Abstract
We discuss the current status and the physics prospects at the LHCb detector, the dedicated B physics detector at the LHC, due to start data taking in 2007.

1 Introduction
LHCb is a dedicated B–physics experiment at the future LHC collider, making use of the large number of B–hadrons expected at the LHC. The experiment is scheduled to start data taking in 2007. Here we will introduce the LHCb detector, and its physics potential, focusing on one of its most exciting features, LHCb’s ability to perform precision measurements on the CKM angle $\gamma$ in many different decay channels, in both the $B^0_s$ and the $B^0_d$ system. This will thoroughly over constrain the Standard Model description of CP violation and provide a sensitive probe for New Physics.

A more detailed description of the LHCb detector and its projected physics performance can be found in the LHCb technical design reports [1].

2 CP Violation
2.1 CP Violation in the Standard Model
In the Standard Model, $\mathcal{CP}$ violation can be accommodated by a single complex phase $\delta_{13}$ in the CKM matrix, which is the matrix that relates the mass–eigenstates of the down–type quarks to the weak isospin partners of the up–type quarks:

$$V_{\text{CKM}} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix}. \tag{1}$$

The transition amplitudes between quarks are proportional to the corresponding elements in the CKM matrix, for example the amplitude for $d_L \to u_L$ is proportional to $V_{ud}$, while the CP-conjugate process, $\bar{d}_R \to \bar{u}_R$ is proportional to the complex conjugate, $V_{ud}^*$. Experimentally, it is found that the magnitudes of the CKM matrix elements follow a clear structure. In terms of the sine of the Cabibbo angle, $\lambda \equiv \sin \theta_C = 0.22$, the order of magnitude of the CKM matrix elements is:

$$\begin{pmatrix} 1 & \lambda & \lambda^3 \\ \lambda & 1 & \lambda^2 \\ \lambda^3 & \lambda^2 & 1 \end{pmatrix}. \tag{2}$$
Figure 1: The CKM phases are observable as phase differences between interfering decay paths to the same final state. Here illustrated for the examples $B_d^0 \to J/\psi K_S$ (sensitive to $\sin 2\beta$) and $B_d^0 \to \pi^+\pi^-$ (sensitive to $\sin(2\beta + 2\gamma)$). This illustration ignores the penguin contributions to $B_d^0 \to \pi^+\pi^-$, which are discussed later in the text.

Up to $\mathcal{O}(\lambda^3)$ in the Wolfenstein parametrisation of the CKM matrix \[10\], only the two smallest elements have complex phases (these phases are not independent and would vanish if $\delta_{13}$ were 0):

$$V_{td} = |V_{td}| e^{-i\beta} \quad \text{and} \quad V_{ub} = |V_{ub}| e^{-i\gamma}. \quad (3)$$

At $\mathcal{O}(\lambda^4)$, another phase appears, $\delta\gamma$:

$$V_{ts} = |V_{ts}| e^{-i\delta\gamma}. \quad (4)$$

All three phases up to $\mathcal{O}(\lambda^4)$, $\beta$, $\gamma$ and $\delta\gamma$, are accessible in B-systems. The phase $\gamma$ appears in all decays involving $b \to u$ transitions, for example $B_d \to \pi^+\pi^-$ and $B_s \to K^+K^-$. The phase $\beta$ appears in $B_d$ mixing, where a $B_d$ meson transforms into a $\bar{B}_d$ meson: $B_d \xrightarrow{-2\beta} \bar{B}_d$. Analogously, the phase $\delta\gamma$ is the mixing angle of the $B_s$ system, $B_s \xrightarrow{-2\delta\gamma} \bar{B}_s$. While $\beta$ and $\gamma$ are $\mathcal{O}(1)$, $\delta\gamma$ is expected to be $\mathcal{O}(10^{-2})$ in the Standard Model.

The complex CKM elements result in phase differences between interfering decay paths to the same final state, one with and one without mixing, as illustrated in figure 1. These phase differences can be observed as the amplitudes of time dependent decay rate asymmetries, for example for $B \to J/\psi K_S$:

$$A(\tau) = \frac{\Gamma(B_d^0 \to J/\psi K_S) - \Gamma(\bar{B}_d^0 \to J/\psi K_S)}{\Gamma(B_d^0 \to J/\psi K_S) + \Gamma(\bar{B}_d^0 \to J/\psi K_S)} = \sin(2\beta) \sin(\Delta m \tau), \quad (5)$$

where $\Delta m$ is the mass difference between the two $B_d^0$ mass eigenstates, $\tau$ is the decay eigentime and the flavours $B_d^0$ and $\bar{B}_d^0$ refer to the flavour at the time of creation ($\tau = 0$). An experiment measuring CP violation in the $B$ systems would therefore require a good time (decay length) resolution, especially to resolve the rapid $B_s$ oscillations. Also, because the branching fractions to CP sensitive decays are typically $\mathcal{O}(10^{-5})$, large, clean data samples are required, and efficient $B$ flavour tagging (the ability to identify the flavour of the $B$ at the time of creation). LHCb is specifically designed to meet these requirements.
2.2 Unitarity Triangle

The only Standard Model prediction with respect to the CKM matrix is that it is unitary:

$$V_{CKM}V_{CKM}^\dagger = \mathbb{I}$$

(6)

This results in 9 equations. The most relevant one for CP violation in the B systems is

$$V_{ub}^*V_{ud} + V_{cb}^*V_{cd} + V_{tb}^*V_{td} = 0.$$  

(7)

which can also be written as:

$$\frac{V_{ub}^*V_{ud}}{V_{cb}^*V_{cd}} + 1 + \frac{V_{tb}^*V_{td}}{V_{cb}^*V_{cd}} = 0.$$  

(8)

Figure 2: Current status of the Unitarity Triangle [13]. The $\bar{\rho}$ – $\bar{\eta}$ plane is effectively the complex plane, using parameters of the improved Wolfenstein [16] parametrisation. The angles $\beta$ and $\gamma$ correspond to the CP-violating phases introduced in Eq 3. The third angle $\alpha$ does not correspond to another complex entry in the CKM matrix, and is defined as $\alpha = \pi - \beta - \gamma$.

Combining direct measurement of $\sin 2\beta$ from oscillation experiments (dominated by $B_d \to J/\psi K_s$ at BaBar and BELLE), restricted to the charmonium results, the Heavy Flavour Averaging Group find [14],

$$\sin 2\beta = 0.736 \pm 0.049$$  

(9)
From a global fit to the Unitarity Triangle, ignoring the direct $\sin 2\beta$ measurements from B oscillations, the CKM-Fitter group find \cite{13}

$$\sin 2\beta = 0.587 - 0.766 \text{ at } 68\% \text{ confidence level}$$  \hspace{1cm} (10)

in excellent agreement. However, the angle $\gamma$ has not yet been measured directly.

By the year 2007, the accuracy of both the side measurements and direct measurements of $\sin 2\beta$ will have increased significantly. While first estimates of $\gamma$ might be possible, the uncertainties are expected to be too large to give strong constraints on the Standard Model description of $\mathcal{CP}$ violation.

3 The LHCb experiment

3.1 Bottom Production at the LHC

The planned Large Hadron Collider (LHC) at CERN will collide protons at a centre–of–mass energy of 14 TeV at a design luminosity of $\sim 10^{34} \text{cm}^{-1}\text{s}^{-1}$ at the high-luminosity interaction points (ATLAS and CMS). The accelerator will be housed in the 27 km tunnel that has been built for the LEP experiment. LHC is scheduled to start data taking in 2007 with a luminosity of $10^{33} \text{cm}^{-1}\text{s}^{-1}$ and upgrade to its full luminosity after a few years. Due to the huge $b$ production cross section of $\sim 500 \mu\text{b}$ \cite{17}, LHC will be the most copious source of B hadrons in the world by several orders of magnitude.

The kinematics of B hadron production at 14 TeV $p–p$, as illustrated in figure \ref{fig:kinematics}, have major consequences of the design of a dedicated B physics detector:

- The B hadrons produced are highly boosted, which results in long decay lengths ($\sim 1 \text{ cm}$) and hence facilitates exact decay time measurements.
- Both, the $b$ and the $\bar{b}$, are predominantly produced in the same forward or backward cone, so that a single–arm spectrometer captures both B–hadrons produced, which is essential for $B^0$–tagging, as discussed in Section 3.10.

3.2 Luminosity at the LHCb interaction point

At the LHC design luminosity, each bunch crossing would involve many inelastic proton–proton interaction. Such multiple interactions severely complicate the task of $B^0$–tagging, and of cleanly locating the primary and secondary vertices.

Therefore the luminosity at the LHCb detector is reduced to $2 \cdot 10^{32} \text{cm}^{-1}\text{s}^{-1}$ by defocussing the beam at the LHCb interaction point. Apart from optimising the number of single interactions, also the trigger performance, detector occupancy and radiation levels are taken into account when choosing the design luminosity. Remaining multiple interactions are identified by the Pile-Up system. While LHCb is optimised for single interactions, remaining multiple interactions are not necessarily discarded. The decision whether to keep or discard a multiple interaction event is made at trigger Level-0.

With this luminosity, LHCb expects about $10^{12} \bar{b}b$ events per year. Due to its comparably moderate luminosity requirements, LHCb can start its full physics programme from the first day of LHC running.
3.3 The LHCb detector

LHCb is specifically designed to make best use of the large number of $b\bar{b}$ pairs produced at the LHC. The LHCb detector is a single arm spectrometer with an angular acceptance from an outer limit of 250 mrad in the non-bending plane, and 300 mrad in the bending plane, down 15 mrad. This geometry is motivated by the kinematics of $b\bar{b}$ production in high energy proton-proton collisions, as discussed above.

Amongst the most important features of the LHCb detector are:

- Acceptance down to small polar angles / large pseudo-rapidity, to maximise B-hadron yield.

- Excellent proper time resolution to exploit the full B physics potential at the LHC, including measurements in the rapidly oscillating $B_s^0$ system.

- Particle identification by two Ring Imaging CHerenkov (RICH) counters, for clean data samples and flavour tagging with Kaons.

- Dedicated B trigger, including high $p_t$ hadron and lifetime triggers for high efficiency.

Figure 4 shows a schematic overview of the LHCb detector. It comprises a vertex detector system, which includes the pile-up veto counter; a magnet and a tracking system; two RICH counters; an electromagnetic calorimeter and a hadron calorimeter, and a muon detector. All detector sub-systems, except for RICH 1, are split into two halves that can be separated horizontally for maintenance and access to the beam pipe.

3.3.1 Material Budget

LHCb has recently undergone a major re-optimisation, which led to a substantially reduced material budget. Particular weight reduction has been achieved in the following subsystems:

- Beam pipe: Now made from Be or Al/Be alloy.
Figure 4: The LHCb Detector

- Vertex Detector: 21, 220 µm thin detector elements.

- RICH: Mirrors are now to be made from light materials (either Carbon fibre or Beryllium), support structures have been moved outside the acceptance.

- Tracking: All tracking stations inside the magnet have been removed. There is 1 (double) station before, and 3 stations behind magnet.

The resulting material “seen” by a particle before RICH 1 is typically 40% of a radiation length, and 12% of an interaction length.

3.4 Magnet

To achieve a precision on momentum measurements of better than half a percent for momenta up to 200 GeV, the LHCb dipole provides integrated field of 4 Tm. As seen in figure 4, the magnet poles are inclined to follow the LHCb acceptance angles. This allows the 4 Tm to be retained with a power consumption of 4.2 MW. The warm magnet design chosen of LHCb allows for regular field inversions to reduce systematic errors in CP violation measurements. The LHCb magnet is currently being installed in the collision hall.
3.5 Tracking

The LHCb tracking system consists of the Vertex Locator (VELO), one tracking station before the magnet ("Trigger Tracker"), and three tracking stations behind the magnet (T1 - T3). The VELO, the Trigger Tracker, and high-occupancy regions in T1-T3 near the beam line ("Inner Tracker") use Si technology, while the outer regions in T1-T3 ("Outer Tracker") use straw tube drift chambers.

3.5.1 The Vertex Locator

To measure the time dependent decay rate asymmetries, a detector with excellent spatial resolution is required, especially for measurements in the rapidly oscillating $B^0_s$ system. At LHCb, this is provided by the Vertex Locator (VELO, Fig[4]), comprising a series of 21 detector station placed along the beam line covering a distance of about 1 m. Each station consists of two pairs of half-circular Si microstrip detectors (Fig[4]), one pair measuring the radial ($r$), and one the azimuthal ($\phi$) co-ordinate. The sensors are made from 220 $\mu$m thin Silicon, and have a readout pitch between 37 $\mu$m and 102 $\mu$m. To achieve the required high acceptance at small polar angles (see section 3.1), the sensitive area starts at only 8 mm from the beam line. To protect the detectors during beam injection, they can be retracted from the beam line. To minimise the material between the interaction region and the detector, the Si sensors are placed inside a secondary vacuum, separated from the primary vacuum by a $\sim \frac{1}{4}$ mm thin Al foil, which also shields the sensors from RF pickup.
from the beam. In addition to the 21 VELO stations which are mostly “downstream” of the interaction point (between the interaction point and the rest of the detector), there are two r-disks upstream of the interaction point which make up the Pile-Up System, used in the trigger Level-0 for identifying multiple interaction events. The VELO provides an impact parameter resolution of $\sigma_{IP} = 14 \mu m + \frac{35 \mu m}{p_T/GeV}$ and a time resolution of $\sigma_{\text{tau}} \sim 40 \text{ps}$ (for $B_0^s \rightarrow D_s \pi$), sufficient to resolve $B_0^s$ oscillations up to $\Delta m_s = 68 \text{ps}^{-1}$ corresponding to $x_s = 105$.

### 3.5.2 Tracking

Each tracking station consists of 4 layers. The outer layers (1 and 4) measure the track coordinate in the bending plane (“$x$-layers”). The inner layers (2 and 3) are rotated by $+5^\circ$ and $-5^\circ$ respectively relative to the $x$-layers (“stereo layers”). This geometry optimises the resolution in the bending plane, for precise momentum measurements, while providing sufficient resolution in the non-bending plane for effective 3-D pattern recognition.

The 4 layers of the Trigger Tracker are split into two sub stations, separated by 30 cm. This allows a rough momentum estimation from the bending of the tracks in the magnetic fringe field. This momentum information is used in the trigger Level-1 decision. The Si detectors in the Trigger Tracker and Inner Tracker have a read out pitch of 198 $\mu m$, with strip lengths of up to 33 cm in the Trigger Tracker, and $11 - 22 \text{ cm}$ in the Inner Tracker. The thickness of Si layers is 320 $\mu m$ for the Inner Tracker, and 500 $\mu m$ for the Trigger Tracker. The Outer Tracker is made of $5 \text{ mm} \times 4.7 \text{ m}$ straw tubes, with a fast drift gas (75$\%$Ar, 15$\%$CF$_4$, 10$\%$CO$_2$), allowing signal collection in less than 50 ns. The LHCb tracking system provides a momentum resolution of $\frac{\delta p}{p} = 0.37\%$. For the example of $B_s \rightarrow D_s K$, this translates into a mass resolution of 14 MeV. The track-finding efficiency is 94$\%$ for tracks with hits in all tracking stations. The Ghost rate is 9$\%$ (3$\%$ for tracks with $p_T > 0.5 \text{ GeV}$).

### 3.6 Calorimetry

The main design constraints for the calorimeter system come from its central role in the Level-0 trigger decision, which must be provided and processed within the 25 ns between each bunch crossing. The general structure of the calorimeter system is as follows: the first element seen by a particle coming from the interaction point is a scintillator pad detector (SPD), that signals charged particles. This is followed by a 12 mm lead wall and another SPD, which together form the preshower detector (PS). This is then followed by 25 radiation lengths ($1.1 \text{ interaction lengths}$) of a Pb/scintillator Shashlik calorimeter (ECAL) and 5.6 interaction length of a iron/scintillator tile hadron calorimeter (HCAL).

Most ECAL modules, and a large fraction of HCAL modules have already been delivered to CERN. In testbeams an energy resolution of

$$\left(\frac{\sigma_E}{E}\right)_{\text{ECAL}} = \frac{9.4\%}{\sqrt{E/\text{GeV}}} \oplus 0.83\% \oplus \frac{0.145 \text{ GeV}}{E}$$

$$\left(\frac{\sigma_E}{E}\right)_{\text{HCAL}} = \frac{75\%}{\sqrt{E/\text{GeV}}} \oplus 10\%$$

has been achieved.
Figure 6: The LHCb RICH system used 2 detectors and 3 radiators, to provide $K - \pi$ separation from $\sim 1$ GeV to beyond 100 GeV. The figure shows RICH 1 and RICH 2 with the respective event displays for a typical event. The points represent the detector response. The rings drawn through the points are the result of a global pattern recognition algorithm, which uses the tracking results as a seed.

3.7 Muon System

The muon system provides offline muon identification, and information for the trigger Level-0. It consists of four stations behind the calorimeters (M2-M5), and one unshielded station in front of the calorimeters (M1). Most of the muon chambers will be Multi-Wire Proportional Chambers (MWPC). For the central region of M1 ($0.6 \text{m}^2$), triple GEM technology will be more suitable due the expected high rates in that area.

3.8 RICH

LHCb intends to perform high precision measurements in many different B decay channels. Many interesting decay channels are themselves backgrounds to topologically similar ones. Typically the branching ratios are of the order of $\sim 10^{-5}$. The particle identification and in particular $K/\pi$ separation provided by the RICH is essential for obtaining the clean samples needed to perform a comprehensive range of high-precision $CP$ violation measurements, and allows the use of Kaons of flavour tagging, dramatically improving the tagging performance at LHCb.

Figure 7 (a) shows the momentum distribution of (a) pions in $B_d^0 \rightarrow \pi^+\pi^-$ events, and (b) tagging Kaons. This illustrates the need for $K/\pi$ separation over a wide range of momenta; LHCb seeks $K/\pi$ separation from momenta of $\sim 1$ GeV to beyond 100 GeV.

RICH (Ring Imaging CHerenkov) counters measure the opening angle $\theta_C$ of the Cherenkov cone emitted by particles as they traverse a transparent medium, by imaging it onto an array of photo detectors as illustrated in Fig 6. This opening angle depends on the speed of the particle. Combining it with the momentum information from the tracking system, allows to identify the particle by its mass. To cover a momentum range from $\sim 1$ GeV to beyond 100 GeV, LHCb employs two RICH detectors and three radiators, Aerogel ($n = 1.03$) and $C_4F_{10}$ gas ($n = 1.0014$) in RICH 1 and $CF_4$ gas ($n = 1.0005$) in
(a) Momenta of tracks in $B \rightarrow \pi \pi$ events, and tagging Kaons. For both, K/$\pi$ separation is essential.

(b) Cherenkov angle $\theta_C$ vs momentum for Kaons and pions for each radiator in the LHCb RICH.

c) Polar angle $\theta$ vs momentum for all tracks in $B^0_d \rightarrow \pi \pi$ events, approx. RICH-coverage indicated.

Figure 7: The LHCb RICH employs 3 Radiators in 2 RICH detectors to provide K/$\pi$ separation from $\sim$ 1 GeV to beyond 100 GeV.

RICH 2. The angular and approximate momentum coverage of the two RICH detectors at LHCb is shown in [superimposed over a scatter plot showing polar angles and momenta of particles in B_d $\rightarrow \pi \pi$ events. Figure [illustrates how the RICH particle ID cleans up the B_s $\rightarrow$ D_sK signal, a $\gamma$-sensitive channel that would otherwise be completely dominated by background from B_s $\rightarrow$ D_s$\pi$ which has a $\sim$ 10 times higher branching fraction.

3.9 LHCb Trigger

The LHCb trigger has the task of reducing the event rate of 40 MHz by a factor of 200,000 to the write-to-tape rate of 200 Hz, while keeping as many interesting B-events as possible. This is achieved in three steps.

- Level-0 uses information from the Pile-Up detector, the Calorimeters and the Muon Chambers, to reduce the event rate from 40 MHz to 1 MHz.

- Level-1 uses momentum and impact parameter information from the VELO and the Trigger Tracker, to reduce the event rate further to 40 kHz.

- The High Level Trigger (HLT) will have access to the complete event information to perform full event reconstruction.

While the Level-0 algorithm will run on dedicated hardware, Level-1 and the HLT will run trigger software on computing farms built from off-the-shelf components.

3.10 Flavour Tagging

To measure the time dependent decay rate asymmetries from which the CKM phases are extracted, the flavour of the reconstructed B meson at the time of creation needs to
Figure 8: Without RICH particle ID, many decays would be swamped by topologically similar background. Illustrated here for the $\gamma$-sensitive channel $B_s \to D_s K$, which has a $\sim 10$ times smaller B.R. than its dominant background, $B_s \to D_s \pi$.

The figure of merit for the tagging performance is given by the “effective tagging efficiency” $\varepsilon_{\text{eff}}$ (also known as $\varepsilon D^2$):

$$\varepsilon_{\text{eff}} = \varepsilon (1 - \omega)^2$$

The statistical significance of $N$ events with an effective tagging efficiency $\varepsilon_{\text{eff}}$ is equivalent to $\varepsilon_{\text{eff}}N$ perfectly tagged events.

Table 1: Tagging efficiencies ($\varepsilon$), wrong-tag fractions ($\omega$) and effective tagging efficiencies $\varepsilon_{\text{eff}} \equiv \varepsilon (1 - 2\omega)^2$ for $B \to hh$.

| Tag           | $\varepsilon$ | $\omega$ | $\varepsilon_{\text{eff}}$ |
|---------------|--------------|---------|-----------------|
| $\mu$         | 11%          | 35%     | 1%              |
| $e$           | 5%           | 36%     | 0.4%            |
| $K_{\text{opp-side}}$ | 17%          | 31%     | 2.4%            |
| $Q_{\text{Vtx}}$ | 14%          | 40%     | 1%              |
| $B_d^0$ all   | 41%          | 35%     | 4%              |
| $K_{\text{same-side}}$ | 18%          | 33%     | 2.1%            |
| $B_s^0$ all   | 50%          | 33%     | 6%              |

Note that the “opposite side” B hadron usually travels into a similar direction as the B hadron of interest, which is crucial given LHCb’s detector geometry.

1Note that the “opposite side” B hadron usually travels into a similar direction as the B hadron of interest, which is crucial given LHCb’s detector geometry.
If there were only the tree \( B^0_d \to \pi \pi \) would measure \( 2(\beta + \gamma) \)... but there are Penguins: 

\[
\begin{align*}
B_d &\to \pi^+ \pi^- \\
&\text{mixing phase from } +\gamma \\
&\text{phase from } -\gamma \\
&\text{phase from } b \to u \\
&\text{b uphase from } b \to u \\
&\text{b uphase from } \text{b uphase from}
\end{align*}
\]

Figure 9: The phase difference between \( B_d \to \pi^+ \pi^- \) and \( B_d \to \bar{B}_d \to \pi^+ \pi^- \) is affected by both tree and penguin contributions. These can be disentangled by simultaneously analysing the U-Spin related decay \( B_s \to \pi \pi \).

### 4 Physics

By the year 2007, we expect a very precise measurement of the angle \( \beta \), from the B-factories and the Tevatron, and results for the mass and lifetime difference of the CP eigenstates of the \( B_s \) system, \( \Delta m_s \) and \( \Delta \Gamma_s \), from the Tevatron. With its huge number of \( b\bar{b} \) pairs, LHCb will be able to significantly improve the precision on all of these measurements within the first year of data taking. However, here we focus on one of the most exciting Physics prospects at LHCb, the experiment’s ability to perform precision measurements of the angle \( \gamma \) in many different decay channels both in the \( B_d \) and \( B_s \) system. Both, the B-factories and CDF expect some measurement of \( \gamma \) by 2007, but this is unlikely to be precise enough to provide a significant constraint on the Unitarity Triangle. LHCb will measure \( \gamma \) in many different channels, some more and some less susceptible to New Physics, with a typical precision of \( 5^\circ - 15^\circ \) for each channel after one year of data taking. We will demonstrate on three examples different strategies of measuring \( \gamma \) at LHCb.

#### 4.1 \( B_d \to \pi \pi \) and \( B_s \to KK \)

##### 4.1.1 Principle

The decay \( B_d \to \pi \pi \) is, due to the \( b \to u \) transition in the tree diagram in figure 9, sensitive to the CKM angle \( \gamma \). However, the presence of penguin contributions severely complicates the interpretation of the observed CP asymmetries in terms of CKM angles. At the same time, penguin diagrams are interesting, because they are sensitive to New Physics. A possible strategy that allows the tree and penguin contributions to be disentangled, and thus measure \( \gamma \), is due to Fleischer [19], and uses U-spin symmetry of the strong interaction to relate observables in \( B \to \pi \pi \) and \( B_s \to KK \). The time dependent decay rate asymmetry can be parametrised as

\[
\frac{\Gamma (B_d \to \pi^+ \pi^-) - \Gamma (\bar{B}_d \to \pi^+ \pi^-)}{\Gamma (B_d \to \pi^+ \pi^-) + \Gamma (\bar{B}_d \to \pi^+ \pi^-)} = A_{\pi \pi}^{\text{Dir}} \cos(\Delta m_d \tau) + A_{\pi \pi}^{\text{Mix}} \sin(\Delta m_d \tau),
\]

and similarly for \( B_s \to KK \). This provides four observables: \( A_{\pi \pi}^{\text{Dir}} \), \( A_{\pi \pi}^{\text{Mix}} \), \( A_{KK}^{\text{Dir}} \), and \( A_{KK}^{\text{Mix}} \). These can be parametrised with the following seven parameters:
| Channel       | # evts per year | B/S  | tagging eff | mistag frac |
|---------------|-----------------|------|-------------|-------------|
| $B \to \pi\pi$| 26 k            | $< 0.7$ | 41.8%       | 34.9%       |
| $B_s \to KK$  | 37 k            | $< 0.5$ | 49.8%       | 33.0%       |

Table 2: Expected reconstruction and tagging performance for $B \to \pi\pi$ and $B_s \to KK$.

\[
\begin{array}{|c|c|c|c|c|}
\hline
\Delta m_s & 15 & 20 & 25 & 30 \\
\sigma(\gamma) & 4.0 & 4.9 & 5.9 & 8.5 \\
\hline
\frac{\Delta m_s}{\Gamma_s} & 0 & 0.1 & 0.2 \\
\sigma(\gamma) & 5.2 & 4.9 & 4.5 \\
\hline
\gamma & 55 & 65 & 75 & 85 & 95 & 105 \\
\sigma(\gamma) & 5.8 & 4.9 & 4.3 & 4.7 & 4.7 & 4.7 \\
\hline
\vartheta & 120 & 140 & 160 & 180 & 200 \\
\sigma(\gamma) & 3.8 & 3.8 & 4.9 & 6.7 & 5.2 \\
\hline
d & 0.1 & 0.2 & 0.3 & 0.4 \\
\sigma(\gamma) & 1.8 & 2.7 & 4.9 & 9.0 \\
\hline
2\delta\gamma & 0 & -0.04 & -0.1 & -0.2 \\
\sigma(\gamma) & 4.9 & 4.9 & 4.9 & 5.4 \\
\hline
\end{array}
\]

Table 3: Statistical uncertainty on $\gamma$ for one year of data. Unless otherwise specified, $\Delta m_s = 20\text{ps}^{-1}$, $\frac{\Delta m_s}{\Gamma_s} = 0.1$, $\gamma = 65^\circ$, $\vartheta = 160^\circ$, $d = 0.3$, $2\delta\gamma = -0.04$. $\Delta m_s$ values are given in $\text{ps}^{-1}$, $2\delta\gamma$ values in radians, while $\gamma$, $\vartheta$ and $\sigma(\gamma)$ are given in degrees.

- $d, \theta$ hadronic parameters describing “penguin-to-tree” ratio and phase in $B_d$.
- $d', \theta'$ hadronic parameters related to “penguin-to-tree” ratio and phase for $B_s$.
- $\phi_d = B_d$ mixing phase, $2\beta$ in SM.
- $\phi_s = B_s$ mixing phase, $2\delta\gamma \approx 0$ in SM.
- $\gamma$ is what we want to measure.

These can be reduced to three parameters, as follows

- $2\beta$ and $2\delta\gamma$ will be known precisely from $B \to J/\psi K_s$ and $B_s \to J/\psi\phi$.
- $d, \theta, d', \theta'$ depend on the strong interaction only. Assuming U-spin symmetry, we set $d = d'$ and $\theta = \theta'$.

Further details can be found in [19]. The expected event yields and tagging performance for $B \to \pi\pi$ and $B_s \to KK$ are given in table 2. LHCb relies heavily on its K/$\pi$ separation
Table 4: Expected statistical uncertainty on $2\delta\gamma + \gamma$ for one year of data. Unless otherwise specified, $\Delta m_s = 20\text{ps}^{-1}$, $\frac{\Delta T_{1/2}}{T_{1/2}} = 0.1$, $2\delta\gamma + \gamma = 65^\circ$ and $\Delta T_{1/2} = 0^\circ$. All values are given in degrees, except $\Delta m_s$ in $\text{ps}^{-1}$.

4.2 $B_s \to D_s K$

An alternative way to tackle the problem of penguin contributions is to look at decays that don’t have any, like $B_s \to D_s K$, or $B_d \to D^{(*)}\pi$ [20]. These decays are expected to be rather insensitive to New Physics contributions, and therefore measure a “Standard Model $\gamma$”, providing a benchmark that other decays, that are more sensitive to New Physics, can be compared against. Since the final state is not a CP eigenstate, two CP-conjugate asymmetries need to be measured,

$$A(\tau) = \frac{\Gamma (B_s \to D_s^-K^+) - \Gamma (\bar{B}_s \to D_s^-K^+)}{\Gamma (B_s \to D_s^-K^+) + \Gamma (B_s \to D_s^-K^+)} , \quad \bar{A}(\tau) = \frac{\Gamma (\bar{B}_s \to D_s^+K^-) - \Gamma (B_s \to D_s^+K^-)}{\Gamma (B_s \to D_s^+K^-) + \Gamma (B_s \to D_s^+K^-)}$$

The CP violating effect is in the difference between those asymmetries. This measurement is sensitive to $2\delta\gamma + \gamma$, and a possible strong phase difference $\Delta T_{1/2}$. Further details are given in [20]. The particle ID capabilities of LHCb are crucial for the reconstruction of this decay, that would otherwise be swamped by background from $B_s \to D_s^-\pi^+$, which has a $\sim 10$ times higher branching ratio. LHCb expects to reconstruct $5.4\,k\,B_s \to D^-K^+$ events per year with a background-to-signal of better than 0.5. This translates into a sensitivity on $\gamma$ of typically $\sim 15^\circ$, depending on other parameters, especially $\Delta m_s$. Results for different parameters sets are given in Table 4.
4.3 $\gamma$ with $B^0_d \rightarrow \bar{D}^0K^{*0}$ $B^0_d \rightarrow D^0_{CP}K^{*0}$

The decay $B^0_d \rightarrow \bar{D}^0K^{*0}$ offers the possibility of measuring $\gamma$, using untagged, time-integrated samples [21]. This method is sensitive to New Physics in $D^0$ oscillations. The following 6 parameters are measured:

\[
\begin{align*}
\Gamma_+ &= \Gamma(B^0 \rightarrow D^0(\pi^+K^-)K^{*0}) \\
\bar{\Gamma}_+ &= \Gamma(\bar{B}^0 \rightarrow D^0(\pi^+K^-)\bar{K}^{*0}) \\
\Gamma_- &= \Gamma(B^0 \rightarrow D^0(K^+\pi^-)K^{*0}) \\
\bar{\Gamma}_- &= \Gamma(\bar{B}^0 \rightarrow D^0(K^+\pi^-)\bar{K}^{*0}) \\
\Gamma_{CP} &= \Gamma(B^0 \rightarrow D^0_{CP}(K^+K^-)K^{*0}) \\
\bar{\Gamma}_{CP} &= \Gamma(\bar{B}^0 \rightarrow D^0_{CP}(K^+K^-)\bar{K}^{*0})
\end{align*}
\]

They are related as follows:

\[
\Gamma_+ = \bar{\Gamma}_- \equiv g_1, \quad \Gamma_- = \bar{\Gamma}_+ \equiv g_2
\] (12)

and

\[
\Gamma_{CP} = \frac{g_1 + g_2}{2} + \sqrt{g_1g_2}\cos(\Delta + \gamma), \quad \bar{\Gamma}_{CP} = \frac{g_1 + g_2}{2} + \sqrt{g_1g_2}\cos(\Delta - \gamma)
\] (13)

Where $\Delta$ is a possible strong phase difference.

LHCb expects within 1 year of data taking to reconstruct 3.6 k events to measure $\Gamma_-, \bar{\Gamma}_-$, 0.49 k events to measure $\Gamma_+, \bar{\Gamma}_+$, and 0.31 k events to measure $\Gamma_{CP}, \bar{\Gamma}_{CP}$. Mainly because no tagging is required, the statistical weight of each reconstructed decay is much higher than in measurements using time-dependent decay rate asymmetries. Therefore, despite the comparably small data sample, a very competitive precision on $\gamma$ of $\sigma(\gamma) = 8.2^\circ$ (for $\gamma = 65^\circ, \Delta = 0$) after one year can be achieved. Results for different values of $\gamma$ are given in table 5.

### Table 5: Expected statistical precision on $\gamma$ for different values of $\gamma$ after one year of data taking. The value of $\Delta$ is set to 0.

| $\gamma$ (deg) | 55 | 65 | 75 | 85 | 95 | 105 |
|----------------|----|----|----|----|----|-----|
| $\sigma(\gamma)$ | 9.0 | 8.2 | 7.6 | 7.1 | 7.0 | 7.0 |

## 5 Summary

The recently re-optimised LHCb detector [3] is on track for data taking in 2007. The detector is designed to make best use of the vast number of B hadrons of all flavours, that are expected at the LHC. LHCb has a comprehensive programme of high-precision B physics, including competitive measurements of the CKM phases $\beta, \gamma$, and mass and lifetime difference in the $B_s$ system within the first year of data taking. The physics programme also includes higher order effects (e.g. $\delta \gamma$), rare B decays, and many more.

In this report we focused on one of the most exciting prospects at LHCb, the possibility to perform precision measurements of the angle $\gamma$ in many different decay channels in both the $B_d$ and $B_s$ system. Some of the measurements will be more and some less sensitive to...
Typical precision in each channel $\sim 5^\circ - 15^\circ$ after 1 year. More channels are under investigation, e.g.: $B_0^d \to D^+_s D^-_d$, $B_0^s \to D^+_s D^-_s$ which is highly sensitive to New Physics, since $\gamma$ enters via penguins only $^{[22]}$. ($B_0^s \to D^+_s D^-_s$ is also sensitive to $\frac{\Delta F_{s}}{F_{s}}$ and $\delta \gamma$).

| Channel | Standard Model | New Physics |
|---------|----------------|-------------|
| $B_0^d \to D^{(*)\pm} \pi^\pm$ | $\checkmark$ | |
| $B_0^d \to D^\pm K^\mp$ | $\checkmark$ | |
| $B_0^d \to \pi^+ \pi^-$ | | $\checkmark$ |
| $B_0^s \to K^+ K^-$ | | $\checkmark$ |
| $B_0^d \to D^0 K^{*0}$ | | $\checkmark$ |
| $B_0^d \to D^0_{CP} K^{*0}$ | | $\checkmark$ |

Table 6: Some $\gamma$ sensitive channels accessible at LHCb. It is indicated if the channels are expected to be sensitive to New Physics, or to the Standard Model $\gamma$.

New Physics contributions. A selection of such channels are listed in Table 6. The typical resolution in $\gamma$ is $5^\circ - 15^\circ$ for each channel, within a single year of data taking. This will thoroughly over constrain the Standard Model description of CP violation, providing important Standard Model measurements with a high sensitivity to New Physics.
