu_\varrho(v)$, for all positions $u \in \text{Mv}(v) \cap Q_i$. Now, by the definition of the lift operator, we have that $\mu_\varrho(u) + v \leq \max\{\mu_\varrho(u) + v : u \in \text{Mv}(v) \cap \overline{Q_i}\} = \mu_\varrho(v)$, for all adjacent $u \in \text{Mv}(v) \cap \overline{Q_i}$ of $v$. Consequently, $\mu_\varrho(u) + v \leq \mu_\varrho(v)$, for all positions $u \in \text{Mv}(v)$, as required by Condition 1 of Definition 2 on $\overline{\text{Q}(\varrho)}$.

- [v \in \mathbb{P}(\varrho_0)]. Again by definition of the lift operator, we have that $\mu_\varrho(u) + v \leq \min\{\mu_\varrho(u) + v : u \in \text{Mv}(v) \cap \overline{Q_i}\} = \mu_\varrho(v)$, for some adjacent $u \in \text{Mv}(v) \cap \overline{Q_i} \subseteq \text{Mv}(v)$ of $v$. Hence, Condition 2 of Definition 2 is satisfied on $\overline{\text{Q}(\varrho)}$ as well.

\[ \text{Theorem 5 (Soundness). } \|\text{sol}(\varrho)\|_0 \subseteq \text{Win}_\varrho, \text{ for every } \varrho \in \text{QDR}. \]
Proof. Let \( g^* \triangleq \text{sol}(g) \) be the result of the solver operator applied to \( g \in \text{QDR} \). By Lemma 6 it holds that \( g^* = \text{prg}_o(g^*) = \text{prg}_+(g^*) \). As a consequence, \( \mu_o \) is a progress measure, due to Lemmas 1 and 2. At this point, by recalling that \( \| g^* \|_{\Box} = \| \mu_o \|_{\Box} \), as reported in Definition 4, the thesis is immediately derived by applying Theorem 1 to \( \mu_o \).

**Theorem 6** (Completeness). \( \| \text{sol}(g) \|_{\Box} \subseteq W_{n_p}, \) for every \( g \in \text{QDR} \).

**Proof.** The thesis immediately follows by considering Theorem 4 and Condition 1b of Definition 4. Indeed, by the statement of the recalled theorem, \( \text{sol}(g) \) is a QDR, independently of the element \( g \in \text{QDR} \) given as input to the solver operator. Thus, thanks to the above condition, it holds the \( \| \text{sol}(g) \|_{\Box} \subseteq W_{n_p} \).

**Lemma 3.** Let \( g^* \triangleq \text{prg}_+(g) \), for some \( g \in \text{QDR} \). Then, \( \mu_o(v) > \mu_o(v) \), for all positions \( v \in \Delta(g) \).

**Proof.** Consider the set \( E \triangleq \text{bep}(g, \Delta(g)) \subseteq \text{esc}(g, \Delta(g)) \) and let \( \sigma \triangleq \text{lift}(g, E, \Delta(g)) \). First observe that \( \mu_o(v) = \mu_o(v) \), for all escape positions \( v \in E \). We now show that \( \mu_o(v) > \mu_o(v) \), via a case analysis on the owner of the position \( v \) itself.

- \([v \in P_{s_E}]\), By definition of the function esc, it holds that \( \sigma_o(v) \notin \Delta(g) \) and \( \mu_o(v) \geq \mu_o(u) + v \), for all adjacents \( u \in Mv(v) \cap \Delta(g) \). Since \( v \in \Delta(g) \), due to the way this specific weak quasi domination is constructed, \( v \in \text{npp}(g) \). Thus, there exists a successor \( u^* \in Mv(v) \) with \( \mu_o(v) < \mu_o(u^*) + v \), from which it follows that \( u^* \notin \Delta(g) \), i.e., \( u^* \in \Delta(g) \). As a consequence, we obtain that \( \mu_o(v) = \mu_o(u^*) + v > \mu_o(v) \). Hence, \( \mu_o(v) > \mu_o(v) \).

- \([v \notin P_{s_E}]\). Since \( v \in \Delta(g) \), we have that \( \mu_o(v) < \mu_o(u) + v \), for all adjacents \( u \in Mv(v) \setminus \Delta(g) \). Thus, \( \mu_o(v) = \min \{ \mu_o(u) + v : u \in Mv(v) \setminus \Delta(g) \} > \mu_o(v) \). Hence, \( \mu_o(v) > \mu_o(v) \) in this case as well.

Now, consider a position \( v \in \Delta(g) \setminus E \). Obviously, \( \mu_o(v) < \infty \). If \( \mu_o(v) = \infty \), the thesis immediately follows. Otherwise, it will be considered as an escape of some weak quasi dominion \( Q \subset \Delta(g) \), after the removal of the first escape positions in \( E \). Due to the non-decreasing property of the sequence of best-escape forfeit shown in the proof of Theorem 2, \( v \) exits from \( Q \) with a forfeit \( f^* \) at least as great as the one \( f \) of \( E \) that we proved to be strictly positive. Indeed, \( f = \mu_o(z) - \mu_o(z) > 0 \), for all \( z \in E \). Therefore, \( \mu_o(v) - \mu_o(v) = f^* \geq f > 0 \), which implies \( \mu_o(v) > \mu_o(v) \).

**Theorem 7** (Complexity). QDPM requires time \( O(n \cdot m \cdot W \cdot \log(n \cdot W)) \) to solve an MPG with \( n \) positions, \( m \) moves, and maximal positive weight \( W \).

**Proof.** To compute \( \text{sol} \) efficiently, we now provide an imperative reformulation of the functional fixpoint algorithm \( \text{sol} \triangleq \text{ifp}_o \left( \text{prg}_+(g) \right) \) with the desired complexity. Recall that, by Lemma 5, each position can only be lifted \( S + 1 \) times, where \( S \triangleq \sum \{ \text{wq}(v) \in \mathbb{N} : v \in P_s \land \text{wq}(v) > 0 \} = O(n \cdot W) \). Therefore, to obtain the claimed complexity, we have to guarantee that the cost of all the computational steps be linear in the number of measure increases. To do so, it suffices to ensure that the algorithm explores the incoming and outgoing moves only of those positions whose measures are actually lifted. This is clearly the case for the lift operator itself, since it only explores the outgoing moves of each position in its source set. The only remaining problem is to be able to identify the positions that need to be lifted in the next iteration, by only exploring the incoming moves of the positions just lifted. Solving this problem requires some technical tricks. Specifically, inspired by [13], we will employ vectors of counters, namely \( c, d \) and \( g \), that associates with \( \oplus \)-positions the number of moves that do not satisfy the progress condition, and with \( \Box \)-positions the number of moves that satisfy it. In addition, we will also use a priority queue \( T \) to allow an efficient identification of the best-escape positions during the computation of the operator
where the term $N$ verified invariants are i
invariants for the next iteration $i$ as defined at Line 1. At the beginning of each iteration $i \in \mathbb{N}$ of the while-loop at Line 4, the variable $\varrho$ maintains the QDR $\varrho_i$ computed by applying to $\varrho_0$ the composition $\text{prg}_+ \circ \text{prg}_0$ $i$ times. Moreover, the sets $N_0$ and $N_+$ contain, respectively, the positions that need to be lifted by $\text{prg}_0$ and the non-progress positions in $\varrho_i$. The formal invariants at Line 4 are: $N_0 = \{ v \in \mathbb{P}_0 : \mu_{\varrho_i}(v) = 0 \neq \mu_{\varrho_{i+1}}(v) \}$ and $N_+ = \text{npp}(\varrho_i)$. Observe that these invariants are trivially satisfied for $i = 0$, thanks to Line 3. After the execution of the progress procedure $\text{prg}_0$ at Line 5, whose code is reported in Algorithm 3, we have that $N_0 \subseteq \{ v \in \mathbb{P}_0 : \mu_{\varrho_{i+1}}(v) = 0 \neq \mu_{\varrho_{i+2}}(v) \}$ and $N_+ \cup A = \text{npp}(\varrho_i^*)$, where $\varrho_i^* \triangleq \text{prg}_0(\varrho_i)$. Thus, Line 6 ensures that $N_+ = \text{npp}(\varrho_i^*)$. Line 7 calls the progress procedure $\text{prg}_+$, which is reported in Algorithm 4 and forces the lift of the measures of all the positions in $\Delta(\varrho_i^*)$, as stated by Lemma 3. In addition, the verified invariants are $N_0 \cup A = \{ v \in \mathbb{P}_0 : \mu_{\varrho_{i+1}}(v) = 0 \neq \mu_{\varrho_{i+2}}(v) \}$ and $N_+ = \text{npp}(\varrho_{i+1})$. Finally, after Line 8, it holds that $N_0 = \{ v \in \mathbb{P}_0 : \mu_{\varrho_{i+1}}(v) = 0 \neq \mu_{\varrho_{i+2}}(v) \}$, as required by the previously discussed invariants for the next iteration $i + 1$. Observe that Line 2 is used to initialize, for each $\square$-position $v \in \mathbb{P}_0$, the counter $c(v)$ to the number of adjacents $u \in Mv(v)$ of $v$ that satisfy the progress inequality $\mu_{\varrho_i}(v) > \mu_{\varrho_i}(u) + v$.

The subsequent analysis of Algorithms 3 and 5 shows that the procedures $\text{prg}_0(\varrho, c, N_0)$ and $\text{prg}_+(\varrho, c, N_+)$ require time

$$O\left( \sum_{v \in N_0} (|Mv(v)| + |Mv^{-1}(v)|) \cdot \log S \right)$$

and

$$O\left( \sum_{v \in \Delta(\varrho)} (|Mv(v)| + |Mv^{-1}(v)|) \cdot \log S \right),$$

respectively, where $\text{npp}(\varrho) = N_+$. In particular, the factor $\log S$ is due to all the arithmetic operations required to compute the stretch of the measures. Since during the entire execution of the algorithm each position $v \in \mathbb{P}_0$ can appear at most once in some $N_0$ and at most $S$ times in some $\Delta(\varrho)$, it follows that the total cost of Algorithm 2 is

$$O\left( n + (S + 1) \cdot \sum_{v \in \mathbb{P}_0} (|Mv(v)| + |Mv^{-1}(v)|) \cdot \log S \right) = O(n + S \cdot m \cdot \log S) = O(n \cdot m \cdot W \cdot \log(n \cdot W)).$$

where the term $n$ is due to the initialization operations at Lines 1-3.

Observe that, the two procedures $\text{prg}_0$ and $\text{prg}_+$, together with the auxiliary one reported in Algorithm 4, share with Algorithm 2 both the current QDR $\varrho$ and the counter $c$ as global variables.

**Algorithm 2: MPG Solver**

signature sol: MPG → QDR

procedure sol(\varrho)

1. $\varrho \leftarrow \{(v \in Ps \mapsto 0), \varnothing\}$
2. $c \leftarrow \{ v \in \mathbb{P}_0 \mapsto \{|u \in Mv(v) : \mu_{\varrho}(v) \geq \mu_{\varrho}(u) + v\}|\}$
3. $(N_0, N_+) \leftarrow \{ v \in Ps : w(v) > 0 \}, \emptyset$
4. while $N_0 \neq \emptyset \lor N_+ \neq \emptyset$
5. $(N_0, A) \leftarrow \text{prg}_0(N_0)$
6. $N_+ \leftarrow N_+ \cup A$
7. $(A, N_+) \leftarrow \text{prg}_+(N_+)$
8. $N_0 \leftarrow N_0 \cup A$
9. return $\varrho$
Algorithm 3: Efficient Progress Zero Operator

signature prg/$\circlearrowleft_0$ : $2^{P_\circlearrowleft_0} \rightarrow 2^{P_\circlearrowleft_0} \times 2^{P_\circlearrowleft_0}$

procedure prg/$\circlearrowleft_0$(N)

1 $Z \leftarrow \emptyset$
2 $\hat{\mu} \leftarrow \{v \in N \mapsto \mu_\circlearrowleft_0(v)\}$
3 $\mu \leftarrow \sup\{\mu, \text{lift}(\mu, N, P_\circlearrowleft_0)\}$
4 $c \leftarrow c[v \in N \cap P_\circlearrowleft_\oplus \mapsto |\{u \in M_\circlearrowleft_0(v) : \mu_\circlearrowleft_0(v) \geq \mu_\circlearrowleft_0(u) + v\}|]$
5 foreach $(v, u) \in M_\circlearrowleft_0(v), u \in N; \mu_\circlearrowleft_0(v) < \mu_\circlearrowleft_0(u) + v$ do
6   if $v \in P_\circlearrowleft_\oplus$ then
7     $Z \leftarrow Z \cup v$
8   else
9     if $v \not\in N \land \mu_\circlearrowleft_0(v) \geq \hat{\mu}(u) + v$ then $c(v) \leftarrow c(v) - 1$
10    if $c(v) = 0$ then $Z \leftarrow Z \cup v$
11 return $(Z \cap \mu_\circlearrowleft_0^{-1}(0), Z \setminus \mu_\circlearrowleft_0^{-1}(0))$

Algorithm 3 simply computes the lift of all the positions contained in its input set N (Line 3) and then identifies the new positions that will be lifted by either the next application of prg/$\circlearrowleft_0$, namely $Z \cap \mu_\circlearrowleft_0^{-1}(0)$, or the subsequent application of prg/$\circlearrowright_+$, namely $Z \setminus \mu_\circlearrowleft_0^{-1}(0)$. To do so, it first reinitializes the counter for the positions just lifted (Line 4) and, then, for each of their incoming moves (Line 5), verifies if there exists a new position whose measure needs to be increased. The case of an incoming $\oplus$-move is trivial (Lines 6-7). Therefore, let us consider the opponent player. A position $v \in P_\circlearrowleft_\oplus$ needs to be lifted only if $\mu_\circlearrowleft_0(v) < \mu_\circlearrowleft_0(u) + v$, for all adjacents $u \in M_\circlearrowleft_0(v)$. Therefore, we decrement the associated counter (Line 8) every time a non-progress move, that previously satisfied the progress condition w.r.t. the unlifted QDR, is identified. The counter reaching zero means that the above condition is satisfied, thus, the considered position need to be lifted in the next iteration (Line 9).
Algorithm 4: Efficient Quasi Dominion Operator

signature $\Delta: 2^{Ps} \to 2^{Ps}$

procedure $\Delta(N)$
1 $Q \leftarrow \emptyset$
2 $d \leftarrow \emptyset$
3 while $N \not\subseteq Q$ do
4 $Q \leftarrow Q \cup N$
5 $N \leftarrow \text{pre}(N)$
6 return $Q$

signature $\text{pre}: 2^{Ps} \to 2^{Ps}$

procedure $\text{pre}(N)$
7 $Z \leftarrow \emptyset$
8 $d \leftarrow d\{v \in (Mv^{-1}(N) \cap Ps\subseteq) \setminus \text{dom}(d) \mapsto c(v)\}$
9 foreach $(v, u) \in Mv; u \in N$ do
10 if $v \in Ps\subseteq$ then
11 if $\sigma_0(v) = u$ then $Z \leftarrow Z \cup v$
12 else
13 if $\mu_0(v) \geq \mu_0(u) + v$ then $d(v) \leftarrow d(v) - 1$

15 return $Z$

Algorithm 4 computes the weak quasi dominion $\Delta(\varrho)$, starting from its trigger set $N = \text{npp}(\varrho)$ that contains all the non-progress positions in $Q(\varrho)$. The implementation almost precisely follows the functional definition of the two operators $\Delta$ and $\text{pre}$, by caring only about keeping the whole computation cost linear in the number of incoming moves in each position contained in the resulting set. To do so, we exploit the same tricks used in the previous procedure employing a counter $d$ for the $\square$-positions. Note that, $d$ contains a copy of the values in $c$, in order to preserve the values in $c$ for the other procedure.

Finally, Algorithm 5 implements the procedure described in Algorithm 1. It first computes the weak quasi dominion $\Delta(\varrho)$, by calling Algorithm 4 (Line 2). After that, it identifies its escape positions and the associated forfeit, in order to identify the set of best-escape positions that need to be lifted (Line 4). To do so, we employ a priority queue $T$ based on a min-heap, which will contain at most $S$ different forfeit values during the entire execution of the algorithm (positions associated with the same forfeit are clustered together). Obviously, each insert, decrease-key, and remove-min operation on $T$ will require time $O(\log S)$. The while-loop at Line 6 simulates the while-loop at Line 2 of Algorithm 1, where instructions at Lines 7-9 precisely correspond to those at Lines 3-5. After the measure update of the best-escape positions in $E$, the associated counters in $c$ are reinitialized (line 10). At this point, an analysis on the incoming moves of $E$ takes place (Line 11). For all moves $(v, u) \in Mv$ with $u \in E$ and $v \not\in Q$, the algorithm performs, at Lines 17-22, almost exactly the same operations done by Algorithm 3 at Lines 6-9. The only difference here is that $\square$-positions can only be forced to lift their measure if they are not yet contained in the quasi dominion $Q(\varrho)$. The case $v \in Q$, instead, identifies a possible discovering of a new escape of the remaining weak quasi dominion (Line 12). If $v \in Ps\square$, this is obviously an escape from $Q$, thus, it needs to be added to the priority queue $T$ paired with the associated best-escape forfeit computed along the move $(v, u)$ (Lines 13-14). If $v$ is already contained in $T$, the associated valued is decreased, if necessary. The case $v \in Ps\square$ is more complicated, since a $\oplus$-position is an escape iff its current strategy exits from $Q$ and it has no move within $Q$ that allows an increase of its measure. To do this check, once again, we employ the counter trick, where this time we associate with a $\oplus$-position
in $\Delta(q)$ the number of moves that satisfy the above property (Line 5). If the move $(v, u)$ satisfies the property w.r.t. the unlifted QDR (i.e., before the lifted of $u$ occurred), then the corresponding counter $g(v)$ is decreased (Line 15). When the counter reaches value 0, the position is necessarily an escape, so, it is added to the queue paired with its best possible forfeit (Line 16). Line 23 calls the win function in order to identify a possible new $\oplus$-dominion. Finally, Lines 24-29 update both the set of positions $Z$ to be lifted in the next iteration and the counter $c$, by executing exactly the same instructions as those at Lines 18-22 on the moves that reach the dominion $Q$. \hfill $\square$
