Many models currently exist which attempt to interpret the excess of gamma rays emanating from the Galactic Center in terms of annihilating or decaying dark matter. These models typically exhibit a variety of complicated cascade mechanisms for photon production, leading to a non-trivial kinematics which obscures the physics of the underlying dark sector. In this paper, by contrast, we observe that the spectrum of the gamma-ray excess may actually exhibit an intriguing “energy-duality” invariance under $E_\gamma \to E_\gamma^2/E_\gamma$ for some $E_\gamma$. As we shall discuss, such an energy duality points back to a remarkably simple alternative kinematics which in turn is realized naturally within the Dynamical Dark Matter framework. Observation of this energy duality could therefore provide considerable information about the properties of the dark sector from which the Galactic-Center gamma-ray excess might arise, and highlights the importance of acquiring more complete data for the Galactic-Center excess in the energy range around 1 GeV.

I. INTRODUCTION

A robust excess in the flux of gamma-ray photons emanating from the Galactic Center (GC) with energies of $\mathcal{O}(\text{GeV})$ has been observed in Fermi Large Area Telescope (Fermi-LAT) data. This excess was first noted in Ref. [1] and corroborated by a number of subsequent, independent analyses [2–12], including a dedicated study by the Fermi-LAT collaboration itself [13]. This excess consists not of a spectral line, but rather of a continuum which extends over a range of photon energies 0.3 GeV $\lesssim E_\gamma \lesssim$ 50 GeV and peaks at approximately $E_\gamma \sim$ 1 GeV.

A variety of possible explanations have been advanced as to the origin of this gamma-ray excess. Possible astrophysical explanations include emission from a population of millisecond pulsars [2,4,6,8,14] and the decay of neutral pions produced by collisions of cosmic-ray hadrons [9,12]. Likewise, a dark-matter particle with mass $m_X \sim (30 - 50)$ GeV and an annihilation cross-section $\langle \sigma v \rangle \approx (1 - 3) \times 10^{-26}$ cm$^3$/s which annihilates primarily to $b\bar{b}$ [9,12]. Likewise, a dark-matter particle with mass $m_X \sim 10$ GeV and an annihilation cross-section $\langle \sigma v \rangle \approx (0.5 - 2) \times 10^{-26}$ cm$^3$/s which annihilates primarily to $\ell^+\ell^-$ [10] also provides a good fit to the Fermi-LAT data, provided that secondary photons produced by inverse Compton scattering and bremsstrahlung processes involving both primary...
and secondary electrons are taken into account. On the other hand, the recent AMS-02 data on the cosmic-ray antiproton flux \([21, 22]\) has begun to exclude states in which a \(q \bar{q}\) final state dominates \([23]\). Concrete models in which the dark-matter candidate annihilates primarily to \(bb\) \([24, 29]\) and to \(\ell^+ \ell^-\) \([30, 31]\) have also been identified. Indeed, additional studies on other final states \([12]\) and generic model constraints \([32]\) have established that there exist further SM channels through which a dark-matter particle can annihilate or decay and reproduce the observed excess. Cascades involving one or more exotic intermediary particles which eventually decay down to SM fermions which in turn subsequently shower or hadronize have also been considered \([33, 34]\).

While dark-matter models of this sort are capable of reproducing the GC excess, the showering and cascade dynamics on which these models rely in order to generate an acceptable gamma-ray spectrum have their disadvantages as well. For example, their complicated dynamics obscures the relationship between the detailed shape of the gamma-ray spectrum and the properties of the underlying dark sector.

In this paper, by contrast, we propose a set of models in which the kinematics connecting the gamma-ray spectrum back to the dark sector is more straightforward. As a result, we find that characteristic imprints in the shape of that spectrum can potentially provide direct information about the dark sector.

We begin our study by identifying a characteristic feature of the GC gamma-ray excess which points back to a particularly simple photon-production kinematics. In particular, we observe that the spectrum of this excess may potentially exhibit an intriguing “energy duality” under which the spectrum remains invariant under the transformation \(E_\gamma \to E_\gamma^2 / E_\gamma\) for some self-dual energy \(E^*_\gamma\). As we shall argue, the presence of such an energy duality is indicative of a particularly simple kinematics in which the signal photons are produced directly via the two-body decays of an intermediary particle.

Energy dualities of this sort have been exploited in other contexts involving similar decay kinematics, such as cosmic-ray pion decay \([37]\) and the decay of heavy (new) particles produced at colliders \([38]\). At present, due to uncertainties in the astrophysical modeling of the GC region and also due to a paucity of reliable information about the shape of the spectrum at photon energies \(\mathcal{O}(10\ \text{MeV}) \lesssim E_\gamma \lesssim \mathcal{O}(1\ \text{GeV})\), the information contained in the Fermi-LAT data alone is not sufficient to conclusively determine whether the spectrum of the GC excess in fact displays such an energy duality. Nevertheless, as we shall discuss, if such a duality were to be confirmed through future experiments, this result would immediately favor a particular class of dark-matter models. Moreover, these observations apply not only for the GC gamma-ray spectrum but also for the spectra from other sources, such as dwarf galaxies, for which backgrounds can be more reliably estimated.

While a spectrum with these duality properties can be realized in certain cascade-based models \([39]\), we shall show that a self-dual gamma-ray spectrum also has a natural interpretation within the Dynamical Dark Matter (DDM) framework \([40, 41]\). Indeed, as we shall show, there exists a simple class of DDM models which yield an energy-dual spectrum that provides an excellent fit to the Fermi-LAT data, with a self-dual energy \(E_* \sim \mathcal{O}(1\ \text{GeV})\). These results further highlight the importance of acquiring more complete gamma-ray data in the energy range \(10\ \text{MeV} \lesssim E_\gamma \lesssim 1\ \text{GeV}\).

This paper is organized as follows. In Sect. [II] we examine the energy spectrum of the GC excess and discuss the extent to which it might potentially exhibit an energy-duality invariance under \(E_\gamma \to E_\gamma^2 / E_\gamma\) with \(E_* \sim \mathcal{O}(1\ \text{GeV})\). In Sect. [III] we then discuss how a gamma-ray spectrum with such an invariance can arise from dark-matter annihilation or decay. In Sect. [IV] we introduce a series of simple DDM models which give rise to a gamma-ray spectrum with this invariance and demonstrate that such DDM models provide a successful fit to the Fermi-LAT data. Our conclusions are then presented in Sect. [V] where we also discuss the potential implications of energy duality for other astrophysical gamma-ray signals which might be observed in the future. Finally, an Appendix contains a derivation of certain results presented in the text.

II. ENERGY DUALITY AND THE GALACTIC-CENTER EXCESS

As discussed in the Introduction, there is evidence of an unexplained gamma-ray excess from the GC in the Fermi-LAT data near 1 GeV that may be due to DM annihilations or decays. We consider the analysis in Ref. [9], in which the gamma-ray excess has been identified out to at least 10° from the GC. The authors of Ref. [9] fit the Fermi-LAT data to background templates consisting of the Galactic and extragalactic diffuse emission and the Fermi Bubbles. They also include a potential signal template for dark-matter annihilations. This latter contribution may be written in terms of a differential-flux contribution from dark-matter annihilation. In a single-particle dark-matter scenario, this flux \(\mathcal{F}\) may be written in the form

\[
\mathcal{F} = \frac{d^2 \Phi}{dE_\gamma d\Omega} = \frac{\mathcal{J} \langle\sigma v\rangle}{4\pi m^2} \frac{dN_{\gamma}}{dE_\gamma},
\]

where \(m\) is the mass of the DM particle and \(\langle\sigma v\rangle\) is its velocity-averaged annihilation cross section. Here \(\mathcal{J} = \int d\rho \rho^2\), where \(\rho\) is the dark-matter energy density and the integral is along the line of sight. Since the only nontrivial angular dependence for \(\mathcal{F}\) arises from \(\mathcal{J}_\omega\) we may replace \(\mathcal{J}\) in Eq. [2.1] by its angular average \(\overline{\mathcal{J}}\) over a relevant angle \(\Delta\Omega\) on the sky, where

\[
\overline{\mathcal{J}} = \frac{1}{\Delta\Omega} \int_{\Delta\Omega} d\Omega \mathcal{J}.
\]
We then find that
\[
\frac{d\Phi}{dE_\gamma} = J \langle \sigma v \rangle \frac{dN_\gamma}{4\pi (4m^2) dE_\gamma}
\]
where \( J \equiv (\Delta \Omega) \mathcal{F} \). In writing Eq. (2.1), we have assumed that the dark-matter particle is distinct from the antiparticle; if the particle and antiparticle are identical, the flux is rescaled by a factor of 2. The energy density \( \rho \) is assumed to follow a generalized Navarro-Frenk-White (NFW) halo profile [12, 13]
\[
\rho(r) = \rho_0 \frac{(r/r_s)^{-\gamma}}{(1 + r/r_s)^{3-\gamma}},
\]
where \( \rho_0 \simeq 0.4 \text{ GeV/cm}^3 \) is the local DM density at \( r \approx 8.5 \text{ kpc} \) and where \( r_s = 20 \text{ kpc} \) is the scale radius. It is then found [9] that inclusion of this additional template with an inner-profile slope in the range \( \gamma \approx 1.1 - 1.3 \) significantly improves the overall fit, with the dark-matter contribution taking the form of a continuum bump which peaks around \( E_\gamma \approx 1 \text{ GeV} \).

This dark-matter excess is shown in Fig. 1 where we plot the residuals of the differential photon flux obtained from the analysis in Ref. [9] of Fermi-LAT data from the GC. In this analysis, each photon is placed into one of 22 energy bins, equally spaced on a logarithmic scale between 0.3 and 50 GeV. We emphasize that the error bars in Fig. 1 are statistical only, and that there are also large astrophysical uncertainties from background modeling which are not shown. Note that there are two regions of interest (ROI) shown in Fig. 1: (i) \( 40^\circ \times 40^\circ \) with \( 1^\circ < |b| < 20^\circ \), \( |l| < 20^\circ \); and (ii) full sky with \( |b| > 1^\circ \), where \( b \) and \( l \) are the Galactic latitude and longitude, respectively. The authors of Ref. [9] also perform an analysis for a third, smaller region \( |b| < 5^\circ \), \( |l| < 5^\circ \), but there are fewer statistics and thus a larger energy binning for this ROI. As we later discuss, our model-independent analysis benefits from using regions with higher statistics.

Our interest in this paper is in the overall shape of this gamma-ray flux excess \( \mathcal{F} \), and in particular the possibility that this spectrum exhibits an energy-duality invariance under \( E_\gamma \rightarrow E_\gamma^2/E_\gamma \) for some \( E_\gamma \). Note that this is equivalent to \( x \rightarrow 1/x \) where \( x = E_\gamma/E_\gamma^* \), or \( \log(x) \rightarrow -\log(x) \). Thus, if this spectrum had an exact energy duality with \( E_\gamma^* \), the plot in Fig. 1 would be completely symmetric on a logarithmic scale. In order to test this hypothesis, we quantify the extent to which this spectrum exhibits an energy duality by calculating the ratio of the asymmetric part versus the symmetric part of the spectrum as a function of the chosen reference bin \( E_\gamma^* \) with respect to which these symmetries are calculated:
\[
\mathcal{R}(n_*) = \frac{\sum_{n=1}^{n_{\max}} |\mathcal{F}_{n_0+n} - \mathcal{F}_{n_0-n}|}{\sum_{n=1}^{n_{\max}} |\mathcal{F}_{n_0+n} + \mathcal{F}_{n_0-n}|}.
\]
Here \( \mathcal{F}_{n_0} \) is that portion of the excess differential flux residing within the \( m \)th energy bin, and \( n_{\max} \equiv \min(n_* - 1, 22 - n_*) \). Our results are plotted in Fig. 2 for \( n_* = 2, \ldots, 21 \). The value of \( n_* \) for which the asymmetric-to-symmetric flux ratio \( \mathcal{R}(n_*) \) is minimized indicates that the spectrum is most consistent with an energy duality for which the self-dual energy \( E_\gamma^* \) is contained in that particular bin. Of course, we do not expect a perfect energy duality to be evident in the data. In particular, aside from statistical fluctuations, we do not expect a binned energy-dual spectrum to have a perfectly vanishing minimum asymmetric-to-symmetric ratio \( \mathcal{R}(n_*) \), since an arbitrary binning will not logarithmically center a particular bin on \( E_\gamma^* \).

The results in Fig. 2 suggest that the GC excess may indeed be energy-dual with respect to the \( n_* = 3 \) energy bin, corresponding to \( E_\gamma \approx 0.5 \text{ GeV} \). However, there are a few difficulties in confidently determining the value of \( E_\gamma \) even if this energy duality does in fact exist. First, the energy binning prevents \( E_\gamma \) from being determined.
to within $\sim 125$ MeV, although any particular energy-dual model may yield a more precise fit. Second, since the statistical variance in the differential flux at lower energies is large, the apparent energy duality may be an artifact of small statistics. Both better energy resolution and higher statistics are important in making a precise model-independent determination of $E_\gamma$. (We note in this context that observations from, e.g., GAMMA-400 [14] are expected to have a better resolution than the Fermi-LAT near 1 GeV.) Third, we see that there are only two bins below that which contains $E_\gamma$. Thus data at even lower energies is needed in order to further test the energy duality from the higher-energy tail of the excess. Satellites that can probe the $10$ MeV $\lesssim E\gamma \lesssim 1$ GeV energy range with sufficient resolution will be crucial in determining if the photon spectrum associated with the GC excess is indeed energy-dual. Finally, we again stress that error bars in Figs. 1 and 2 represent only statistical errors, and our discussion assumes that the systematic uncertainties (which we have been ignoring) do not ruin the energy duality.

Assuming the GC excess is indeed energy-dual, it is also nevertheless possible that certain spectral features are masked due to the finite energy binning. As the photon energy approaches $E_\gamma \sim 0.5$ GeV, the spectrum has a single, sharp peak and falls off (nearly) monotonically above and below $E_\gamma$. However, the spectrum could potentially consist of multiple overlapping peaks that cannot be resolved. Indeed, such a scenario could still be energy-dual. Alternatively, the spectrum could exhibit a plateau or smooth bump instead of a cuspy peak, as long as the critical size needed to distinguish between these possibilities is smaller than the size of the energy bins.

In the following sections, we shall assume that the GC gamma-ray excess indeed exhibits an energy-dual spectrum and discuss the physical implications that such an observation might have in terms of annihilating and/or decaying dark matter.

### III. BOOSTS AND BOXES: BUILDING AN ENERGY-DUAL SPECTRUM

In this section, we shall discuss the underlying kinematics that might lead to an energy-dual photon spectrum. Our focus shall be on energy-dual spectra which resemble a single continuum “bump” — i.e., spectra whose magnitudes first rise as a function of energy and then fall.

#### A. Filling boxes through boosts

The most trivial example of a self-dual photon energy spectrum is a spectral line corresponding to mono-energetic photons with $E_\gamma = E_\gamma$. Indeed, this spectrum is self-dual regardless of the spatial orientations of the various photon momenta, and is thus self-dual if the photon momenta are distributed isotropically. However, what is perhaps less trivial is that the energy spectrum of such photons remains self-dual even if such photons are boosted relative to the lab frame in which the photon energies are measured. Indeed, all that is required is that the photons continue to be distributed isotropically in the boosted frame. To see this, let us imagine that a given photon with energy $E_\gamma$ is boosted with a velocity $\beta$, with an angle $\theta$ between the photon momentum and the boost direction. In the lab frame, the corresponding photon energy will be given by

$$E_\gamma = \gamma E_\gamma (1 + \beta \cos \theta)$$

(3.1)

where $\gamma = (1 - \beta^2)^{-1/2}$ is the usual relativistic factor. Since the probability distribution for these photons is assumed to be isotropic in the boosted frame, all values of $\cos \theta$ are sampled with equal probability. Thus, the resulting photon spectrum will fill out a spectral “box” in energy space stretching between $E_\gamma^{\pm} \equiv \gamma E_\gamma (1 \pm \beta)$. It is easy to verify that such a spectrum continues to be duality invariant. For $\beta = 0$ (vanishing boost), this box collapses to the original spectral line at $E_\gamma = E_\gamma$. However for non-zero boosts this spectral line expands in a self-dual way to form a box of width

$$\Delta E \equiv E_\gamma^{+} - E_\gamma^{-} = 2\gamma \beta E_\gamma$$

(3.2)

logarithmically centered at $E_\gamma = E_\gamma^{\pm}$.

Such a kinematics is easy to realize if our mono-energetic photons are isotropically emitted through the decay of a massive particle $\phi$ with momentum $p_\phi$. In this case the momentum $p_\phi$ produces the required boost, whereupon we can identify $\gamma = E_\phi/m_\phi$ and $\gamma \beta = p_\phi/m_\phi$. The width of the resulting spectral box is then given by

$$\Delta E = 2E_\phi p_\phi/m_\phi = 2E_\gamma m_\phi \sqrt{E_\phi^2 - m_\phi^2}.$$  

(3.3)

This width vanishes in the zero-boost limit $E_\phi \to m_\phi$. Otherwise, the width of this box grows as a function of $E_\phi$ and encompasses an ever-increasing range of energies. We can further ensure that the photons emitted through such a $\phi$ decay will be isotropic if $\phi$ is spinless or at least unpolarized; likewise such photons will be mono-energetic in the $\phi$ rest frame if this is a two-body decay, i.e., $\phi \to \gamma Y$ for some particle $Y$. In this case we find that

$$E_\gamma = \frac{m_\phi^2 - m_Y^2}{2m_\phi}.$$  

(3.4)

Given this setup, we may ask what minimum boost (i.e., what minimum value of $E_\phi$) is required in order for our resulting photon spectrum in the lab frame to include a given energy $E_\gamma$. Clearly, this is tantamount to determining the minimum value of $E_\phi$ for which $E_\gamma^{-} \leq E_\gamma \leq E_\gamma^{+}$. Solving these inequalities, we find that we must have

$$E_\phi \geq \frac{m_\phi}{2} \left(x + \frac{1}{x}\right) \quad \text{where} \quad x = \frac{E_\gamma}{E_\gamma}.$$  

(3.5)
This result displays the expected energy-duality invariance under $x \rightarrow 1/x$, and thus holds regardless of whether $E_\gamma < E_\gamma$ or $E_\gamma > E_\gamma$. Moreover, as expected, we see that no boost at all is required if $E_\gamma = E_\gamma$: indeed for $x = 1$ we find from Eq. (3.5) that any $E_\phi \geq m_\phi$ will suffice.

**B. Stacking boxes to build an energy-dual spectrum**

Thus far, we have seen that any massive particle $\phi$ that decays isotropically into a two-body final state including at least one photon will lead to a self-dual “box”-like photon energy spectrum. However, given this, it is not hard to imagine how we might realize a given self-dual “bump”-like energy spectrum: we simply stack different boxes on top of each other, utilizing boxes with suitably chosen widths and heights. Indeed, any self-dual bump-like spectrum can be decomposed into a collection of such boxes, in much the same way as any periodic curve can be Fourier-decomposed into cosines and sines of different frequencies. This stacking procedure is illustrated in Fig. 3.

At a physical level, this procedure may be interpreted kinematically as follows. As we have seen, a given box represents the energy spectrum of a photon emerging from the two-body decay of a massive particle $\phi$ with a given boost energy $E_\phi$: the width of the box corresponds to the boost energy $E_\phi$ via Eq. (3.3), while the height of the box is determined by the (differential) number of such $\phi$ particles with that boost energy. A given collection of boxes with various widths and heights therefore corresponds to a specific (differential) number $N_\phi$ of $\phi$ particles as a function of boost energy $E_\phi$.

Mathematically, if our bump-like photon spectrum corresponds to a differential photon number $dN_\gamma/dE_\gamma$, the process of superposition in Fig. 3 corresponds to writing

$$\frac{dN_\gamma}{dE_\gamma} = n_\gamma \int_{m_\phi}^{E_\phi} dE_\phi \frac{dN_\phi}{dE_\phi} \Theta(E_\gamma^+ - E_\gamma) \Theta(E_\gamma - E_\gamma^-)$$

(3.6)

where $dN_\phi/dE_\phi$ represents the corresponding differential number of decaying $\phi$ particles. Indeed, as described above, we may realize any self-dual function $dN_\gamma/dE_\gamma$ in Eq. (3.6) through an appropriate choice of $dN_\phi/dE_\phi$, provided that $dN_\gamma/dE_\gamma$ is truly “bump-like”, decreasing monotonically away from its maximum in either direction with no smaller peaks elsewhere. In Eq. (3.6), the Heaviside theta-functions in the numerator of the integrand enforce the upper and lower energy limits of each box, while the width $\Delta E$ in the denominator provides a proper corresponding normalization. Finally, the quantity $n_\gamma$ denotes the number of mono-energetic photons produced per $\phi$ decay. For the process $\phi \rightarrow \gamma Y$ we have $n_\gamma = 1$ unless $Y = \gamma$, in which case $n_\gamma = 2$.

Note that Eq. (3.6) may equivalently be written as

$$\frac{dN_\gamma}{dx} = n_\gamma \int_{m_\phi}^{E_\phi} dE_\phi \left[ \frac{dN_\phi}{dE_\phi} \frac{m_\phi}{2 \sqrt{E_\phi^2 - m_\phi^2}} \right]$$

(3.7)

where $x \equiv E_\gamma/E_\gamma$ and where the lower limit of integration comes from Eq. (3.5). Of course, in writing these integrals we are assuming an essentially “continuous” collection of boxes, as would be required in order to produce a net photon energy spectrum which rises and falls smoothly compared with a corresponding detector resolution/binning. Note that the integral in Eq. (3.7) depends on $x$ only through the lower limit of integration and the integrand is non-negative; thus, $dN_\gamma/dx$ decreases as the lower limit of integration increases. However, $x + 1/x$ is minimized at $x = 1$ and grows monotonically as $x$ departs from 1 in either direction. Thus, the spectrum $dN_\gamma/dx$ is maximized at $x = 1$, and decreases monotonically as $x$ either increases or decreases away from this limit.

In stacking our boxes, it is interesting to distinguish between three distinct cases: those which lead to a cusp for $dN_\gamma/dE_\gamma$ at the self-dual energy $E_\gamma = E_\gamma$, those which lead to a smoothly rounded maximum, and those which lead to a flat plateau. These cases can be distinguished by examining the derivative of the differential photon number as we approach the self-dual energy $E_\gamma$:

$$\frac{d^2N_\gamma}{dx^2} \bigg|_{x \rightarrow 1} = \text{sgn}(1-x) n_\gamma \left[ \frac{m_\phi}{2 \sqrt{E_\phi^2 - m_\phi^2}} \right]$$

(3.8)

Thus, if $dN_\phi/dE_\phi$ is non-vanishing as $E_\phi \rightarrow m_\phi$, then the derivative of the spectrum is discontinuous, implying that $dN_\gamma/dx$ has a cuspy peak at $x = 1$. By contrast, if $dN_\phi/dE_\phi$ approaches zero smoothly as
In general, DDM models contain multiple dark-matter components which together form an ensemble whose phenomenological viability is the result of a balancing between decay widths and relic abundances across the ensemble. If the mass splitting between the ensemble components is smaller than the energy resolution of the detector in question, the boost distribution of the intermediary particles $\phi$ appears continuous and thus the resulting photon spectrum appears as a continuum bump. A similar idea has been adopted in Ref. [51] within the context of MeV-range gamma-ray detection experiments.

### IV. DYNAMICAL DARK MATTER AND THE GALACTIC-CENTER EXCESS

In principle, one can imagine many models of dark-sector physics in which dark-matter annihilations or decays produce a particle $\phi$ whose subsequent decays produce the photons which are observed emanating from the Galactic Center. Likewise, there are many possibilities which give rise to a non-trivial injection spectrum $dN_\phi/dE_\phi$ for these intermediary particles. For example, dark-matter decays or annihilations involving $N$-body final states with $N > 2$ will lead to a non-trivial injection spectrum $dN_\phi/dE_\phi$ if $\phi$ is one of the resulting decay products. Other more complicated scenarios are also possible.

One particularly simple possibility, however, is to imagine that each of the “boxes” discussed in Sect. [11] corresponds to a different dark-matter particle $\chi_n$ in the dark sector. Each $\chi_n$ can then decay or annihilate, producing a pair of intermediary particles $\phi$ which subsequently decay into two photons. This kinematics is sketched in Fig. 4. In the limit in which each $\chi_n$ is non-relativistic with respect to the lab (observer) frame, the intermediaries $\phi$ resulting from each such annihilation or decay will be generated with a fixed boost whose magnitude depends on the mass of $\chi_n$. Thus, if we wish to construct dark-matter models based on the kinematic configurations shown in Fig. 4, we are naturally led to consider dark sectors comprising different dark-matter particles $\chi_n$ of different masses.

Remarkably, this is precisely one of the ingredients of the Dynamical Dark Matter (DDM) framework [40, 41]. In general, DDM models contain multiple dark-matter components which together form an ensemble whose phenomenological viability is the result of a balancing between decay widths and relic abundances across the ensemble. If the mass splitting between the ensemble components is smaller than the energy resolution of the detector in question, the boost distribution of the intermediary particles $\phi$ appears continuous and thus the resulting photon spectrum appears as a continuum bump. A similar idea has been adopted in Ref. [51] within the context of MeV-range gamma-ray detection experiments.

#### A. Constructing a DDM model

Towards this end, we therefore consider a DDM model in which a (potentially) large number of DM components $\chi_n$ form a dark-matter ensemble. We label the DDM components by the index $n = 0, \ldots, N$ in order of increasing mass. We assume that each $\chi_n$ has a relic abundance $\Omega_n$ such that the ensemble as a whole carries the observed total dark-matter relic abundance. Indeed, such DDM ensembles are realized in various well-motivated physics models beyond the SM, including scenarios with extra spacetime dimensions [10, 11, 52], confining hidden-sector gauge groups [53], large spontaneously-broken symmetry groups [54, 55], and even certain string configurations [56, 57].

In the case of DM annihilation, we consider a pair of $\chi_n$’s that annihilate to two $\phi$’s, each of which subsequently decays into two photons, as shown in Fig. 4(a). (For simplicity, we shall not consider the possibility of coannihilation by $\chi_m$ and $\chi_n$ where $m \neq n$.) As an example, $\chi_n$ could be a Dirac fermion and $\phi$ a singlet pseudoscalar (e.g., a “dark pion” or an axion-like particle). A possible Lagrangian would then take the form

$$\mathcal{L}_{\text{ann}} \supset \sum_{n=0}^{N-1} \left[ \lambda_n \chi_n \phi \phi + \frac{1}{f_\phi} \phi F_{\mu\nu} \tilde{F}^{\mu\nu} \right],$$

where $\tilde{F}^{\mu\nu}$ denotes the usual dual field strength tensor, $\Lambda$ is the scale of the effective field theory that governs DM annihilations, and $f_\phi$ is the symmetry-breaking scale that gives mass to the axion-like particle. The coupling

![FIG. 4: Annihilating and decaying DDM model scenarios under consideration. The DDM components $\chi_n$ annihilate or decay into the same intermediary particles $\phi$, which subsequently decay to two photons.](image-url)
between $\phi$ and $\chi_n$ generically differs from component to component and so is also indexed by $n$.

In the case of DM decay, by contrast, we imagine a similar process in which a single $\chi_n$ decays into two $\phi$'s, i.e., $\chi_n \rightarrow 2\phi \rightarrow 4\gamma$, as shown in Fig. 4(b). One possible scenario involves a scalar $\chi_n$ that decays into a pair of singlet pseudoscalar $\phi$ particles. The possible corresponding Lagrangian would then take the form

$$\mathcal{L}_{\text{dec}} \equiv \sum_{n=0}^{N} c_n^2 M_{\chi_n} \phi \phi + \frac{1}{f_{\phi}} \phi F_{\nu \mu} \tilde{F}^{\mu \nu}, \quad (4.2)$$

where $M$ is an associated mass scale which depends on the details of the underlying model. As in the annihilation case, the coupling $c_n^2$ between $\phi$ and $\chi_n$ can be different for different components.

However, this is not all. DDM models do not merely have a random assortment of dark-matter components — these components must also have properties such as masses, abundances, and decay widths which obey specific scaling relations. These scaling relations emerge naturally from a variety of underlying DDM constructions \cite{10,11,22,25}. The question that remains, then, is whether there exists a non-trivial intermediate injection spectrum $dN_\phi/dE_\phi$ that can fit the GC excess, but whether this injection spectrum is also consistent with an underlying dark sector whose individual components exhibit scaling relations of the sort DDM assumes. Only this would be the true test of an underlying DDM-based origin for the GC excess.

We therefore consider how physical quantities such as the relic abundances, cross sections, and decay widths associated with our dark-matter components $\chi_n$ vary across the ensemble. In general, these quantities can be parametrized in terms of the corresponding masses $m_n$. As a result, the photon flux $\Phi_n$ associated with $\chi_n$ (resulting from either decay or annihilation) will also depend on the mass $m_n$. For concreteness, just as in Ref. \cite{51}, we shall consider the case where $\Phi_n$ scales with $m_n$ according to a simple power law of the form

$$\Phi_n = \Phi_0 \left( \frac{m_n}{m_0} \right)^\xi = \Phi_0 \left( \frac{\sqrt{s_n}}{\sqrt{s_0}} \right)^\xi, \quad (4.3)$$

where the scaling exponent $\xi$ is taken to be a free parameter. Note that we replace the masses in Eq. (4.3) by the center-of-mass (CM) energies $\sqrt{s_n}$ in order that our results are expressed in a form applicable to both the annihilation and decay scenarios. In the non-relativistic regime, $\sqrt{s_n}$ is equal to $2m_n$ or $m_n$ for annihilating or decaying DM models, respectively.

In most DDM models, the masses $m_n$ can typically be parametrized in terms of the mass $m_0$ of the lightest DDM component, a mass-splitting parameter $\Delta m$, and a scaling exponent $\delta$:

$$m_n = m_0 + n^\delta \Delta m. \quad (4.4)$$

The CM energy gap between neighboring DM states, i.e., $\Delta(\sqrt{s_n}) = \sqrt{s_{n+1}} - \sqrt{s_n}$, is simply given by

$$\Delta(\sqrt{s_n}) = \begin{cases} 2\left[(n+1)^\delta - n^\delta\right] \Delta m & \text{for annihilation} \\ \left[(n+1)^\delta - n^\delta\right] \Delta m & \text{for decay}, \end{cases} \quad (4.5)$$

which is valid up to $n = N - 1$. In this paper, we shall choose $\delta = 1$, as arises in cases where the DDM ensemble are the states in a Kaluza-Klein tower. With this choice of $\delta$, the mass spectrum of the DDM ensemble has a uniform spacing. This allows us to write the CM energy gap as $\Delta(\sqrt{s})$ and thereby eliminate the unnecessary subscript $n$. Indeed, we find that $\Delta(\sqrt{s}) = 2\Delta m$ for annihilation and $\Delta m$ for decay.

Given this scaling behavior, we can now calculate the differential photon number $dN_\phi/dE_\phi$ corresponding to our DDM ensemble. To do this, we shall work in the continuum limit in which $\Delta m \to 0$. In this limit, we no longer have a discrete set of energies $\sqrt{s_n}$; instead we have a continuous CM energy $\sqrt{s}$ stretching between $\sqrt{s_0}$ and $\sqrt{s_N}$. Indeed, we may replace sums $\sum_{n=0}^{N}$ with integrals $\int_{\sqrt{s_0}}^{\sqrt{s_N}} d\sqrt{s}/\Delta(\sqrt{s})$. Likewise, we no longer have a discrete set of individual contributions $\Phi_n$ to the total flux at different discrete values of $\sqrt{s}$; instead we have a function $\Phi(\sqrt{s})$ which describes the total flux emerging from an underlying dark-matter annihilator or decay with CM energy $\sqrt{s}$. In other words, in this limit, Eq. (4.3) becomes

$$\Phi(\sqrt{s}) = \Phi_0 \left( \frac{\sqrt{s}}{\sqrt{s_0}} \right)^\xi. \quad (4.6)$$

Note that since $\Phi(\sqrt{s})$ is not a differential flux, it carries no spectral information about the resulting photons. Rather, this quantity represents a particular contribution to the total gamma-ray flux.

While there are many ways in which we might calculate the total flux corresponding to our DDM ensemble, we shall here follow a somewhat quick and intuitive path which is similar in spirit to the “stacking boxes” discussion above. A more rigorous derivation leading to the same result (and justifying its overall normalization) appears in the Appendix.

We shall assume that each ensemble constituent $\chi_n$ annihilates or decays into a pair of $\phi$ particles, each with energy $E_\phi = \sqrt{s_n}/2$, and that each such $\phi$ particle in turn decays into a pair of photons. Thus, the differential number of $\phi$ particles produced by dark-matter annihilation or decay with energy $E_\phi$ is proportional to the total flux density at $\sqrt{s} = 2E_\phi$:

$$\frac{dN_\phi}{dE_\phi} \propto \Phi(2E_\phi). \quad (4.7)$$

Next, we recognize that for each ensemble component $\chi_n$, the corresponding contribution to $dN_\phi/dE_\phi$ may be
written as
\[
\frac{dN_{\phi}^{(n)}}{dE_{\phi}} = 2 \delta (E_{\phi} - \sqrt{s_n}/2) \tag{4.8}
\]
where the prefactor indicates that there are precisely two \(\phi\) particles produced from the annihilation/decay of each \(\chi_n\). Thus, just as we stack boxes with appropriate heights in order to build our total spectrum as in Fig. 3, we can sum over all of the states in the ensemble with the appropriate weightings given in Eq. (4.7) in order to build our total “effective” differential number \(dN_{\phi}/dE_{\phi}\):
\[
\frac{dN_{\phi}}{dE_{\phi}} \propto 2 \int_{\sqrt{s_0}}^{\sqrt{s_n}} d\sqrt{s} \frac{\sqrt{s}}{\Delta(\sqrt{s})} \frac{\sqrt{s}}{\sqrt{s_0}} \frac{\xi}{\sqrt{s_0}} \delta(E_{\phi} - \sqrt{s}/2)
\]
\[
= \frac{4}{\Delta(\sqrt{s})} \left( \frac{2E_{\phi}}{\sqrt{s_0}} \right)^\xi
\times \Theta \left( \frac{\sqrt{s_0}}{2} - E_{\phi} \right) \Theta \left( E_{\phi} - \frac{\sqrt{s_0}}{2} \right). \tag{4.9}
\]
Indeed, this precisely is the injection spectrum \(dN_{\phi}/dE_{\phi}\) which has appeared throughout the main body of this paper thus far. This notion of an “effective” \(dN_{\phi}/dE_{\phi}\) will be discussed more precisely in the Appendix.

Note that the behavior of the injection spectrum \(dN_{\phi}/dE_{\phi}\) as \(E_{\phi} \to m_{\phi}\) depends on \(\xi\) and \(s_0\). For \(s_0 > 4m_{\phi}^2\), this injection spectrum is identically zero in the range \(m_{\phi} \leq E_{\phi} \leq \sqrt{s_0}/2\), yielding a plateau-like maximum in the photon spectrum. On the other hand, for \(s_0 \sim 4m_{\phi}^2\), the injection spectrum decreases as \(E_{\phi} \to m_{\phi}\) for positive \(\xi\), yielding only a mild discontinuity in the derivative of the resulting photon spectrum near its maximum. For negative \(\xi\), however, one would find a sharper peak.

Evaluating the photon spectrum that follows from this result for \(dN_{\phi}/dE_{\phi}\) is now simply a matter of substituting Eq. (4.9) into Eq. (3.7) with \(n_\gamma = 2\). We thus obtain
\[
\frac{dN_{\gamma}}{dx} \propto \frac{2m_{\phi}}{\Delta(\sqrt{s})} \left( \frac{2m_{\phi}}{\sqrt{s_0}} \right)^\xi
\times \left[ B_{z+} \left( -\frac{\xi}{2} \frac{1}{2} \right) - B_{z-} \left( \frac{\xi}{2} \frac{1}{2} \right) \right], \tag{4.10}
\]
where \(B_z(a, b)\) denotes the incomplete Euler beta function and where
\[
z_+ \equiv \max \left( \frac{4m_{\phi}^2}{s_N}, \min \left[ \frac{4m_{\phi}^2}{s_0}, \frac{4}{(x+1/x)^2} \right] \right),
\]
\[
z_- \equiv \frac{4m_{\phi}^2}{s_N}. \tag{4.11}
\]

Our final step is to convert this expression for \(dN_{\gamma}/dx\) into a total differential flux \(d\Phi/dE_\gamma\). However, in terms of the total “effective” \(dN_{\gamma}/dE_\gamma\) given in Eq. (4.10), we know that
\[
\frac{d\Phi}{dE_\gamma} = \frac{dN_\gamma}{dE_\gamma} = \frac{dN_{\gamma}(0)}{4}, \tag{4.12}
\]
It then follows that
\[
\frac{d\Phi}{dE_\gamma} = \frac{\Phi_0}{4} \frac{dN_{\gamma}}{dE_\gamma} = \frac{\Phi_0}{4} \frac{dN_{\gamma}}{dE_\gamma}, \tag{4.13}
\]
where \(dN_{\gamma}/dx\) is given in Eq. (4.10).

The result in Eq. (4.13) is sufficient for understanding the shape of the overall photon spectrum. The normalization of this spectrum nevertheless remains unixed because of the unknown normalization in Eq. (4.10). In general, the derivation we have provided is not capable of determining the correct normalization. However, given the prefactors already present in Eq. (4.10), we shall see in the Appendix that the remaining constant of proportionality in Eq. (4.10) is actually equal to one. Thus, in what follows, we shall feel free to replace the proportionality sign in Eq. (4.10) with an equals sign.

### B. Fitting the observed excess

Given the expression in Eq. (4.13) for the differential flux predicted by our DDM model, we can now perform a fit to the spectrum of the GC excess observed in the Fermi-LAT data. Note that the data reported in Ref. 9 is actually quoted in terms of the rescaled differential flux \(E_\gamma^2d\Phi/(dE_\gamma dx) = E_\gamma^2 F\). Thus, putting the pieces together, we shall therefore fit this data to the predicted DDM template function
\[
E^2_\gamma F = \frac{E_\gamma^2}{\Delta \Omega} \Xi \left( \frac{4E_\gamma}{\sqrt{s_0}} \right)^\xi
\]
\[
\times \left[ B_{z+} \left( -\frac{\xi}{2} \frac{1}{2} \right) - B_{z-} \left( \frac{\xi}{2} \frac{1}{2} \right) \right], \tag{4.14}
\]
where
\[
z_+ \equiv \max \left( \frac{16E_\gamma^2}{s_N}, \min \left[ \frac{16E_\gamma^2}{s_0}, \frac{4}{(E_\gamma/E_\gamma + E_\gamma/E_\gamma)^2} \right] \right)
\]
and where
\[
\Xi \equiv \frac{\Phi_0}{\Delta(\sqrt{s})}. \tag{4.16}
\]

Note that within this template we have replaced \(m_{\phi}\) in favor of the self-dual energy \(E_\gamma\). Moreover, because it provides a better fit to the spatial morphology of the excess, we shall focus on the annihilating dark-matter case, for which \(\sqrt{s_0} = 2m_0\). Thus, we take \(\{m_0, m_N, \xi, E_\gamma, \Xi\}\) as the five free parameters to which we perform our fit. Since the first four parameters describe the underlying particle-physics model, we would expect similar best-fit values to emerge for both ROI’s. By contrast, the normalization factor \(\Xi\) depends not only on our specific particle-physics model but also on astrophysical information about the particular ROI — information encapsulated by the corresponding \(J\)-factor which is implicit.
FIG. 5: The GC photon excess spectra (black dots and error bars) extracted from Ref. [9], corresponding to ROI’s (i) and (ii) for the left and right panels respectively, with the best-fit DDM flux superimposed in red. Input parameters for these best-fit curves are also shown in each panel, with the best-fit values for \( m_0 \), \( m_N \), and \( E_\ast \) quoted in GeV. These results indicate that our DDM model is successful in modelling the GC photon flux excess.

within \( \Phi_0 \). For this reason, the best-fit values of \( \Xi \) for our two ROI’s need not be the same as each other.

In our analysis of the data for both ROI’s, we perform our fits using the standard \( \chi^2 \) statistic as our measure of goodness of fit. Our best-fit results for ROI (i) and ROI (ii) are displayed in the left and right panels of Fig. 5 respectively. The corresponding central values (black dots) for the gamma-ray flux in each bin are also shown in each panel, along with their associated error bars. The results shown in Fig. 5 indicate that our signal model reproduces the observational data for both ROI’s rather well. Indeed, the \( \chi^2 \) values for the fits performed on the data from ROI (i) and ROI (ii) are 36 and 19, respectively, with 17 degrees of freedom in each case (as there are 22 data points for each of our five-parameter fits). These numbers indicate that this DDM scenario is indeed successful in accounting for the GC excess.

The best-fit values for the parameters \( m_0 \), \( m_N \), \( \xi \), and \( E_\ast \) are shown in Fig. 5 with the first, second, and fourth of these quantities quoted in GeV. All of the reported errors are given at the 68% confidence level. We also find that

\[
\Xi = \begin{cases} 
1.81^{+0.15}_{-0.17} \times 10^{-6} \text{ (GeV cm}^2 \text{s)}^{-1} & \text{for ROI (i)}, \\
30.26^{+2.80}_{-2.85} \times 10^{-6} \text{ (GeV cm}^2 \text{s)}^{-1} & \text{for ROI (ii)}.
\end{cases}
\]

With the exception of \( m_N \), we see that all of the model parameters measured for both ROI’s are in good agreement with each other. This indicates that the shape of the excess does not change appreciably with the ROI and that our energy-dual scenario works well for both ROI’s.

The mismatch in the \( m_N \) measurement is not surprising because only the upper and lower endpoints of the energy spectrum (i.e., the horizontal edges of the widest box) are sensitive to \( m_N \), and it is precisely here where the signal statistics are relatively poor. An over- or under-estimate of the foreground/background flux could therefore easily shift both endpoints rather substantially. Likewise, the best-fit values for \( E_\ast \) for each ROI, while consistent with each other, do not quite agree with the results of the model-independent analysis in Sect. II. However, as discussed above, the choice of energy-binning scheme may skew the model-independent results, as \( E_\ast \) does not have to lie at the center of a given energy bin. If this type of DDM scenario is realized in nature, one would expect the best-fit values for \( E_\ast \) from the two analyses to more closely coincide as more data is acquired and as the energy resolution of the detector is improved.

Finally, we observe that general features of our best-fit DDM models coincide nicely with the observed data. As pointed out at the end of Sect. II, the observed data is consistent with a relatively sharp peak in the photon spectrum near the global maximum — a result which suggests that the injection spectrum \( dN_\phi/dE_\phi \) of the intermediary particle \( \phi \) remains non-zero as \( E_\phi \to m_\phi \). Furthermore, the rapidly falling nature of the photon energy spectrum, as shown in Fig. 5 suggests that the injection spectrum of \( \phi \) should fall quickly as \( E_\phi/m_\phi \) increases. In typical examples, the injection spectrum of \( \phi \) particles produced from the annihilation/decay of a DDM ensemble typically follows a power law, as in Eq. (4.9). One would therefore expect that the best fit to the Fermi-LAT data would arise from a falling power law (i.e., from a negative scaling exponent \( \xi < 0 \)). The results obtained in our fit coincide with this expectation.
V. CONCLUSIONS

The possibility that the excess in the flux of gamma rays emanating from the vicinity of the GC is the result of annihilating or decaying dark matter is an intriguing one. If dark matter is indeed responsible for this excess, one pressing question is what, if anything, we can learn about the properties of the dark sector from the spectral information associated with that excess. Dark-matter models of the gamma-ray excess typically rely on complicated cascade mechanisms for photon production in order to reproduce the spectrum of the excess — mechanisms whose non-trivial kinematics obscures the connection between the properties of that spectrum and the properties of the dark-matter candidate.

In this paper, by contrast, we have considered an alternative dark-matter interpretation of the gamma-ray excess — one in which a more direct connection exists between the properties of the underlying dark sector and the spectral shape of the gamma-ray excess to which it gives rise. In particular, we have pointed out that the spectrum of the observed excess in the Fermi-LAT data is potentially invariant with respect to an energy duality transformation of the form \( E_\gamma \rightarrow E_\gamma^* / E_\gamma \), for a self-dual energy \( E_s \sim \mathcal{O}(1 \text{ GeV}) \). Motivated by this observation, we have presented a broad class of physical scenarios wherein such an energy self-duality is realized. In these scenarios, dark-matter annihilating/decay produces a non-trivial injection spectrum \( dN_\phi / dE_\phi \) of intermediary particles \( \phi \), each of which subsequently decays into a final state involving one or more photons which are mono-energetic and isotropically distributed in the \( \phi \) rest frame. We have also shown that an appropriate injection spectrum of \( \phi \) particles for describing the Fermi-LAT data is naturally realized within the context of the DDM framework.

It is clear that our scenario relies directly on the existence of a multi-component dark sector, as this is a primary ingredient of the DDM framework. The possibility of non-minimal dark sectors has received increasing attention because many DM models predicated upon such sectors not only have non-trivial cosmological consequences (e.g., “assisted freeze-out” [57]), but also often interesting phenomenological implications as well (e.g., “boosted dark matter” [58–60] as well as collider, direct-detection, and indirect-detection signatures [61–65] that transcend those normally associated with traditional WIMP-like single-component dark-matter scenarios). Indeed, multi-component dark sectors can even give rise to enhanced complementarity relations which can be used to probe and constrain the parameter spaces of such models [66]. Thus, our explanation of the GC excess within the context of the DDM framework — if corroborated by future experiments — could provide an interesting window into the physics of the dark sector. Indeed, it would be interesting to study the cosmological and phenomenological implications of the particular set of DDM parameters obtained in our fit to the Fermi-LAT data.

It is also important to realize that our discussion of the energy duality of the photon spectrum under \( E_\gamma \rightarrow E_\gamma^* / E_\gamma \) has a broad applicability that extends well beyond its application to the gamma-ray excess observed in the Fermi-LAT data. Indeed, this duality can be used as a tool for deciphering the origins of any generic continuum excess which might potentially be observed at future X-ray or gamma-ray facilities. As discussed in Sect. [11], a broad range of spectral shapes can be realized within scenarios of the sort described above. In particular, any bump-like feature in the gamma-ray spectrum can be realized in such a scenario, provided

- the spectral feature is self-dual under the transformation \( E_\gamma \rightarrow E_\gamma^* / E_\gamma \); and
- the spectral feature has a global maximum at \( E_\gamma = E_s \) and decreases monotonically as \( E_\gamma \) either increases or decreases away from \( E_s \).

Moreover, we have shown that in scenarios of this sort, the shape of the spectral feature is directly correlated with the behavior of the intermediary injection spectrum at \( E_\phi = m_\phi \). In particular, information about the kinematics of \( \phi \) production and decay is manifest in the behavior of \( dN_\phi / dE_\phi \) near its maximum:

- If \( dN_\phi / dE_\phi \) remains non-zero as \( E_\phi \rightarrow m_\phi \), the photon spectrum will exhibit a cuspy peak at \( E_s \).
- If \( dN_\phi / dE_\phi \rightarrow 0 \) as \( E_\phi \rightarrow m_\phi \), the photon spectrum will be smooth at \( E_s \).
- If \( dN_\phi / dE_\phi \) vanishes below some threshold energy \( \overline{E} > m_\phi \), the photon spectrum will exhibit a plateau around \( E_s \).

Thus, an excess of photons emanating from any astrophysical source which possesses the above features not only lends itself to an interpretation in terms of our annihilating/decaying dark-matter scenario, but can also yield additional information about the properties of the underlying dark sector.

One final comment is in order. In particular, we stress that although the gamma-ray excess observed in the Fermi-LAT data is consistent with an energy duality of the kind we have discussed in this paper, there are significant uncertainties in the spectral shape of the excess which, at present, preclude any more definitive statements along these lines. These include not only statistical uncertainties, but also systematic uncertainties in the astrophysical foregrounds/backgrounds in the vicinity of the GC and uncertainties resulting from the energy resolution of the the Fermi-LAT instrument. Moreover, the preferred value for the self-dual energy \( E_s \sim \mathcal{O}(1 \text{ GeV}) \) is very close to the lower limit of the energy range for which reliable data exists. As a result, current data does not yet permit us to distinguish between the annihilating/decaying dark-matter scenario we have described here and other possible explanations of the CG excess.
gamma-ray excess. However, there are new astronomical instruments, both planned and under consideration, which are far better equipped to investigate whether the gamma-ray spectrum from the GC indeed exhibits such an energy-duality. For example, GAMMA-400 is expected to have a better energy resolution than Fermi-LAT in the $E_{\gamma} \sim 1$ GeV regime. A variety of instruments designed to study the gamma-ray spectrum in the 10 MeV $\lesssim E_{\gamma} \lesssim 1$ GeV regime, such as ASTROGAM [64], have also recently been proposed, often with energy resolutions far superior to those of similar experiments past or present. High-statistics data from such experiments could potentially definitively rule out or else lend significant credence to our scenario. Indeed, this illustrates that even when an excess of photons observed at indirect-detection experiments has the form of a broad continuum bump, precision measurements of the spectral shape of this bump can prove crucial for our understanding of the underlying physics.

Appendix A: Calculating the Photon Flux of the DDM Model

In this Appendix we provide a rigorous calculation of the differential photon flux $d\Phi/dE_{\gamma}$ corresponding to the DDM model introduced in Sect. IV A. This derivation will also confirm the normalization factors introduced in Eq. (4.14) and likewise clarify the meaning of the “effective” differential number $dN_{\phi}/dE_{\phi}$ given in Eq. (4.9). By and large, our approach will generally follow that of Ref. [51].

We begin by noting that while the expression for the differential flux $d\Phi/dE_{\gamma}$ in Eq. (2.3) is suitable for a single dark-matter candidate $\chi$, in multi-component con-
Given this, we may identify the entire quantity on the second line of Eq. (A7) as an “effective” $dN\phi/dE\phi$, one which combines not only the Dirac $\delta$-function contribution in Eq. (A6) but also the scaling factor $(\sqrt{s}/\sqrt{s_0})^\xi$. Indeed, this is precisely the quantity which was constructed in Eq. (4.9) and which (by abuse of notation) was casually denoted $dN\phi/dE\phi$ throughout the body of the text. As such, it is this effective quantity which encodes not only the widths but also the heights of the stacked “boxes” in Fig. 5.

Eq. (A3) also affords us another way of interpreting this effective number $dN\phi/dE\phi$. In Eq. (A3), it is the quantity in parentheses which varies across the ensemble and which, in so doing, exhibits the DDM scaling behavior. However, for the purposes of calculating fluxes, we can equivalently imagine that the quantities within the parentheses in Eq. (A3) are actually constant, and that their scaling behavior has been absorbed into an effective differential number $dN\phi/dE\phi$ instead. Indeed, it is precisely for these reasons that a simple relation such as that in Eq. (4.12) holds when written in terms of effective number densities.

Given the expression in Eq. (A7), evaluation of the flux $d\Phi/dE\phi$ now proceeds directly. This then yields the results listed in Sect. IV.A and confirms the overall normalizations quoted there.
