Abstract. We study the free energy distribution function of a weakly disordered Ising ferromagnet in terms of the $D$-dimensional random temperature Ginzburg–Landau Hamiltonian. It is shown that besides the usual Gaussian ‘body’ this distribution function exhibits non-Gaussian tails both in the paramagnetic and in the ferromagnetic phases. Explicit asymptotic expressions for these tails are derived. It is demonstrated that the tails are strongly asymmetric: the left tail (for large negative values of the free energy) is much slower than the right one (for large positive values of the free energy). It is argued that at the critical point the free energy of the random Ising ferromagnet in dimensions $D < 4$ is described by a non-trivial universal distribution function which is non-self-averaging.

Keywords: classical phase transitions (theory), disordered systems (theory), energy landscapes (theory), fluctuations (theory)

ArXiv ePrint: 1204.1831
1. Introduction

Ferromagnetic systems with weak disorder (e.g. with a small concentration of non-magnetic impurities) have been under intensive study during last four decades. As disorder of this type cannot destroy the ferromagnetic ground state, most of the efforts (theoretical, experimental and numerical) have been concentrated on the critical properties of such systems (see, e.g., [1, 2]) where even weak disorder has been proved to be a ‘relevant variable’. It turns out that the presence of quenched disorder can essentially modify the critical behavior of the system such that new universal critical exponents may set in. Another interesting phenomenon which appear due to quenched randomness in the Ising ferromagnet is the so called Griffiths singularities in the thermodynamical functions [3]. Apart from these two big issues the effects produced by weak quenched disorder on the thermodynamical properties of a ferromagnet (away from the critical point) have usually been considered as more or less irrelevant corrections to the pure case.

The aim of this study is to demonstrate that due to the presence of weak disorder the statistical properties of the (random) free energy of the Ising ferromagnet become rather non-trivial. Of course, in the thermodynamic limit due to self-averaging the free energy distribution function turns into the δ-function. However, if the volume of the system is large but finite (which, in particular, is the case in numerical simulations) the situation is much more complicated. Away from the critical point at scales much larger than the correlation length $R_c$ the system could be considered as a set of more or less independent regions with the size $R_c$. In this case one would naively expect that the free energy distribution function must be Gaussian. In fact this is not the case. It can be shown that besides the central Gaussian part this distribution has asymmetric and essentially non-Gaussian tails. Approaching the critical point one finds that the range of validity of the Gaussian ‘body’ shrinks while the ‘tails’ become of the same order as the ‘body’. Moreover, if we naively imitate the critical point by assuming that the correlation length becomes of the order of the system size we formally find that the free energy distribution function turns into a universal curve.

Free energy distribution function of a random Ising ferromagnet

The present investigation of the finite volume fluctuations of the free energy will be performed in terms of the replica method. This approach has already been successfully used for the study of the free energy distribution function in mean-field spin-glasses and other strongly disordered systems [4]. Here it will be applied for systems containing weak disorder.

In our study the Ising ferromagnet with quenched disorder will be considered in terms of the random temperature \( D \)-dimensional Ginzburg–Landau Hamiltonian

\[
H[\phi, \xi] = \int d^D x \left[ \frac{1}{2} (\nabla \phi(x))^2 + \frac{1}{2} (\tau - \xi(x))\phi^2(x) + \frac{1}{4} g_o \phi^4(x) \right]
\]

where independent random quenched parameters \( \xi(x) \) are described by the Gaussian distribution function

\[
P[\xi(x)] = \prod_x \left[ \frac{1}{\sqrt{4\pi u_0}} \exp \left( -\frac{1}{4u_0} \xi^2(x) \right) \right]
\]

where \( u_o \) is the parameter which describes the strength of the disorder, \( \bar{\xi}^2 = 2u_o \). In what follows it will be supposed that the disorder is weak: \( u_o \ll \tau^2 \) and \( u_o \ll g_o \).

For a given realization of the disorder the partition function of the considered system is

\[
Z[\xi] = \int D\phi \exp (-H[\phi, \xi]) = \exp (-F[\xi])
\]

where \( \int D\phi \) denotes the integration over all configurations of the fields \( \phi(x) \) and \( F[\xi] \) is the free energy of the system.

The distribution function of the random quantity \( F[\xi] \) can be analyzed by studying the moments of the partition function. Taking the integer \( n \)th power of the expression in equation (3) and averaging over the disorder parameters \( \xi(x) \) (with the Gaussian distribution, equation (2)) we get the replica partition function

\[
\overline{Z^n[\xi]} \equiv Z(n) = \int D\phi_1 \cdots \int D\phi_n \exp (-H_n[\phi])
\]

where the replica Hamiltonian

\[
H_n[\phi] = \int d^D x \left[ \frac{1}{2} \sum_{a=1}^n (\nabla \phi_a(x))^2 + \frac{1}{2} \tau \sum_{a=1}^n \phi^2_a(x) + \frac{1}{4} \sum_{a,b=1}^n g_{ab} \phi^2_a(x) \phi^2_b(x) \right]
\]

depends on \( n \) interacting fields \( \phi \equiv \{ \phi_1, \ldots, \phi_n \} \), and the coupling \( (n \times n) \) matrix

\[
g_{ab} = g_o \delta_{ab} - u_o.
\]

Taking into account the definition of the free energy in equation (3), the replica partition function, equation (4), can also be represented as follows:

\[
Z(n) = \exp \left( -n F[\xi] \right)
\]

or

\[
Z(n) = \int_{-\infty}^{+\infty} dF P(F) \exp (-nF)
\]

where \( P(F) \) is a free energy distribution function.

doi:10.1088/1742-5468/2012/05/P05027
Usually the replica partition function, equation (4), is studied to derive the average value of the free energy. The heuristic (not well justified) procedure for the replica calculations requires one to perform the analytic continuation of the function $Z(n)$ from integer to arbitrary values of the replica parameter $n$. Then, taking the limit $n \to 0$ in both sides of equation (8) (and taking into account that $\int dFP(F) = 1$) we formally get

$$
\lim_{n \to 0} \frac{Z(n) - 1}{n} = \int_{-\infty}^{+\infty} dFP(F) F \equiv \overline{F}.
$$

(9)

In fact if we are interested not just in the average free energy of the system but in the properties of its distribution function the situation even with weak disorder turns out to be rather non-trivial. Considering the system away from the critical point one would naively expect that at least at scales greater than the correlation length (where the system is expected to split into a set of more or less independent ‘cells’ of the size of the correlation length) ‘everything must be Gaussian distributed’. One can easily prove that this is not true. Indeed, let us consider the coupling matrix $g_{ab}$, equation (6). It has $(n - 1)$ eigenvalues $\lambda_1 = g_o - u_o$ and one eigenvalue $\lambda_2 = g_o - nu_o$. We see that for $n > g_o/u_o$, the eigenvalue $\lambda_2$ becomes negative. Thus, according to equations (4) and (5), we find that all moments of the partition function $Z(n)$ with $n > g_o/u_o$ must be divergent! On the other hand, according to the relation (8) this indicates that the free energy distribution function of the considered system cannot be Gaussian. Moreover, since it is evident that the divergence in the integration in the rhs of equation (8) takes place in the limit $F \to -\infty$, we can easily guess that the left asymptotic of the distribution function $P(F)$ has the following simple form:

$$
P(F \to -\infty) \sim \exp \left( -\frac{g_o}{u_o} |F| \right).
$$

(10)

It should be stressed that this phenomenon must be quite general: it takes place for any dimension of the system independently of the value of the temperature parameter $\tau$ (except for the critical point) both in the paramagnetic and in the ferromagnetic phases.

2. Toy model

To analyze the properties of the free energy distribution function of a random ferromagnet one can start with a very simple ‘toy’ model. Let us consider the system described by the Hamiltonian containing only one degree of freedom:

$$
H(\phi, \xi) = \frac{1}{2}(\tau - \xi)\phi^2 + \frac{1}{4}g_o\phi^4.
$$

(11)

The random quenched parameter $\xi$ is described by the Gaussian distribution function

$$
P(\xi) = \frac{1}{\sqrt{4\pi u}} \exp \left( -\frac{1}{4u_o} \xi^2 \right)
$$

(12)

and its typical value $\overline{\xi^2} = 2u_o$ is supposed to be small, $u_o \ll \tau^2$ and $u_o \ll g_o$. Besides, to simplify the calculations it will be assumed that the coupling parameter $g_o$ is also small, $g_o \ll \tau^2$. 

doi:10.1088/1742-5468/2012/05/P05027
2.1. ‘Paramagnetic’ region ($\tau > 0$)

To simplify notations let us redefine $\xi \rightarrow \tau \xi$, $u_o \rightarrow \tau^2 u$, $g_o \rightarrow \tau^2 g$ and $\phi \rightarrow \phi / \sqrt{\tau}$. In these new notations the partition function of the system is

$$Z_{\text{para}}(\xi) = \int_{-\infty}^{+\infty} \frac{d\phi}{\sqrt{2\pi}} \exp \left[ -\frac{1}{2}(1 - \xi)\phi^2 - \frac{1}{4}g\phi^4 \right] = \exp \left[ -F_{\text{para}}(\xi) \right]$$ (13)

where $F_{\text{para}}(\xi)$ is the (random) free energy of the system. For the replica partition function we get

$$Z_{\text{para}}(n) = \int_{-\infty}^{+\infty} \frac{d\xi}{\sqrt{4\pi u}} \exp \left( -\frac{1}{4u}\xi^2 \right) (Z_{\text{para}}(\xi))^n.$$ (14)

On the other hand,

$$Z_{\text{para}}(n) = \int_{-\infty}^{+\infty} dF P_{\text{para}}(F) \exp [-nF]$$ (15)

where $P_{\text{para}}(F)$ is a free energy distribution function. The above relation is the bilateral Laplace transform. Performing analytic continuation of the function $Z_{\text{para}}(n)$ from integer $n$ to arbitrary complex values, by inverse Laplace transform we obtain

$$P_{\text{para}}(F) = \int_{-i\infty}^{+i\infty} \frac{dz}{2\pi i} Z_{\text{para}}(z) \exp [zF].$$ (16)

Under conditions $u \ll g \ll 1$ one can easily perform (approximate) calculations of the partition function, equation (13). For $\xi < 1$ the main contribution in the integration over $\phi$ comes from the vicinity of the point $\phi = 0$. On the other hand, at $\xi > 1$ the integral is dominated by the vicinity of the ‘ferromagnetic’ points $\phi = \pm \sqrt{(\xi - 1)/g}$. Thus,

$$Z_{\text{para}}(\xi) \simeq \exp \left[ -f_0(\xi) + \frac{(\xi - 1)^2}{4g} \theta(\xi - 1) \right]$$ (17)

where

$$f_0(\xi) \simeq \begin{cases} \frac{1}{2} \log |\xi - 1|, & \text{for } |\xi - 1| \gg \sqrt{g} \\ \frac{1}{4} \log(g), & \text{for } |\xi - 1| \ll \sqrt{g}. \end{cases}$$ (18)

Correspondingly, for the replica partition function, equation (14), we find

$$Z_{\text{para}}(n) \simeq \int_{-\infty}^{+\infty} \frac{d\xi}{\sqrt{4\pi u}} \exp \left[ -\frac{1}{4u}\xi^2 - nF_{\text{para}}(\xi) \right]$$ (19)

where

$$F_{\text{para}}(\xi) \simeq f_0(\xi) - \frac{(\xi - 1)^2}{4g} \theta(\xi - 1).$$ (20)

One can easily note here that since $F_{\text{para}}(\xi \rightarrow +\infty) \sim -(1/4g)\xi^2$ the partition function $Z_{\text{para}}(n)$ in equation (19) is divergent for all values $n > g/u$. 

doi:10.1088/1742-5468/2012/05/P05027
Finally, substituting equations (19) and (20) into (16) (where the integration contour can be chosen to be just the imaginary axes, $z = i\omega$) we obtain

$$P_{\text{para}}(F) = \int_{-\infty}^{+\infty} \frac{d\omega}{2\pi} \int_{-\infty}^{+\infty} \frac{d\xi}{\sqrt{4\pi u}} \exp \left[ -\frac{1}{4u} \xi^2 + i\omega (F - F_{\text{para}}(\xi)) \right].$$

$$= \int_{-\infty}^{+\infty} \frac{d\xi}{\sqrt{4\pi u}} \exp \left[ -\frac{1}{4u} \xi^2 \right] \delta(F - F_{\text{para}}(\xi)) . \quad (21)$$

The right part of this distribution function $P_{\text{para}}^{(+)}(F)$ valid for $-\frac{1}{4} \log(1/g) \ll F < +\infty$ is defined by the region $-\infty < (\xi - 1) \ll -\sqrt{g}$, where $F_{\text{para}}(\xi) \simeq \frac{1}{2} \log(1 - \xi)$. Using equation (21) we get

$$P_{\text{para}}^{(+)}(F) \simeq \frac{1}{\sqrt{\pi u}} \exp \left[ 2F - \frac{1}{4u} (\exp(2F) - 1)^2 \right]. \quad (22)$$

In the vicinity of the point $F_* = u$ the above distribution has the Gaussian form:

$$P_{\text{para}}^{(G)}(F) \simeq \frac{1}{\sqrt{\pi u}} \exp \left[ -\frac{1}{u} (F - u)^2 \right]. \quad (23)$$

However, the above form of the distribution is valid only for $|F| \ll 1$. For large (positive) values of the free energy the distribution becomes essentially non-Gaussian:

$$P_{\text{para}}(F \to +\infty) \sim \exp \left[ -\frac{1}{4u} \exp(4F) \right]$$

which goes to zero much faster than the Gaussian curve.

The left asymptotic of the distribution function, $P_{\text{para}}^{(-)}(F)$, valid for $-\infty \ll F \ll -\frac{1}{4} \log(1/g)$ is defined by the region $\sqrt{g} \ll (\xi - 1) < +\infty$, where $F_{\text{para}}(\xi) \simeq -(1/4g)(\xi - 1)^2$. Using equation (21) we get

$$P_{\text{para}}^{(-)}(F) \simeq \sqrt{\frac{g}{4\pi u |F|}} \exp \left[ -\frac{1}{4u} \left(1 + \sqrt{4g|F|}\right)^2 \right]. \quad (25)$$

Thus we find that the left tail of the free energy distribution function $P_{\text{para}}(F)$ is also non-Gaussian,

$$P_{\text{para}}(F \to -\infty) \sim \exp \left( -\frac{g}{u} |F| \right), \quad (26)$$

and it goes to zero much slower than the Gaussian curve.

In conclusion we find that the free energy distribution function of the ‘toy’ model, equation (11), at $\tau > 0$ is essentially non-Gaussian and strongly asymmetric: its right tail, equation (24), is much steeper than the left one, equation (26). The example of the entire distribution function $P_{\text{para}}(F)$ for $g = 0.1$ and $u = 0.01$ is shown in figure 1.
2.2. ‘Ferromagnetic’ region \((\tau < 0)\)

For the negative values of the temperature parameter \(\tau\) in the toy model, equation (11), we redefine \(\xi \rightarrow -|\tau|\xi\), \(u \rightarrow \tau^2 u\), \(g \rightarrow \tau^2 g\) and \(\phi \rightarrow \phi/\sqrt{|\tau|}\). In these new notations the partition function of the system becomes

\[
Z_{\text{ferro}}(\xi) = \int_{-\infty}^{+\infty} \frac{d\phi}{\sqrt{2\pi}} \exp \left[ \frac{1}{2} (1 - \xi)\phi^2 - \frac{1}{4} g\phi^4 \right] = \exp \left[ -F_{\text{ferro}}(\xi) \right]
\]

(27)

where the random parameters \(\xi\) are described by the Gaussian distribution, equation (12). The calculations for the ‘ferromagnetic’ case are quite similar to the case \(\tau > 0\) considered in the previous subsection. In particular, for the partition function we get

\[
Z_{\text{ferro}}(n) \simeq \int_{-\infty}^{+\infty} \frac{d\xi}{\sqrt{4\pi u}} \exp \left[ -\frac{1}{4u} \xi^2 - nF_{\text{ferro}}(\xi) \right]
\]

(28)

where

\[
F_{\text{ferro}}(\xi) \simeq f_0(\xi) - \frac{(1 - \xi)^2}{4g} \theta(1 - \xi).
\]

(29)

Here \(f_0(\xi)\) is defined in equation (18). As in the ‘paramagnetic’ case, one can easily note that since \(F_{\text{ferro}}(\xi \rightarrow -\infty) \sim -\xi^2/4g\), the partition function \(Z_{\text{ferro}}(n)\), equation (28), with \(n > g/u\) is divergent.

Similarly to equation (21), for the free energy distribution function we get

\[
P_{\text{ferro}}(F) = \int_{-\infty}^{+\infty} \frac{d\omega}{2\pi} \int_{-\infty}^{+\infty} \frac{d\xi}{\sqrt{4\pi u}} \exp \left[ -\frac{1}{4u} \xi^2 + i\omega (F - F_{\text{ferro}}(\xi)) \right]
\]

\[
= \int_{-\infty}^{+\infty} \frac{d\xi}{\sqrt{4\pi u}} \exp \left[ -\frac{1}{4u} \xi^2 \right] \delta (F - F_{\text{ferro}}(\xi)).
\]

(30)

The right tail of this function, \(P_{\text{ferro}}^+(F)\), valid for \(-\frac{1}{4} \log(1/g) \ll F < +\infty\) is defined by the region \(\sqrt{g} \ll (\xi - 1) < +\infty\) where \(F_{\text{ferro}}(\xi) \simeq \frac{1}{2} \log(\xi - 1)\). Using equation (30) we
Free energy distribution function of the ‘ferromagnetic’ toy model, equation (27), with $g = 0.1$ and $u = 0.01$.

$$P_{\text{ferro}}^{(+)}(F) \simeq \frac{1}{\sqrt{\pi u}} \exp \left[ 2F - \frac{1}{4u} (\exp(2F) + 1)^2 \right].$$  \hspace{1cm} (31)

Thus the decay of the right tail of this function coincides with the decay of the ‘paramagnetic’ function, equation (24),

$$P_{\text{ferro}}(F \to +\infty) \sim \exp \left[ -\frac{1}{4u} \exp(4F) \right].$$  \hspace{1cm} (32)

The left tail of the free energy distribution function, $P_{\text{ferro}}^{(-)}(F)$, valid for $-\infty < F \ll -\frac{1}{4} \log(1/g)$ is defined by the region $-\infty < (\xi - 1) \ll -\sqrt{g}$ where $F_{\text{ferro}}(\xi) \simeq -(1/4g)(1 - \xi)^2$. Using equation (30) we find

$$P_{\text{ferro}}^{(-)}(F) \simeq \sqrt{\frac{g}{4\pi u |F|}} \exp \left[ -\frac{1}{4u} \left( 1 - \sqrt{4g|F|} \right)^2 \right].$$  \hspace{1cm} (33)

In the vicinity of the ‘ferromagnetic’ average free energy $F^* = -1/4g$ this distribution is Gaussian,

$$P_{\text{ferro}}^{(G)}(F) \simeq \frac{g}{\sqrt{\pi u}} \exp \left[ -\frac{g^2}{u} \left( F + \frac{1}{4g} \right)^2 \right].$$  \hspace{1cm} (34)

However, at large negative values of the free energy (similarly to the ‘paramagnetic’ case) the distribution becomes essentially non-Gaussian:

$$P_{\text{ferro}}(F \to -\infty) \sim \exp \left( -\frac{g}{u} |F| \right).$$  \hspace{1cm} (35)

The example of the entire distribution function $P_{\text{ferro}}(F)$ for $g = 0.1$ and $u = 0.01$ is shown in figure 2. Again, like in the ‘paramagnetic’ case this function is strongly asymmetric: its left tail, equation (35), is much slower that its right one, equation (32).
Free energy distribution function of a random Ising ferromagnet

3. Macroscopic system

Let us consider a $D$-dimensional random ferromagnet described by the Ginzburg–Landau Hamiltonian, equation (1). In the mean-field approximation away from the critical point (in the paramagnetic phase, $\tau > 0$) this system can be considered as a set of $N \sim V/R_c(\tau)$ independent ‘cells’, where $V$ is the volume of the system and $R_c(\tau) \sim 1/\sqrt{\tau}$ is the correlation length. Performing spatial rescaling $x \rightarrow R_c x = \tau^{D/2} x$, according to the standard ideas of the scaling theory we have to rescale $\phi \rightarrow \tau^{(D-2)/2} \phi$, $g_0 \rightarrow \tau^{-(D-4)/4} g$ and $u_0 \rightarrow \tau^{-(D-4)/2} u$. Then in terms of the new (rescaled) parameters the partition function of the considered system can be estimated as follows:

$$Z[\xi] \approx \prod_{k=1}^{N} \int_{-\infty}^{+\infty} \frac{d\phi}{\sqrt{2\pi}} \exp \left[ -\frac{1}{2} (1 - \xi_k) \phi^2 - \frac{1}{4} g \phi^4 \right] = \prod_{k=1}^{N} Z_{\text{para}}(\xi_k)$$ \hspace{1cm} (36)

where the function $Z[\xi]$ depends on $N$ random parameters $\xi \equiv \{\xi_1, \ldots, \xi_N\}$ and $Z_{\text{para}}(\xi)$ is the partition function of the toy model, equation (13). The parameters $\{\xi_k\}$ are described by the independent Gaussian distributions

$$P[\xi] = \prod_{k=1}^{N} \left[ \frac{1}{\sqrt{4\pi u}} \exp \left( -\frac{1}{4 u} \xi^2_k \right) \right].$$ \hspace{1cm} (37)

Correspondingly, for the replica partition function we obtain

$$\overline{Z}^n \equiv Z(n) \approx \left[ \int_{-\infty}^{+\infty} \frac{d\xi}{\sqrt{4\pi u}} \exp \left( -\frac{1}{4 u} \xi^2 \right) (Z_{\text{para}}(\xi))^n \right]^N = (Z_{\text{para}}(n))^N$$ \hspace{1cm} (38)

where $Z_{\text{para}}(n)$ is the replica partition function of the toy model, equation (14). On the other hand,

$$Z(n) = \int_{-\infty}^{+\infty} dF P(F) \exp (-nF)$$ \hspace{1cm} (39)

where $P(F)$ is the total free energy distribution function of the considered macroscopic system. Performing the inverse Laplace transform we get

$$P(F) = \int_{-i\infty}^{+i\infty} \frac{dz}{2\pi i} (Z_{\text{para}}(z))^N \exp (zF).$$ \hspace{1cm} (40)

Taking $z = i\omega$, introducing the free energy density, $f = F/N$, and substituting here equation (19), for the corresponding probability distribution function we find the following expression:

$$\tilde{P}(f) = \int_{-\infty}^{+\infty} \frac{d\omega}{2\pi} \left[ \int_{-\infty}^{+\infty} \frac{d\xi}{\sqrt{4\pi u}} \exp \left( -\frac{1}{4 u} \xi^2 + i\omega [f - F_{\text{para}}(\xi)] \right) \right]^N$$ \hspace{1cm} (41)

where the function $F_{\text{para}}(\xi)$ is defined in equations (20) and (18).
The main Gaussian part of the above distribution valid for the values $|f| \ll 1$ is defined by the region $|\xi| \ll 1$ where $F_{\text{para}}(\xi) \simeq \frac{1}{2} \log(1 - \xi) \simeq -\frac{1}{2} \xi$. In this case

\[
\mathcal{P}^{(G)}(f) \simeq \int_{-\infty}^{+\infty} \frac{d\xi}{2\pi} \left[ \int_{-\infty}^{+\infty} \frac{d\omega}{\sqrt{4\pi u}} \exp \left( -\frac{1}{4u} \xi^2 + \frac{i}{2} \omega \xi + i\omega f \right) \right]^N
\]

\[
= \frac{1}{\sqrt{\pi Nu}} \exp \left( -\frac{N}{u} f^2 \right). \tag{42}
\]

Correspondingly, for the distribution function of the total free energy $F = fN = fV/R_c^D$ we get

\[
\mathcal{P}^{(G)}(F) = \sqrt{\frac{R_c^D}{V\pi u}} \exp \left( -\frac{R_c^D}{V u} F^2 \right). \tag{43}
\]

One can easily note that in the thermodynamic limit $V \rightarrow \infty$ this distribution function turns into the $\delta$-function which assumes that the considered random system is self-averaging. However, at large but finite volume of the system one can easily prove that both the left and the right tails of the function $\mathcal{P}(F)$ are essentially non-Gaussian.

The right tail $\mathcal{P}^{(+)}(f)$ of the distribution function, equation (41), valid for the values $f \gg 1$ is defined by the region $|\xi| \gg 1$ ($\xi < 0$) where $F_{\text{para}}(\xi) \simeq -\frac{1}{2} \log |\xi|$. In this case

\[
\mathcal{P}^{(+)}(f) \simeq \prod_{k=1}^{N} \left[ \int_{-\infty}^{+\infty} \frac{d\xi_k}{\sqrt{4\pi u}} \right] \exp \left[ -\frac{1}{4u} \sum_{k=1}^{N} \xi_k^2 \right] \int_{-\infty}^{+\infty} \frac{d\omega}{2\pi} \exp \left[ i\omega \sum_{k=1}^{N} \left( f - \frac{1}{2} \log |\xi_k| \right) \right]
\]

\[
\sim \exp \left[ -\frac{N}{4u} \exp(4f) \right] = \exp \left[ -\frac{V}{4uR_c^D} \exp(4f) \right]. \tag{44}
\]

Correspondingly, for the right tail of the total free energy distribution function we get

\[
\mathcal{P}^{(+)}(F) \sim \exp \left[ -\frac{V}{4uR_c^D} \exp \left( \frac{R_c^D}{V} F \right) \right]. \tag{45}
\]

which is valid for $F \gg V/R_c^D$.

The left tail $\mathcal{P}^{(-)}(f)$ of the distribution function, equation (41), valid for $f < 0$ and $|f| \gg 1$ is defined by the region $\xi \gg 1$ where $F_{\text{para}}(\xi) \simeq -(1/4g)\xi^2$. In this case

\[
\mathcal{P}^{(-)}(f) \simeq \int_{-\infty}^{+\infty} \frac{dz}{2\pi i} \int_{-\infty}^{+\infty} \frac{d\xi}{\sqrt{4\pi u}} \exp \left[ -\frac{1}{4u} \left( 1 - \frac{u}{g} \right) \xi^2 \right] \exp \left( Nfz \right)
\]

\[
= \int_{-\infty}^{+\infty} \frac{dz}{2\pi i} \left( 1 - \frac{u}{g} \right)^{-N/2} \exp \left( -N|f|z \right). \tag{46}
\]

Shifting here the integration contour to the right by the value $g/u$: $z = g/u + i\omega$ and neglecting the pre-exponential factor, we obtain

\[
\mathcal{P}^{(-)}(f) \sim \exp \left( -N \frac{g}{u} |f| \right) \tag{47}
\]

or, for the total free energy (the result already discussed in the introduction, equation (10)),

\[
\mathcal{P}^{(-)}(F) \sim \exp \left( -\frac{g}{u} |F| \right) \tag{48}
\]

which is valid for $|F| \gg V/R_c^D$. 

doi:10.1088/1742-5468/2012/05/P05027
Thus, according to equations (43), (45) and (48) for the entire free energy distribution function of the random Ising ferromagnet (in the paramagnetic phase away from the critical point) we find the following result:

\[
P(F) \sim \begin{cases} 
\exp\left(-\frac{g}{u}|F|\right); & \text{for } F < 0 \text{ and } |F| \gg \frac{V}{R_c} \\
\exp\left(-\frac{R_c^D}{V u} F^2\right); & \text{for } |F| \ll \frac{V}{R_c} \\
\exp\left[-\frac{V}{4uR_c^D} \exp\left(\frac{4R_c^D}{V} F\right)\right]; & \text{for } F \gg \frac{V}{R_c^D}
\end{cases}
\tag{49}
\]

where (in the framework of the mean-field scaling theory) \( R_c = 1/\sqrt{\tau} \) is the correlation length, \( V \) is the volume of the system, \( u = \tau^{(D-4)/2} u_0 \) is the rescaled strength of the disorder, equation (2), and \( g = \tau^{(D-4)/2} g_0 \) is the rescaled coupling constant of the original Ginzburg–Landau Hamiltonian, equation (1).

One can easily repeat similar calculations for the free energy distribution function in the ferromagnetic phase to obtain a result similar to equation (49). The only difference is that in this case the Gaussian central part of the distribution will be concentrated around the ferromagnetic ground state energy \( F_0 = -(1/4g)(V/R_c^D) = -(\tau^2/4g_0)V \).

4. Conclusions

One can easily note at least three apparent consequences of the obtained result, equation (49), for the free energy distribution function of the random Ising ferromagnet.

Firstly, in the thermodynamic limit, \( V \to \infty \), this distribution turns into the \( \delta \)-function. This is not surprising and it just indicates that the considered system is self-averaging.

Secondly, at large but finite volume of the system in addition to the trivial Gaussian ‘body’ the distribution function exhibits essentially non-Gaussian tails. Moreover, these tails are strongly asymmetric: the left tail, at \( F \to -\infty \), is much slower than the right one, at \( F \to +\infty \). It is this type of asymmetry of the free energy distribution function (the left tail is slow while the right tail is fast) which is observed in other random systems \([5]–[8]\). It is interesting to note that the result, equation (49), has to be very general taking place at all temperatures (except for the critical region) and in all dimensions. On the other hand the behavior of each tail (both left and right) looks rather universal. Indeed, at large negative values of the free energy the logarithm of the distribution function is expected to be linear in \(|F|\), while at large positive energies it is the double logarithm of the distribution function which is expected to be linear in \( F \). Presumably these two types of asymptotics could be relatively easy recovered by computer simulations.

Thirdly, while approaching the critical point we observe that the range of validity of the Gaussian ‘body’ of the distribution function shrinks while the ‘tails’ become of the same order as the ‘body’. Of course, the simple mean-field calculations considered in this paper are not valid at the critical point. Nevertheless, if we naively imitate the critical point by assuming that the correlation length becomes of the order of the system size (i.e. \( R_c^D \sim V \)) while the coupling parameters \( g \) and \( u \) (in dimension \( D < 4 \)) become equal to their universal (depending only of the dimension \( D \)) fixed point values \( g_* \) and \( u_* \) \([1]\).
we find that (in the thermodynamic limit $V \to \infty$) the free energy distribution function turns into the universal curve such that

$$
\mathcal{P}_{\text{crit}}(F) \sim \begin{cases} 
\exp \left( -\frac{g_u}{u} |F| \right) ; & \text{for } F < 0 \text{ and } |F| \gg 1 \\
\exp \left( -\frac{1}{u} F^2 \right) ; & \text{for } |F| \ll 1 \\
\exp \left[ -\frac{1}{4u} \exp (4F) \right] ; & \text{for } F \gg 1 .
\end{cases}
(50)
$$

All this evokes the old idea that the free energy (as well as some other thermodynamic quantities) of random ferromagnets could be non-self-averaging at the critical point [9]. Of course, the systematic derivation of the free energy distribution function at the critical point requires a special consideration.
