In this talk I review the current status of lattice QCD calculations at nonzero temperature and density. I focus on the QCD phase structure and bulk QCD thermodynamics at zero and nonzero chemical potentials.

34th annual International Symposium on Lattice Field Theory
24-30 July 2016
University of Southampton, UK

∗Speaker.
†The work is supported by the National Natural Science Foundation of China under the grant no. 11535012.
1. Introduction

Lattice QCD has been an excellent tool to study the properties of strong-interaction matter under extreme conditions, e.g. high temperature $T$, nonzero chemical potentials $\mu$ and strong magnetic field etc. Two long-time goals of lattice QCD computations at nonzero temperature have been completed in the past years: one is Equation of State at vanishing baryon density in a wide temperature range and the other is the nature of the transition from hadronic phase to quark gluon plasma phase. With lattice QCD many more knowledge on the thermodynamic as well as the dynamic properties of the QCD medium under extreme conditions have been acquired.

Many remarkable achievements have been made since the lattice QCD conference in the year of 2015. Due to the limitation of the length of the proceedings, I restrict myself reviewing several selected topics at $T>0$ and $\mu=0$ in Sections 2 and 3, and at $T>0$ and $\mu>0$ in Sections 4 and Sections 5. Here Section 2 includes topics on the QCD phase structure in the quark mass plane, Section 3 is on the QCD equation of state and topological susceptibility at high temperature, Section 4 on the QCD equation of state at nonzero baryon number density, and Section 5 on the QCD phase structure at nonzero chemical potentials.

For topics that are not covered and exhaustively discussed here please find them in recent reviews [1, 2, 3], proceedings of recent lattice plenary talks [4, 5, 6, 7, 8, 9] as well as lattice conference write-ups.

2. QCD phase structure in the quark mass plane

The nature of the QCD transition depends crucially on the values of the quark masses $m_q$ and the number of flavors ($N_f$). Basic features of this transition can be understood by invoking universality arguments [10]. These features are summarized as follows: 1) in the limit of $m_q \to 0$ or $m_q \to \infty$ for $N_f=3$ QCD, there exists a first order phase transition. The first order phase transition regions end at two second order phase transition lines belonging to the universality class of the 3-d, $Z(2)$ symmetric Ising model. These two second order phase transition lines are separated by a cross over region; 2) In the limit of $m_q \to 0$ for $N_f=2$ QCD there are two cases: a) if $U_A(1)$ symmetry is broken there exists a second order phase transition belonging to O(4) universality class; b) if $U_A(1)$ symmetry is effectively restored the transition will be of first order [10] or a second order belonging to $O(2)\times O(4)$ universality class[11, 12]; 3) If the QCD phase transition is of second order in the limit of $m_q \to 0$ there exists a tri-critical point where three different types of transitions meet.

The above features of QCD phase structure can only be confirmed through non-perturbative calculations. Recent investigations on the above issues from lattice QCD computations are shown in the following subsections.

2.1 Boundary of the first order chiral/deconfinement phase transition region

The first order chiral phase transition in 3-degenerate flavor QCD has been investigated on coarse lattices using unimproved [13, 14, 15, 16] as well as improved actions [17, 18, 19, 20, 21, 22, 23, 24]. However, the value of pion mass at the critical point where the first order phase transition ends, $m_{\pi_c}$, is not yet determined in the continuum limit and its value at finite lattice cutoff varies from $\sim 300$ MeV to $\sim 70$ MeV, strongly depending on the lattice spacing and discretization.
schemes of the action. By using the standard staggered action it was found that the critical pion mass \( m_c^{\pi} \) is about 300 MeV[13, 14] while using the improved p4 action \( m_c^{\pi} \) is about 70 MeV [19]. These results are obtained on the lattices with the temporal extent \( N_T = 4 \). Other calculations using p4 and asqtad actions on finer lattices disfavor a critical pion mass of 300 MeV [21, 20]. On finer lattices with \( N_T = 6 \) it has been shown that \( m_c^{\pi} \) becomes smaller compared with the one obtained from simulations on \( N_T = 4 \) lattices using standard staggered fermions [15].

Figure 1: State-of-the-art estimates on the critical pion mass where the first order chiral phase transition ends on the second order Z(2) transition line. Left: Simulations carried out using HISQ fermions on \( N_T = 6 \) lattices [25]. An upper bound of critical pion mass is obtained, i.e. \( m_c^{\pi} \lessgtr 50 \) MeV. Right: Preliminary results on the continuum extrapolation of \( m_c^{\pi} \) obtained from simulations using clover-improved Wilson fermions on \( N_T = 4, 6, 8 \) and 10 lattices [26]. The critical pion mass in the continuum limit is estimated to be around 100 MeV.

Recently the first order chiral phase transition region has been investigated using Highly Improved Staggered Quark action on \( N_T = 6 \) lattices [25]. It is expected that the chiral order parameter \( M \) at the pseudo critical temperature should have a scaling behavior of \( M \sim (m - m_c)^{1/\delta} \) as the system is close to the Z(2) critical line. Here \( m \) is the quark mass and \( m_c \) is the critical quark mass. Though the chiral condensate is not the true order parameter for the chiral phase transition in the 3-flavor QCD it is argued that \( \langle \bar{\psi} \psi \rangle \sim (m - m_c)^{1/\delta} \) holds in the case of small \( m \). By performing a simultaneous scaling fit to both chiral condensates and disconnected chiral susceptibilities as shown in the left panel of Fig. 1 an upper bound for the critical pion mass is obtained \( m_c^{\pi} \lessgtr 50 \) MeV [25].

Most recently the study has also been performed using improved clover-Wilson fermions [23] on \( N_T = 4, 6, \) and 8 lattices. The estimate critical pion mass in the continuum limit is reduced from \( \sim 300 \) MeV to \( \sim 100 \) MeV after including the analyses on the new data produced on \( N_T = 10 \) lattices [26]. Uncertainties arising from the Binder cumulant of the chiral condensate rather than that of a proper order parameter are also discussed in S. Takeda’s talk [26].

Concerned with the rooting issues in the staggered theory P. de Forcrand presented in this conference his study on QCD with 4-degenerate flavor using unimproved staggered fermions. The simulations have been performed on lattices with \( N_T = 4, 6, 8 \) and 10. The general conclusion is that the critical quark mass becomes smaller as approaching to the continuum limit [27].

All these studies mentioned above suggested that the chiral first order phase transition could be small and this region may has mild influence to thermodynamics happening in the real world.
Alternatively the 2nd order phase transition belonging to the O(4) universality class, which will be discussed in the next subsection, would be more relevant to the thermodynamics at the physical point.

The value of the critical pion mass where the first order deconfinement phase transition starts to end on the 2nd order Z(2) phase transition line has been studied quite a while ago on $N_\tau = 4$ lattices using the standard Wilson action $[28]$. An updated study has been presented for $N_f = 2$ QCD using the standard Wilson action on $N_\tau = 8$ lattices $[29]$. The estimated $m^c_{\pi}$ is within the range of 2.9 GeV $< m^c_{\pi} < 4.7$ GeV and note that $a m_{\pi}$ is larger than 1 in the simulation $[29]$. Generally the requirement of $a m_{\pi} < 1$ in the lattice simulation makes the continuum extrapolation costly in the heavy quark mass region.

2.2 Chiral phase transition in $N_f = 2+1$ and $N_f = 2$ QCD

In the vicinity to a second order phase transition the order parameter (magnetization) $M$ of system can be described by a single scaling function $f_G$, i.e. Magnetic Equation of State (MEoS)

$$\frac{M}{h^{1/\delta}} = f_G(t/h^{1/\beta \delta}). \quad (2.1)$$

Here $h$ is the external field which is proportional to quark mass, and $t = \frac{1}{T} \left( \frac{T - T_c}{T_c} \right)$ is the reduced temperature. They describe the proximity of the system to the critical window. $\beta$ and $\delta$ are critical exponents which are universal for theories with the same global symmetry. By looking into the temperature and quark mass dependences of $M$ and/or its susceptibilities the chiral phase transition of $N_f = 2$ QCD has been studied on the lattice using both Wilson $[30, 31, 32, 33, 34]$ and staggered fermions $[35, 36, 37, 38, 39, 40, 41]$. In all these mentioned investigations the $U_A(1)$ symmetry is implicitly assumed to be broken.

S.-T. Li from the Bielefeld-BNL-CCNU collaboration presented the updated scaling analyses of chiral observables in $N_f = 2+1$ QCD using HISQ fermions on $N_\tau = 6$ lattices $[42]$. It is found that in general the scaling violations become larger compared to previous studies using the p4fat3 action. As seen from the left panel of Fig. 2 the chiral condensates obtained with $m_{\pi} = 80$ and 90 MeV can be described by the MEoS without an regular term. A Z(2) scaling fit was also performed to the chiral condensate and the critical quark mass $m_c$ is compatible with zero within the errors. This suggests that $m^{tri}_{c} < m^{phy}_{c}$. While in the case that three quark flavors are not degenerate and the ratio of light to strange quark is fixed to be about 1/27 $m^{c}_{\pi}$ is suggested to be around 50 MeV from the study using the stout fermions on $N_\tau = 6$ lattices $[22]$.

T. Umeda from the WHOT-QCD Collaboration presented in this conference the updated study on the chiral phase transition in $N_f = 2$ QCD $[43]$. The simulations were carried out using clover-improved Wilson fermions on $16^3 \times 4$ lattices. As seen from the right panel of Fig. 2 that the rescaled chiral condensate, which is defined by a Ward-Takahashi identity, falls on the O(4) scaling curve. This suggests a 2nd order phase transition in the massless two-flavor QCD. Same conclusion was drawn from the so-called many flavor approach $[44, 45]$, although a first order transition is also suggested from a novel approach using simulations carried out at imaginary chemical potentials using standard staggered fermions $[46]$ and unimproved Wilson fermions $[47]$ on $N_\tau = 4$ lattices.
Figure 2: Left: O(2) scaling behavior observed based on simulations of \( N_f = 2 + 1 \) QCD using HISQ fermions on \( N_T = 6 \) lattices [42]. Right: O(4) scaling behavior from simulations of \( N_f = 2 \) QCD using clover-improved Wilson fermions on \( N_T = 4 \) lattices [43].

2.3 Fate of \( U(1)_A \) symmetry at nonzero temperature

As mentioned previously the nature of the chiral phase transition may depend crucially on the strength of \( U(1)_A \) symmetry breaking. The key question is whether \( U(1)_A \) symmetry is restored at the same temperature as the \( SU_L(2) \times SU_R(2) \) symmetry. In general two-point correlation functions of pseudo-scalars and scalars are used to probe the restoration of the \( U(1)_A \) and \( SU_L(2) \times SU_R(2) \) symmetries. E.g.: the degeneracy between the pseudo-scalar/iso-vector \( \pi \) and the scalar/iso-scalar, \( \sigma \) (the scalar/iso-vector \( \delta \) and the pseudo-scalar/iso-scalar \( \eta \)) signals the restoration of the \( SU_L(2) \times SU_R(2) \) symmetry, while the degeneracy between \( \pi \) and \( \delta \) (\( \sigma \) and \( \eta \)) is for the restoration of the \( U(1)_A \) symmetry.

The study has been carried out in \( N_f = 2 + 1 \) QCD using Möbius Domain Wall fermions on \( N_T = 8 \) and \( N_T = 16-32 \) lattices with \( m_\pi = 200 \) and 135 MeV [48, 49, 50]. Shown in the two left plots of Fig. 3 is \( \chi_\pi - \chi_\sigma \) and \( \chi_\pi - \chi_\delta \) for two different values of pion masses obtained from these studies. Here susceptibilities \( \chi_{\pi,\delta,\sigma,\eta} \) are the four volume integration of the corresponding two-point correlation functions. It can be clearly seen that at the temperature when \( \chi_\pi - \chi_\sigma \) becomes vanishing, i.e. the \( SU_L(2) \times SU_R(2) \) symmetry is restored, \( \chi_\pi - \chi_\delta \) remains nonzero and thus the \( U(1)_A \) symmetry is still broken. Only at \( T \gtrsim 200 \) MeV it starts to be restored. The right two plots of Fig. 3 show the results obtained in \( N_f = 2 \) QCD using Optimal Domain Wall fermions on \( N_T = 6 \) and \( N_T = 16 \) lattices [51]. Similar conclusions on the fate of the \( U(1)_A \) symmetry can be drawn.

Very recently the JLQCD collaboration updated their previous studies [52] by carrying out simulations in \( N_f = 2 \) QCD using Möbius Domain Wall fermions on \( N_T = 8 \) and 12 lattices in a temperature window above the critical temperature [53]. By decomposing the \( U_A(1) \) susceptibility \( \Delta = \chi_\pi - \chi_\delta \) into a chiral symmetric part and a chiral violation part \( \Delta^{GW} \) it is found that the chiral violation part dominates in \( \Delta \) in particular in the chiral limit as seen from the left plot of Fig. 4. Through the reweighting of the Domain Wall fermion determinant to that of the Overlap fermion the \( U(1)_A \) susceptibility \( \Delta^{OV} \) is obtained and its dependences on quark masses and temperature are shown as dashed symbols in the right panel of Fig. 4. The \( U(1)_A \) susceptibility with chiral zero modes subtracted, \( \bar{\Delta}^{OV} \), is also shown as colored symbols in the plot. It can be seen from the plot...
that $U(1)_A$ symmetry is restored at $T \gtrsim 200 \text{ MeV}$ in the chiral limit. This is consistent with the findings in Ref. [48, 49, 50, 51].

Other than chiral fermions the fate of the axial $U(1)$ symmetry has also been studied using staggered [57, 58, 54] as well as Wilson fermions [56]. The most recent results are shown in Fig. 5. Based on simulations of $N_f =2+1$ QCD using HISQ fermions with $m_\pi \approx 160 \text{ MeV}$, the results on $\chi_\pi - \chi_\delta$ [54] and screening masses [55] in various channels are shown in the left and middle panels, respectively. The $U(1)_A$ susceptibility shown in the left panel suggests that the axial $U(1)$ symmetry starts to get restored at $T \gtrsim 1.4 \ T_c$. From the perspective of screening masses the degeneracy between pseudo-scalar and scalar channels only shows up till $\sim 1.2 \ T_c$, while as expected the screening masses in the vector and axial-vector channels become degenerate already in the chiral cross over temperature $T_c$ region (shown as yellow band in the middle panel). On the other hand, the differences of screening masses between pseudo-scalar and scalar channels, $\Delta M_{ps}$, obtained from lattice computations using $O(a)$-improved Wilson fermions with $200 \text{ MeV} < m_\pi < 540 \text{ MeV}$, does not vanish at the chiral symmetry restoration temperature [56].

As a short summary, while the fate of the $U(1)_A$ symmetry in the chiral limit remains elusive as much more needs to be understood, e.g. detailed temperature and quark mass dependences of
$\chi_\pi - \chi_\delta$ as well as $\Delta M_{PS}$, the $U(1)_A$ symmetry is clearly broken at physical pion masses from current studies.

### 2.4 Chiral and deconfinement aspects of the QCD transition

At nonzero quark masses there is no true phase transition in $N_f = 2 + 1$ (2) QCD which may also due to the fact that binding energy, size and mass etc vary from particles. It has been shown in Ref. [61, 62] that heavier hadrons, e.g. open charm and open strange hadrons get deconfined in the chiral crossover temperature region. While it is found that in the SU(3) gauge theory susceptibilities of the imaginary and the real parts of the Polyakov loop can be used to probe the deconfinement phase transition [63], recently in the case of dynamic QCD the single-quark entropy $S_Q$ was introduced based on the Polyakov loop $P(x)$ as follows

$$S_Q = -\frac{\partial F_Q}{\partial T}, \quad F_Q = -T \log \left( \langle P(x) \rangle \right). \quad (2.2)$$

The temperature dependence of $S_Q$ is shown in the left panel of Fig. 6. By rescaling the temperature with the corresponding transition temperature $T_c$, $S_Q$ peaks at temperature just around $T_c$. This suggests that there could be possible connections between the deconfinement and chiral aspects of the QCD transition. Although the connection between the Polyakov loop susceptibilities and the Dirac eigenvalue spectrum is found to be weak [64, 65], the correlation between the local Polyakov loop and the lowest Dirac eigenmode is clearly observed in the middle and right panels of Fig. 6 [60]. At temperature below $T_c$, i.e. $T=171$ MeV, both high and low eigenmodes are delocalized and the local square norm of the Dirac eigenmode $|\psi(x)|^2$ has mild dependence on the real part of the trace of the local Polyakov loop $ReP(x)$. This is in contrast with the case at the temperature larger than $T_c$, i.e. $T=220$ MeV. There the high modes remain almost unaffected by the temperature and the low modes surely become localized in the area about $ReP(x) = 1/3$. 
Figure 6: Left: Temperature dependence of a single-quark entropy [59]. The x axis is rescaled by the corresponding lattice result for the transition temperature, i.e. here $T_c = 153, 193, 200$ and $270$ MeV for $N_f = 2 + 1, N_f = 3, N_f = 2$ and $N_f = 0$ (quenched) QCD, respectively. The red band shows the continuum extrapolated results based on simulations using HISQ fermions on $N_t = 6, 8, 10$ and $12$ lattices. Middle and Right: The local square norm of the Dirac Eigenmode $|\psi(x)|^2$ in correlation with the real part of the trace of the local Polyakov loop $Re[P(x)]$ obtained from simulations using Domain Wall fermions [60]. Every single line corresponds to one eigenmode on one configuration. The color of the line represents the location of the eigenmode in the Dirac eigenvalue spectrum as shown in the contour bar. The green horizontal line represents a normalized flat mode where there is no correlation between the eigenmode and the Polyakov loop. The vertical red line labels the location of $Re[P(x)] = 1/3$.

3. QCD thermodynamics at high temperature

3.1 Equation of State of $N_f = 2 + 1$ and $N_f = 0$ QCD

Figure 7: Left: Continuum extrapolated results for equation of state of $N_f = 2 + 1$ QCD obtained using HISQ [66] and stout fermions [67]. Right: The critical energy density $\epsilon_c$ in $N_f=2+1$ QCD. The band gives the continuum extrapolated result for the energy density taken from Ref. [66].

One of the milestones in the lattice QCD computation at finite temperature is the conclusive continuum extrapolated results for the equation of state (EoS) of $N_f = 2 + 1$ QCD with physical strange quark and light quark masses. The continuum extrapolated results on trace anomaly, pressure and entropy density from simulations using HISQ [66] and stout fermions [67], as shown in the left panel of Fig. 7, agree with each other. In the right panel the critical energy density $\epsilon_c$, where chiral crossover transition happens is shown, i.e. $0.18 < \epsilon_c < 0.5$ GeV/fm$^3$. Note that $\epsilon_c$ is at the
same order with the energy density of the nuclear matter, $\varepsilon_{\text{nuclear\ matter}} \approx 0.15$ GeV/fm$^3$ and the energy density inside a nucleon $\varepsilon_{\text{nuclear\ matter}} \approx 0.45$ GeV/fm$^3$ assuming the radius of nucleon to be $\approx 0.8$ fm. These mentioned calculations are based on the so-called T-integration method [68] and they are rather time-consuming as a subtraction of the zero temperature contributions is needed to eliminate divergent vacuum contributions. An alternative approach which is free of this issue is exploited in Refs. [69, 70, 71]. The general idea is to extract the entropy from the off-diagonal elements of the energy-momentum tensor which can be computed from ensembles defining in a moving frame. The other thermodynamic quantities can be computed from thermodynamic relations. The application of this method is now only to the SU(3) gauge theory and the very recent results on EoS are presented in this conference [72]. The obtained trace anomaly and pressure are quite consistent with results from the conventional T-integration method. By going to very high temperature, i.e. up to $1000 T_c$, the simulations become challenging as the physical spatial extent $L = a N_\sigma = N_\sigma / (T N_\tau)$ should not shrink as $T$ increases. This requires a larger ratio $N_\sigma / N_\tau$ at higher temperatures.

Another interesting method to compute EoS is to use the gradient flow [73, 74, 75]. The method to calculate the energy-momentum tensor in the SU(3) gauge theory has been proposed in Ref. [76]. It is observed in the lattice QCD computations that the signal-to-noise ratio of bulk properties, e.g. pressure and energy density obtained using the gradient flow is significantly reduced. And these bulk quantities computed by the FlowQCD collaboration are consistent with the results obtained from high precision T-integration results [77, 78]. The method has been extended to full QCD [79] and the first numerical results for $N_f = 2+1$ QCD with $O(a)$-improved Wilson quarks and pion mass larger than the physical one are reported in this conference [80, 81]. This method is promising also for the further calculations of energy-momentum tensor related quantities, e.g. viscosities etc [82].

3.2 Equation of State including contributions from charm quarks

Introducing heavy quarks, i.e. charm and bottom quarks on the lattice requires finer lattice spacing so that $am_{HQ} < 1$. Earlier computations on equation of state including charm quarks have been carried out by the MILC [83, 84], Wuppertal-Budapest [85] and ETM collaborations [86]. In Ref. [84] the trace anomaly was obtained using HISQ fermions with $m_\pi \approx 300$ MeV on $N_\tau = 6, 8$ and 10 lattices. It was found that the charm contribution to the trace anomaly becomes non-negligible starting at $T \approx 300$ MeV and reaches its maxima at $T \approx 500$ MeV. The non-negligible contribution from charm quarks was also found at the temperature above the chiral crossover temperature employing twisted Wilson fermions and the fixed-scale approach with $m_\pi \approx 370$ MeV on $N_\tau = 3, 4, \cdots 24$ lattices [86].

Very recently the Wuppertal-Budapest collaboration updated the EoS results of $N_f = 2 + 1 + 1$ QCD using 4stout fermions with physical charm, strange and light quark masses on $N_\tau = 6, 8, 10$ and 12 lattices [87]. Continuum extrapolated results for trace anomaly of $N_f = 2 + 1 + 1$ QCD up to $T = 1$ GeV are shown in the left panel of Fig. 8. Large aspect ratios, i.e. $N_\tau / N_\tau \sim 6$ are used to control the volume effects in high temperature region. By comparing to the trace anomaly of $N_f = 2 + 1$ QCD it is clearly seen that the effect of the charm quark starts to be relevant at $T \approx 300$ MeV. The effect of bottom quark is expected to appear at even higher temperature and the perturbation theory could then be applicable. Based on the analytic formula of pQCD up to
Figure 8: Left: Continuum extrapolated results for trace anomaly of $N_f = 2 + 1$ and $N_f = 2 + 1 + 1$ QCD based on simulations using 4stout fermions with physical charm, strange and light quark masses on $N_{\tau} = 6, 8, 10$ and 12 lattices. Right: Reconstructed trace anomaly of $N_f = 3 + 1 + 1$ QCD based on the lattice simulations of $N_f = 2 + 1 + 1$ QCD and the perturbative QCD calculations up to $\mathcal{O}(g^6)$. Figures are taken from Ref. [87].

$\mathcal{O}(g^6 \ln g)$ [88] and a one-parameter ($q_c$) fit of the numerical including the $\mathcal{O}(g^6)$ term [89] with $m_c(m_c) = 1.29$ GeV, the trace anomaly was extrapolated from lattice data for $N_f = 2 + 1 + 1$ QCD to those for $N_f = 3 + 1 + 1$ QCD with $m_b(m_b) = 4.18$ GeV in a broader temperature window as shown in the right plane of Fig. 8. The contributions to pressure and energy density from photons, neutrinos, charged leptons as well as electroweak sectors are also added up in Ref. [87] and the resulting EoS could then be relevant for the usage in cosmology.

3.3 Topological susceptibility at finite temperature

The topological susceptibility of QCD $\chi_t$ is one of the most important observables that can be used to study the QCD vacuum properties at finite temperature, e.g. whether dyons exists around the chiral crossover temperature and when a dilute gas of instantons can be a good description of the QCD vacuum etc [90]. Recently understanding $\chi_t$ becomes intensively investigated on the lattice [91, 92, 93, 54, 94, 95, 87] also due to its cosmological importance. The topological susceptibility is proportional to the squared mass of the axion which might be a possible candidate of dark matter [96]. The computation of the topological susceptibility on the lattice, however, is highly non-trivial [97]. Firstly the index theorem is not uniquely defined on the lattice and careful continuum extrapolations are needed. Secondly from the dilute instanton gas model [90] the topological susceptibility decreases with temperature with a power law $\chi_t \sim T^{-\gamma}$ and $\gamma$ is found to be $6 + 2N_f/3$ by including quantum fluctuations to the leading order in strong coupling constant over classical instanton action [98]. This power-law decreasing behavior of $\chi_t$ with $T$ indicates that the weight of the configurations with nonzero topology decreases with the same power in $T$. Thus statistics of Monte Carlo simulations should be increased accordingly. Moreover the topological freezing which prevents the tunneling between topological sectors makes the computation more difficult.

To circumvent the above mentioned issues several strategies are proposed, including the usage of the topological charge density [99], assuming a Gaussian distributions of topological charges
in sub-volumes [100], artificial decreasing the weight of the trivial sector [92], gradient flow [95] and the fixed topology sector [101, 87]. Recently \( \chi_t \) has been computed on the lattice in quenched QCD [91, 92, 93], \( N_f = 2 + 1 \) QCD having physical pion masses with stout [94], HISQ [54], Wilson fermions [95] and HISQ/overlap fermions [102] as well as \( N_f = 2 + 1 + 1 \) QCD [87] using stout/overlap fermions. Continuum extrapolated results for \( \chi_t \) in quenched and full QCD by three groups [93, 94, 54, 87] are shown in Fig. 9. Further detailed studies are needed to resolve the discrepancies among various groups.

Figure 9: Continuum extrapolated results for topological susceptibility in quenched QCD [93], \( N_f = 2 + 1 \) QCD with the gluonic definition of the topological charge [94], \( N_f = 2 + 1 \) QCD with a) gluonic definition and b) \( \chi_t = m^2 \chi_{\text{disc}} [54] \), and \( N_f = 2 + 1 + 1 \) QCD with fixed topology sector method [87].

4. QCD Equation of State at nonzero baryon number density

QCD equation of state (EoS) at nonzero baryon density is indispensable for the hydrodynamic modeling of the conditions met in the current/future heavy ion experiment program at low beam energies. In the current beam energy scan program at RHIC the freeze-out baryon chemical potential \( \mu_B \) is within the range of 20 to 400 MeV and the freeze-out temperature \( 140 \lesssim T \lesssim 170 \) MeV [103, 104]. This thus requires an EoS at nonzero baryon density for \( 0 \lesssim \mu_B / T \lesssim 3 \). At nonzero baryon chemical potential lattice QCD computations are hindered by the so-called sign problem. To circumvent this problem the Taylor expansion [105, 106] and Imaginary \( \mu \) [107, 108] methods are commonly used to compute QCD thermodynamics at the physical pion mass. In the framework of the Taylor expansion method, the difference of the pressure at nonzero and vanishing values of \( \mu_B \) can be expressed as the following Taylor series

\[
\frac{P(T, \mu_B) - P(T, 0)}{T^4} = \sum_{n=1}^{\infty} \frac{\chi_{2n}^B(T)}{(2n)!} \left( \frac{\mu_B}{T} \right)^{2n}
= \frac{1}{2} \chi_2^B(T) \hat{\mu}_B^2 \left( 1 + \frac{1}{12} \frac{\chi_4^B(T)}{\chi_2^B(T)} \hat{\mu}_B^2 + \frac{1}{360} \frac{\chi_6^B(T)}{\chi_2^B(T)} \hat{\mu}_B^4 + \ldots \right),
\]

where \( \chi_{2n}^B(T) = \frac{\partial^n P(T, \hat{\mu}_B)}{\partial (\hat{\mu}_B)^n} |_{\hat{\mu}_B = 0} \) is the 2\( n \)th order Taylor expansion coefficient and can be computed directly at \( \hat{\mu}_B = \mu_B / T = 0 \) on the lattice. Here the odd order of the coefficient vanishes due to...
the C-symmetry of the QCD action. Once the expansion coefficients are obtained all other bulk quantities can be obtained according to thermodynamic relations. To provide an EoS that is reliable up to $\mu_B/T \approx 3$ at least 8th order of the Taylor expansion coefficients are needed. And the main challenge in lattice QCD computations of the Taylor expansion coefficients is that the number of the fermion matrix inversions increases significantly at such a high order derivatives and so does the noise-to-signal ratio. While in the simulations at imaginary chemical potentials, there is no sign problem and thermodynamic quantities can be computed directly. However, an analytic continuation to real chemical potentials from imaginary chemical potentials is needed and is one of the main sources of uncertainties.

Figure 10: Left: Pressure differences of $N_f = 2 + 1$ QCD for $\mu_B/T=1, 2$ and 2.5 truncated at the orders of $\hat{\mu}_B^2$, $\hat{\mu}_B^4$ and $\hat{\mu}_B^6$ obtained from the Taylor expansion method using HISQ fermions [109]. The EoS as shown is reliable at $\mu_B/T \lesssim 2$, i.e. beam energy $\sqrt{s_{NN}} \gtrsim 12$ GeV [109]. Right: Consent of EoS in the continuum limit at both zero and nonzero $\mu_B$ obtained from analytic continuation from imaginary chemical potentials using stout fermions [110] and the Taylor expansion method using HISQ fermions [109]. The total energy density (upper two curves) and three times pressure (lower two curves) of $N_f = 2 + 1$ QCD at $\mu_B = 0$ and 2 obtained from simulations using HISQ fermions and the Taylor expansion method are shown [109]. The dark lines show the results obtained from analytic continuation with sixth order polynomials in $\hat{\mu}_B$ from simulations at imaginary chemical potentials using stout fermions [110]. Figures are taken from Ref. [109].

E. Laermann from the Bielefeld-BNL-CCNU collaboration presented in this conference the Equation of State of $N_f = 2 + 1$ QCD evaluated up to six order of baryon chemical potential $\hat{\mu}_B$ using the Taylor Expansion Method [109]. The simulations are carried out using HISQ fermions on $N_\tau = 6, 8, 12$ and 16 lattices. To have accurate determinations of coefficients a large number of gauge configurations, $\sim 10^5$ for each $T$, and the linear $\mu$ method for high order coefficients [111, 112] are used in the computation. To meet the strangeness neutral case, i.e. mean value of the strangeness $n_S$ is zero and the ratio of the mean values of electrical charge and baryon number $n_Q/n_B$ is 0.4, in the heavy ion collision experiment, the dependence of $\mu_B$ on the electrical charge $\mu_Q$ and strangeness chemical potential $\mu_S$ has to be taken into account. This is done by re-expressing the Taylor expansion coefficients also in terms of pressure derivates of $\mu_S$ and $\mu_Q$ computed at the vanishing values of potentials. As shown in the left panel of Fig. 10 the computation of the pressure difference meeting the strangeness neutral case between nonzero and zero $\mu_B$ is
reliable at \( \mu_B/T \lesssim 2 \) with the expansion truncated at the 6th order of Taylor expansion coefficients.

J. Günther from the Wuppertal-Budapest collaboration also presented their recent study on equation of state of \( N_f = 2 + 1 \) QCD at nonzero \( \mu_B \) [110]. The EoS is obtained from analytic continuation from simulations at imaginary chemical potentials using stout fermions on \( N_c = 10, 12 \) and 16 lattices. The conditions met in the heavy ion collisions, i.e. \( n_S=0 \) and \( n_Q/n_B=0.4 \), are imposed directly in the lattice simulation [113]. The uncertainties from analytic continuation are studied with various forms. The obtained energy density and three times pressure are shown as the dark lines in the right panel of Fig. 10. It is clearly seen that the results from two groups are in good agreement.

5. QCD phase structure at nonzero chemical potentials

Searching the critical point in the QCD \( T - \mu_B \) diagram is one of the main goals in the Beam Energy Scan program at RHIC [114]. One of the important probes is the fluctuations of conserved charges which is computable and measurable on the lattice and in the heavy ion experiment, respectively. The full understanding of the non-monotonic behavior of the ratio, i.e. 4th order to 2nd order proton number fluctuations, \( \kappa_p \sigma_p^2 = \chi_{L}^B/\chi_{S}^B \), observed in the STAR experiment certainly requires computations of higher-than-6th order Taylor expansion coefficients. As mentioned in the previous section the computation of high order Taylor expansion coefficients, from which the fluctuations of conserved charges at nonzero \( \mu_B \) can be constructed, is a great challenge. While the continuum extrapolated results for second and fourth order Taylor expansion coefficients have been computed [115, 116, 117, 118, 119], the 6th order Taylor expansion coefficient of pressure in the continuum limit are published very recently [109, 110] as shown in Fig. 11. The striking behavior seen in the \( T \) dependence of the coefficient is the flip of the sign at the temperature slightly larger than the chiral cross over temperature. This is comparable with the results obtained from Polyakov loop extended quark meson model having a global O(4) symmetry [120]. Together with the positivity of the 2nd and 4th order coefficients the decreasing behavior with beam energy of \( \kappa_p \sigma_p^2 \) measured in BES can be qualitatively described assuming the same condition on lattice can be imposed to the experiment data.

![Figure 11](image-url)

**Figure 11:** Six order Taylor expansion coefficient of the QCD pressure \( (P_6 \text{ and } c_6) \) obtained from simulations using HISQ fermions [109] and stout fermions at imaginary chemical potentials [110].
It is also important to study the feasibility of detecting the critical point in the heavy ion experiment. As in the heavy ion experiment the freeze-out line is ‘measured’ while the critical point is located on the crossover transition line. While the curvature of the crossover line/chiral phase transition line can be naturally computed on the lattice [121, 122, 123, 124, 113], it was proposed that the freeze-out temperature and the curvature of the freeze-out line can also be extracted by comparing the experimental cumulant ratios with those computed on the lattice [125, 126, 127]. The lattice computations on the parameterization of freeze out lines are also presented in Refs. [128, 126, 129, 130]. Additionally it has been argued quite successfully that lines on which certain thermodynamic observables or ratios thereof stay constant can describe the thermal conditions at the time of the chemical freeze-out in heavy ion collisions [131, 103]. Very recently the isentropic lines, i.e. with constant ratio of entropy to baryon number are presented [110]. And the μB dependences of lines of constant pressure P, entropy s and energy density ε are computed using the Taylor expansion method [109].

The obtained curvatures are

\[
0.0064 \leq \kappa_2^P \leq 0.0101 \quad , \quad 0.0087 \leq \kappa_2^s \leq 0.012 \quad , \quad 0.0074 \leq \kappa_2^\varepsilon \leq 0.011 . \tag{5.1}
\]

These curvatures are comparable to the curvature of the crossover lines 0.0066 \lesssim \kappa_2^{\text{crossover}} \lesssim 0.018 [121, 122, 123, 124, 113]. In the left panel of Fig. 12 lines of constant pressure P, entropy s and energy density ε as well as the crossover transition and freeze-out lines are shown. While an upper bound on the curvature of the freeze-out line \kappa_2^{\text{freeze-out}} \lesssim 0.011 is obtained by comparing the lattice QCD results to the RHIC data [127], the freeze-out line obtained by the STAR collaboration, ALICE collaboration and a hadronization model are not consistent among each other [132, 133, 134].

The location of a possible critical point, on the other hand, has not been determined reliably yet from lattice QCD computations. The radius of convergence of the Taylor expansion series, R, can be used to estimate the possible location of the critical point,

\[
R = \lim_{n \to \infty} \frac{r_n^\chi}{r_{2n}^\chi} = \left| \frac{2n(2n-1)\chi_{2n}^B}{\chi_{2n+2}^B} \right|^{1/2} , \tag{5.2}
\]

if all \chi_{2n}^B stays asymptotically positive at real values of \mu_B. Here \chi_{2n}^B is the 2nth order derivatives of the pressure with respect to \mu_B evaluated at \mu_B = 0 as shown in Eq. (4.2). The right panel of Fig. 12 summarizes current values of \chi_{2n}^B calculated from different groups. From the plot it is concluded that a critical point at \mu_B/T \lesssim 2 is strongly disfavored in the temperature range 135 MeV \leq T \leq 155 MeV and its location at higher values of temperature seems to be ruled out [109].

Other than Taylor expansion and imaginary chemical potential methods many promising approaches, e.g. Lefschetz thimbles [138, 9], complex Langevin simulations [139, 140], density of sate methods [141, 142], canonical approaches [143, 144] have been proposed to solve the sign problem and then to study the QCD phase diagram at nonzero baryon number density directly. However, their applicability to full QCD have not been proven yet and more work needs to be done.

Recent studies on the QCD phase structure at finite isospin chemical potential \mu_I have been presented by B. Brandt and G. Endrodi in this conference [145]. The sign problem is not present in QCD at nonzero \mu_I so the conventional algorithms can be applied in the lattice QCD simulations. A novel method based on the singular value spectrum of the massive Dirac operator and a
leading-order reweighting are shown to better determine the renormalized pion condensate. Preliminary results for the phase boundary to the pion condensation phase and crossover line from chiral condensates are shown and the nature of transitions on these boundary lines are being pursued.

Updated studies on the Roberge-Weiss phase transition in $N_f = 2 + 1$ QCD have also been presented by M. Mesiti [146] in this conference. The continuum extrapolated results on the Roberge-Weiss phase transition temperature $T_{RW} = 208$ MeV is obtained by simulations using stout fermions with physical pion mass on $N_T = 4, 6, 8$ and $10$ lattices. Based on the finite size scaling analyses the order of the transition is more likely to be second order belonging to 3d-Ising universality class rather than first order for $N_T = 4$ and 6 lattices. Studies on the Roberge-Weiss phase in $N_f = 2$ QCD using standard Wilson fermions [147] and staggered fermions [148] are also presented.

Acknowledgements

I would like to thank members of the Bielefeld-BNL-CCNU collaboration for the collaborations over the past years. Thanks also go to people who sent me materials/plots before my talk: Pedro Bicudo, Jacques Bloch, Szabolcs Borsanyi, Bastian Brandt, Falk Bruckmann, Guido Cossu, Gergely Endrodi, Philippe de Forcrand, Jana Günther, Yoichi Iwasaki, Kazuyuki Kanaya, Sándor Katz, Masakiyo Kitazawa, Yu Maezawa, Atsushi Nakamura, Yoshifumi Nakamura, Alexander Rothkopf, Jonivar Skullerud, Yusuke Taniguchi, Helvio Vairinhos, Takashi Umeda although not all of their achievements are included in my proceedings/talk.
