Aging is associated with increased cellular senescence, which is hypothesized to drive the eventual development of multiple comorbidities1. Here we investigate a role for senescent cells in age-related bone loss through multiple approaches. In particular, we used either genetic (i.e., the Ink4a-Attac ‘suicide’ transgene encoding an inducible caspase 8 expressed specifically in senescent cells2–4) or pharmacological (i.e., ‘senolytic’ compounds5–6) means to eliminate senescent cells. We also inhibited the production of the proinflammatory secretome of senescent cells using a JAK inhibitor (JAKi)3,7. In aged (20- to 22-month-old) mice with established bone loss, activation of the Ink4a-Attac caspase 8 in senescent cells or treatment with senolytics or the JAKi for 2–4 months resulted in higher bone mass and strength and better bone microarchitecture than in vehicle-treated mice. The beneficial effects of targeting senescent cells were due to lower bone resorption with either maintained (trabecular) or higher (cortical) bone formation as compared to vehicle-treated mice. In vitro studies demonstrated that senescent-cell conditioned medium impaired osteoblast mineralization and enhanced osteoclastogenesis. Collectively, these data establish a causal role for senescent cells in bone loss with aging, and demonstrate that targeting these cells has both anti-resorptive and anabolic effects on bone. Given that eliminating senescent cells and/or inhibiting their proinflammatory secretome also improves cardiovascular function8, enhances insulin sensitivity9, and reduces frailty7, targeting this fundamental mechanism to prevent age-related bone loss suggests a novel treatment strategy not only for osteoporosis, but also for multiple age-related comorbidities.

The accumulation of DNA damage and/or other cellular stressors (for example, oncogenic insults, reactive metabolites, and proteotoxic stress)1,8–10 causes proliferating cells11,12, as well as terminally differentiated, nondividing cells13–16, to undergo senescence, a process characterized by profound chromatin and secretome changes. Cellular senescence is also associated with increased expression of the senescence biomarker p16Ink4a (also known as Cdkn2a) and resistance to apoptosis1,7. In addition, senescent cells can develop the senescence-associated secretory phenotype (SASP), consisting of proinflammatory cytokines, chemokines, and extracellular matrix–degrading proteins, which have deleterious paracrine and systemic effects8,18–20. Indeed, even a relatively low abundance of senescent cells (for example, ~10–15% in aged primates21) is sufficient to cause tissue dysfunction. We recently demonstrated that with aging, multiple cell types in the bone microenvironment become senescent, although senescent myeloid cells and senescent osteocytes predominantly develop the SASP16. Consistent with this, further characterization revealed that p16Ink4a expression in mouse osteocytes increases markedly after ~18 months of age in both sexes (Supplementary Fig. 1a,b), coinciding with the timing of accelerated age-related bone loss in both female and male mice (Supplementary Fig. 1c–j)22,23.

Eliminating a relatively small proportion (~30%) of senescent cells using a ‘suicide’ transgene, Ink4a-Attac, that permits inducible elimination of p16Ink4a-expressing senescent cells upon the administration of a drug (AP20187; Supplementary Fig. 2) extends health span and prevents the development of multiple age-related morbidities in both progeroid and normal, chronologically aged mice2–4. However, the skeletal phenotype of these animals has not been characterized, and the potential role of senescent cells in age-related bone loss has not been investigated. To test the hypothesis that senescent cells mediate age-related bone loss, female Ink-Attac transgenic mice2–4 were randomized to either vehicle or AP20187 treatment twice weekly for 4 months, starting at 20 months of age (Fig. 1a). As anticipated, AP20187 treatment resulted in markedly lower p16Ink4a mRNA expression (by ~59%) in bone relative to that in vehicle-treated mice (Fig. 1b), as well as lower enhanced green fluorescent protein (EGFP) mRNA (by ~48%) encoded by the Ink-Attac transgene5,6 (Fig. 1c), consistent with the clearance of senescent cells. This was confirmed by a finding of fewer senescent osteocytes in AP20187-treated relative to vehicle-treated mice (by ~46%), as assessed by an established

senescence biomarker (senescence-associated distention of satellites (SADS)) in young mice, the lower bone number in trabecular bone was higher in AP20187-treated relative to vehicle-treated mice. The systemic clearance of senescent cells by AP20187 was further demonstrated by lower p16\(^{ink4a}\) (Fig. 1g) and EGFP (Fig. 1h) mRNA levels in adipose tissue.

Relative to vehicle treatment, AP20187-treated mice had better spine trabecular bone microarchitecture (for example, a 52% higher bone volume/total volume (BV/TV); (Fig. 1i–n), and demonstrated similar improvements in trabecular bone at the femur (Supplementary Fig. 4a–f). AP20187 treatment also resulted in significantly higher cortical thickness and bone strength (by microfinite element analysis (μFEA)) at the femur (Fig. 1o–q). In addition and in keeping with the μFEA results, we found substantially better caudal vertebral bone biomechanical properties (as assessed by biomechanical testing) in AP20187-treated as compared to vehicle-treated mice (Supplementary Fig. 5a–c), whereas bone matrix properties (as assessed by nano-indentation testing) were not different between AP20187- and vehicle-treated mice (Supplementary Fig. 5f.g).

In contrast to the treatment of aged mice, treatment of young adult (12-month-old) INK-ATTAC mice with AP20187 did not alter bone parameters (Supplementary Fig. 6a–o), indicating that this strategy is specific to the prevention of age-related bone loss. Trabecular bone histomorphometry in the old INK-ATTAC mice demonstrated significantly lower bone resorption (osteoclast numbers per bone perimeter, \(P < 0.001\); Supplementary Fig. 7a) in AP20187-treated relative to vehicle-treated mice, without a coupled reduction in bone-formation indices (osteoblast numbers, mineral apposition rate, and bone formation rate (Supplementary Fig. 7b–d)). We excluded possible direct effects of AP20187 on osteoblasts by demonstrating that whereas the administration of treatment for 4 months in old INK-ATTAC mice resulted in significantly lower concentrations of the circulating bone resorption marker, C-terminal telopeptide of type I collagen (CTX, \(P < 0.01\); treatment of young INK-ATTAC mice for either 1.5 months or 4 months had no effect on CTx levels (Supplementary Fig. 8a). In addition, in vitro treatment of mature osteoclasts generated from the INK-ATTAC mouse bone marrow using AP20187 did not induce osteoclast apoptosis (Supplementary Fig. 8b–d)). Despite these findings, however, it is still possible that with aging, a subset of osteoclasts becomes senescent and may be directly cleared by AP20187, thereby contributing to the observed inhibition of bone resorption.

Osteoblast numbers were markedly lower in aged as compared to young mice and were unchanged by AP20187 treatment (Supplementary Fig. 8e). By contrast, AP20187 treatment resulted in significantly lower osteoclast numbers (\(P < 0.001\); Supplementary Fig. 8f), resulting in an improvement in the osteoblast/osteoclast ratio in aged AP20187-treated mice (Supplementary Fig. 8g). The lower bone resorption in AP20187-treated as compared to vehicle-treated mice was also evident on the endocortical surface of the femur (Fig. 1r); additionally, on this surface, osteoblast numbers, mineral apposition rate, and bone-formation rate were all higher in the AP20187-treated mice than in the vehicle-treated ones (Fig. 1s–u), thus suggesting that the accumulation of senescent cells led to an impairment in bone formation that was improved by their clearance. To further test this, osteoblastic MC3T3 cells (a cell line derived from mouse calvaria) were exposed to conditioned medium (CM) collected from control or senescent cells. Senescent cell CM treatment markedly impaired the mineralization of MC3T3 cells as compared to that of control CM (Fig. 1v, w). Therefore, the reduction in senescent cell burden in aged (but not young) mice using a genetic approach resulted in improved trabecular- and cortical-bone parameters associated with lower bone resorption, and either maintained (trabecular) or increased (cortical) bone formation. To further define potential mechanisms, we assessed mRNA expression of key regulators of bone formation (Sost) and bone resorption (Tnfrs11b (Opg), and Tnfsf11 (Rankl)) in osteocyte-enriched bones from these mice and found significantly lower Sost mRNA expression in AP20187-treated relative to vehicle-treated mice (\(P < 0.001\); Supplementary Fig. 9a–d)). Clearance of senescent cells also resulted in significantly lower numbers, perimeter, and volume/tissue volume of bone marrow adipocytes (all \(P < 0.01\); Supplementary Fig. 9e–g).

As an alternative to the genetic approach and one potentially applicable to humans, we have exploited the dependence of senescent cells on specific prosurvival pathways and identified a combination of senolytics–dasatinib (D; an FDA-approved tyrosine kinase inhibitor) and quercetin (Q; a flavanol present in many fruits and vegetables)—that specifically kills senescent cells without affecting proliferating or quiescent, differentiated cells. To test this approach, 20-month-old male C57BL/6 mice were randomized to either vehicle or D + Q treatment once monthly for 4 months (Fig. 2a). D + Q treatment led to significantly lower p16\(^{ink4a}\) mRNA in bone (Fig. 2b), as well as a lower percentage of senescent osteocytes, as assessed by a SADS assay (Fig. 2c), in D + Q–treated mice relative to vehicle-treated mice. The systemic clearance of senescent cells with D + Q was verified by demonstrating lower p16\(^{ink4a}\) mRNA (Fig. 2d) and SA-β-gal-positive cells (Fig. 2e–g) in adipose tissue of 24-month-old D + Q–treated mice. As in the INK-ATTAC model, D + Q administration for 4 months resulted in substantially better spine trabecular bone microarchitecture than in vehicle-treated controls (Fig. 2h–m), with similar improvements in trabecular bone at the femur (Supplementary Fig. 10a–f). Similarly to the INK-ATTAC model, trabecular bone histomorphometry demonstrated lower osteoclast numbers per bone perimeter in D + Q–treated than in vehicle-treated mice (Supplementary Fig. 10g), and there were no differences in osteoblast numbers, mineral apposition rate, or bone formation rate (Supplementary Fig. 10h–j). Also similarly to the INK-ATTAC model, D + Q treatment resulted in higher femur cortical thickness and μFEA-derived bone strength (Fig. 2n–p). This was associated with lower osteoclast numbers on the endocortical surface (Fig. 2q), along with higher endocortical osteoblast numbers (Fig. 2r), mineral-apposition rate (Fig. 2s), and bone-formation rate (Fig. 2t).

Thus, both the genetic (INK-ATTAC) and pharmacological (D + Q) approaches for clearing senescent cells led to virtually identical improvements in trabecular and cortical bone microarchitecture, demonstrating similar underlying cellular mechanisms in trabecular and cortical bone compartments.

Because senescent-cell clearance was associated with lower osteoclast numbers and bone resorption \(in vivo\), we next tested the direct effects of senescent cells on osteoclastogenesis. Pre-treatment of whole-mouse bone marrow with senescent-cell CM resulted in greater osteoclast differentiation potential of nonadherent marrow cells than that achieved by control CM pre-treatment, as evidenced by the markedly higher number of tartrate-resistant acid phosphatase (TRAP)-positive, multinucleated osteoclasts (Fig. 3a,b). The senescent cell CM–treated osteoclast differentiation cultures also exhibited...
significantly higher mRNA expression of the osteoclast markers Ctsk, Oc-stamp, Oscar, Tnfrs11a (Rank), and Acp5 (Trap) (Fig. 3c).

To determine the mechanism underlying the increase in osteoclastogenic potential, nonadherent bone marrow cells were assessed following CM pre-treatment. Flow cytometry demonstrated that the percentage of early osteoclast progenitor cells (defined as CD115 (monocyte marker)+/receptor activator of nuclear factor (NF)-kB (RANK-)) was higher by more than two-fold in cells exposed to senescent-cell CM relative to those exposed to control CM (Fig. 3d,e). Given that RANK expression increases with osteoclast differentiation30, these data indicate that senescent-cell CM increased the number of early monocyte osteoclast progenitors that had not yet acquired RANK expression. This increase was due to enhanced survival, given that apoptosis was significantly lower in cells exposed to senescent-cell CM relative to those exposed to control CM (Fig. 3f).
CM pre-treatment did not alter the differentiation of monocyte-enriched cultures plated at equal densities, indicating no direct effect of senescent-cell CM on monocyte differentiation into osteoclasts (Supplementary Fig. 11a).

We have previously shown that the JAKi ruxolitinib attenuates the production of multiple SASP components by senescent cells3,7. Consistent with this, CM from JAKi-treated senescent cells exhibited a markedly reduced ability to promote osteoclast differentiation as compared to CM from senescent cells (Fig. 3h,i). This effect was due to JAKi effects on senescent-cell SASP secretion, because adding the JAKi directly to senescent-cell CM did not affect osteoclastogenesis (Supplementary Fig. 11b,c). In our earlier study7, we identified interleukin (IL)-6, IL-8 (human homolog to mouse CXCLI), and plasminogen activator inhibitor-1 (PAI-1) as the most critical components of the SASP that were markedly downregulated by JAK inhibition; because these cytokines also modulate bone resorption31–33, we next used neutralizing antibodies to each of them, which revealed that, as compared to an IgG control, neutralization of each of these SASP components attenuated the pro-osteoclastogenic effects of senescent-cell CM (Fig. 3j).

To test the effects of SASP inhibition in vivo on age-related bone loss, 22-month-old male C57BL/6 mice were treated with ruxolitinib for 2 months (Fig. 4a). Relative to vehicle-treated mice, JAKi-treated mice had better spine trabecular-bone microarchitecture (Fig. 4b–g), with similar differences in the femur (Fig. 4h–m). JAKi treatment also resulted in significantly higher bone strength of the femur (Fig. 4n). By contrast, 2 months of treatment of young adult male C57BL/6 mice (7 months old) with the JAKi did not alter bone parameters (Supplementary Fig. 12), indicating that this strategy is specific to the prevention of age-related bone loss. Similarly to the trabecular-bone histomorphometry findings following the reduction of senescent cells using the INK-ATTAC suicide transgene or following D + Q treatment, trabecular-bone histomorphometry in the JAKi-treated aged mice revealed significantly lower osteoclast numbers per bone perimeter as compared to vehicle-treated mice (Fig. 4o), with no significant differences in osteoblast numbers (Fig. 4p). Ex vivo analysis of bone marrow revealed significantly lower osteoclast progenitor colony-forming units (CFU)–granulocyte monocyte (CFU-GM) (P < 0.01) and CFU monocytes (CFU-M) (P < 0.05; Supplementary Fig. 13a,b). In addition, bone marrow isolated from aged JAKi-treated mice had significantly impaired osteoclastogenic potential as compared to vehicle treatment (P < 0.001; Supplementary Fig. 13c,d); consistent with a lack of effect of the JAKi on skeletal parameters in young mice, the osteoclastogenic potentials of bone marrow from young vehicle-treated and JAKi-treated mice were virtually identical (Supplementary Fig. 13e). Finally, to further validate our in vitro findings, we also measured circulating levels of IL-6, CXCLI (IL-8), and PAI-1 in the vehicle-treated and JAKi-treated mice, and, as shown in Supplementary Figure 14a, all three cytokines were lower in the JAKi-treated than in the vehicle-treated mice. By contrast, these cytokines were not lower in plasma from INK-ATTAC (Supplementary Fig. 14b) or D + Q–treated (Supplementary Fig. 14c) mice, suggesting that the JAKi has more systemic effects on the SASP, whereas changes in SASP factors following the specific elimination of senescent cells may be more localized to their microenvironment.

Age-related cellular senescence has been causally linked to declining cardiovascular and metabolic function3,4, as well as to frailty7. Here we examine another major aging comorbidity, osteoporosis, and establish the causal role of senescence in age-related bone loss. We use three different approaches to attenuate both the systemic and paracrine detrimental effects of senescent cells in 20- to 22-month-old...
mice, which have substantial bone loss that mimics osteoporosis in elderly humans. Concomitant with reducing the burden of senescent cells (genetically or pharmacologically) or with inhibiting the production of the SASP by senescent cells (pharmacologically), we demonstrate a markedly better skeletal phenotype, relative to vehicle treatment, with all three approaches. Using bone histomorphometry, we further demonstrate that targeting senescent cells results in lower bone resorption. Importantly, despite lower bone resorption, bone formation is either maintained (trabecular bone) or is higher (cortical bone) following reduction of the senescent-cell burden. The inhibition of bone resorption without a concomitant reduction or an actual stimulation, in bone formation resulting from targeting senescent cells is in contrast to all currently available anti-resorptive drugs for osteoporosis (bisphosphonates, denosumab, estrogen, or raloxifene), in which a reduction in bone resorption is uniformly associated with a reduction in bone formation. The only other drugs to inhibit bone resorption with comparatively lesser effects on bone formation than bisphosphonates or denosumab were the cathepsin-K inhibitors. Unfortunately, the development of this pharmacologic class has recently been halted, owing to an unforeseen increase in stroke risk in a large, phase 3 odanacatib trial. Importantly, new drugs such as senolytics, which inhibit bone resorption without a concomitant reduction in bone formation, would be expected to be efficacious in treating age-related osteoporosis, because the ‘pure’ anti-resorptive bisphosphonate zoledronic acid increased bone mineral density and reduced subsequent vertebral and nonvertebral fractures in a group of women and men with a mean age of ~75 years.

It should be noted that, on the basis of the availability of very old mice from the National Institute on Aging mouse colony, female mice were used in the INK-ATTAC study, whereas male mice were used in the D+Q and JAKi studies. This accounts for the differences in BV/TV in the vehicle-treated mice in the three studies. Given that qualitatively similar effects were seen using all three approaches in different sexes, it could be argued that this strengthens our conclusions.

In our previous work, we found that multiple cell types in the bone microenvironment, including hematopoietic cells, had increased p16INK4a expression with aging. Moreover, not only senescent osteocytes, but also senescent myeloid cells, developed the SASP. Because none of our three approaches was cell-specific, whether the elimination of senescent hematopoietic (for example, myeloid cells) or senescent mesenchymal cells (for example, osteocytes) was specifically responsible for the beneficial effects of reducing senescent cell burden or the SASP on skeletal parameters in mice with...
Figure 4 Suppression of the SASP by treatment with the JAK1/2 inhibitor ruxolitinib prevents age-related bone loss. (a) Experimental design for testing the effect of SASP inhibition induced by ruxolitinib on age-related bone loss: 22-month-old male C57BL/6 mice were randomized to either vehicle (n = 8) or JAKi (n = 7) treatments daily for 2 months. (b) Representative μCT images of bone microarchitecture at the lumbar spine (n = 8 vehicle-treated and n = 7 JAKi-treated mice). (c-g) Quantification of μCT-derived bone volume fraction (BV/TV; %) (c), trabecular number (Tb.N; 1/mm) (d), trabecular thickness (Tb.Th; mm) (e), trabecular separation (Tb.Sp; mm) (f), and SMI (g). (h) Representative μCT images (n = 8 vehicle-treated and n = 7 JAKi-treated mice) of bone microarchitecture at the femoral metaphysis. (i-n) Quantification of femoral metaphysis μCT-derived BV/TV (%)(i), Tb.N (1/mm) (j), Tb.Th (mm) (k), Tb.Sp (mm) (l), SMI (m), and failure load (N) (n). Femoral metaphysis trabecular quantification of osteoclast numbers per bone perimeter (N.Oc/B.Pm; 1/mm) (o) and osteoblast number per bone perimeter (N.Ob/B.Pm; 1/mm) (p). Data represent mean ± s.e.m. (error bars). *P < 0.05; **P < 0.01; ***P < 0.001 (independent samples t-test). (q,r) Comparing the effects of anti-resorptive versus senolytic therapies on bone metabolism. (q) Senescent cells (SCs) accumulate in the bone microenvironment with aging, where they (2) increase bone resorption by osteoclasts (OCs) and (3) decrease bone formation by osteoblasts (OBs). (4) Anti-resorptive therapy inhibits or eliminates OCs and decreases bone resorption; owing to (5) coupling, there is a concomitant reduction in bone formation. (r) (1) Senolytic therapy reduces the burden of (2) SCs, which in turn (3) suppresses bone resorption with (4) either an increase (cortical bone) or maintenance (trabecular bone) in bone formation, leading to (5) uncoupling between OCs and OBs.

aging will require further study. In addition, it is possible that the skeletal effects of targeting senescent cells are due to changes occurring outside of bone, through systemic factors such as cytokines, growth factors, or hormones.

Although clearing senescent cells using a genetic approach is not feasible in humans, the two pharmacological approaches described here are clearly translatable. Although JAK inhibition does have effects on multiple tissues, and effects of the JAKi besides SASP inhibition could be contributing to its skeletal effects, suppressing the SASP to enhance bone mass is indeed novel, and other potentially emerging compounds that have similar actions in bone without deleterious effects in other tissues could be translated to the clinic. Moreover, targeting senescent cells using senolytic drugs is another viable, translatable approach. This is because these drugs would need to be given only intermittently, thereby killing senescent cells without inducing other, off-target effects. Note that in our study, D + Q were administered once monthly, thereby minimizing possible effects related to pathways other than their senolytic effects. In addition, on the basis of prosurvival pathways previously shown to confer apoptosis resistance to senescent cells5,6, additional senolytic agents such as the Bcl-2 family inhibitor navitoclax (ABT263)37, have been identified. Regardless of which specific senolytic compounds are eventually used for
osteoarthritis and other aging morbidities, our study provides a critical proof of concept for the feasibility of this approach for treatment of age-related bone loss.

In conclusion, osteoporosis is an enormous public-health problem that will only increase in scope with the aging of the population. In addition to the morbidity associated with fractures, up to 25% of elderly individuals who have experienced hip fractures die within a year of this devastating event. Thus, there is a crucial need to identify novel therapeutic paradigms for age-related bone loss. The approaches identified here for either eliminating senescent cells or suppressing their SASP represent, to our knowledge, the first therapeutic paradigm to treat age-related osteoporosis by targeting not just bone-specific pathways, as with all currently available (or soon to be available) drugs, but rather by targeting a fundamental aging mechanism present in all tissues. Indeed, whereas conventional anti-resorptive therapy predominantly targets osteoclasts to decrease bone resorption, with a concomitant decrease in bone formation owing to coupling (Fig 4q), senolytics reduce senescent-cell burden, which in turn suppresses bone resorption with either an increased (cortical bone) or maintenance (trabecular bone) in bone formation (Fig 4r). Furthermore, eliminating senescent cells or inhibiting the production of their SASP has been shown to improve cardiovascular function, enhance insulin sensitivity, and reduce frailty in old mice. The present work demonstrates that a similar approach may also be useful for treating osteoporosis, making it fundamentally different from all current therapies for osteoporosis, which benefit bone only. Therefore, therapeutically targeting senescent cells would not only be a novel strategy for treating osteoporosis by simultaneously reducing bone resorption and enhancing bone formation, but also for concurrently preventing multiple aging comorbidities by targeting a fundamental aging mechanism.

ONLINE METHODS

General experimental approaches. No samples, mice or data points were excluded from the reported analyses. Animals were randomized to experimental groups, as indicated below. Analyses were performed in a blinded fashion, as noted below. Detailed information on experimental design and reagents is available through the accompanying Life Sciences Reporting Summary.

Mouse strains and drug treatments. Mice were housed in ventilated cages and maintained within a pathogen-free, accredited facility under a 12-h light–dark cycle with constant temperature (23 °C) and access to food (standard mouse diet, Lab Diet 5053, St. Louis, MO) and water ad libitum. All animal protocols were approved by the Institutional Animal Care and Use Committee (IACUC), and all experiments were performed in accordance with IACUC guidelines. Both sexes were studied as specified below and in the figure legends.

The generation and characterization of the INK-ATTAC transgenic mouse line has been described2. Based on the original idea and initial experimental strategies devised by J.L.K. and T.T., INK-ATTAC mice were co-developed by the Kirkland and J. van Deursen (Mayo) laboratories and bred onto a C57BL/6 background in the van Deursen laboratory, and then the Kirkland laboratory genotyped them to select INK-ATTAC heterozygotes and let them age to 6–12 (young) or 20 (old) months. All experiments using the INK-ATTAC mice were performed on transgenic line 3, which contains 13 copies of the transgene, inserted into a single locus8. Female INK-ATTAC mice from this cohort were randomly assigned to be injected (intraperitoneally (i.p.)) with vehicle or AP20187 (B/B homodimerizer, Clontech; 10 mg of AP20187 per kg body mass (drug/body mass)) twice weekly, beginning at 20 months of age for a total of 4 months (all old mice were killed at 24 months of age). This dosing regimen was chosen because it was effective at clearing senescent cells in chronologically aged old INK-ATTAC mice in previous studies3,4. Young (12-month-old) female INK-ATTAC mice were treated using the same dosing regimen for 1.5 months (killed at 13.5 months of age). In addition, from a previous study in the Kirkland laboratory in which no bones were harvested, we obtained plasma samples from young (6-month-old) female INK-ATTAC mice that were treated using the same dosing regimen for 4 months.

C57BL/6 male mice were obtained from the National Institute on Aging (NIA) at 7, 20 or 22 months of age. Alternatively, C57BL/6 breeding colonies were maintained to generate animals for in vitro osteoclastogenesis assays. 20-month-old male C57BL/6 mice were randomly assigned to one of several groups: oral gavage with dasatinib and quercetin (D + Q) or vehicle for 4 months9. In pilot studies, weekly and biweekly D + Q were also evaluated, with similar effects to once monthly dosing. The once-monthly dosing regimen was chosen to avoid potential off-target effects and because it was effective at clearing senescent cells in a previous cohort of old mice1. D and Q were diluted in 10% PEG400 and delivered by oral gavage at dosages of 5 mg/kg and 50 mg/kg, respectively, in 100 µl.

7-month-old (young) or 22-month-old (old) male C57BL/6 mice were randomly assigned to treatment with either the JAK 1/2 inhibitor, ruxolitinib (JAKi), or vehicle for 2 months (mice were killed at 9 months (young) or 24 months (old) age), as part of a previously published study7. JAKi was dissolved in DMSO and mixed with chow. DMSO (vehicle) chow or JAKi chow was administered daily (0.5 g per animal) for 2 months at a dose of 60 mg/kg (drug/body mass). This dosing regimen was effective at blocking the SASP in old mice7.

Note that whereas female mice were used in the INK-ATTAC study, on the basis of availability from the National Institute on Aging mouse colony, male mice were used in the senolytic and JAK-inhibitor studies.

Tissue collection. Mice were killed, body mass was recorded and serum/plasma was collected via carotid puncture at time of death and stored at −80 °C. The right femur/tibia and lumbar vertebrae were fixed in 10% neutral buffered formalin and stored in ethanol to be used for microcomputed tomography (µCT), histomorphometry and SADS. The remaining vertebrae were used for osteocyte-enriched cell isolations. The tail was collected at the base and stored in PBS-soaked gauze at −20 °C for biomechanical compression and biomaterial nanoindentation testing of the caudal vertebrae. For in vitro analyses of osteoclast progenitors or osteoclastogenesis, left femurs/tibiae were isolated and dissected free of soft tissue, epiphyses were removed and marrow was flushed with PBS. As described7, perigonadal adipose tissue was collected and either fixed (for SA-β-gal staining) or snap-frozen in liquid nitrogen for RNA and subsequent RT-qPCR analyses.

Isolation of osteocyte-enriched cells. Detailed methods and validation of our osteocyte-enriched cell isolation protocol are presented elsewhere15,27. Briefly, mouse vertebrae were stripped of muscle and connective tissues, minced and sequentially digested twice for 30-min in collagenase (Liberase; Roche Diagnostics GmbH, Mannheim, Germany). As shown previously16, the remaining cell fraction represents a highly enriched population of osteocytes used for RT-qPCR analyses.

SADS analysis of senescent osteocytes. SADS 6 was measured in vivo in a blinded fashion, as described16, in osteocytes located in cortical bone in the long bone diaphyses. Briefly, the decalcified right tibiae of mice were fixed, embedded in methylmethacrylate (MMA), and sectioned, which was followed by fluorescence in situ hybridization (FISH)19. Bone sections were cross-linked with 4% paraformaldehyde (PFA) for 20 min, washed three times in PBS (5 min each), and dehydrated in graded ethanol as follows: 70%, 90%, and 100% (3 min each). Following a brief air drying, sections were denatured for 10 min at 80 °C in hybridization buffer: 70% formamide (Sigma–Aldrich), 25-mM MgCl₂, 0.1-M Tris (pH 7.2), 5% blocking reagent (Roche) containing 1.0 µg/ml of Cy3-labeled (F3002, reacts to both human and mouse), and CENPB-specific (ATTGTTGTGAAACGGGTA) peptide nucleic acid (PNA) FISH probe (Panagene, South Korea), which was followed by hybridization for 2 h at room temperature in the dark. Slides were washed, stained, and mounted with vectashield DAPI-containing mounting media (Life Technologies). In addition, we performed the SADS assay on primary murine osteocytes isolated from long-bone diaphyses using the Boneyard Laboratory technique42; cells were either untreated or treated with 10 µg of cesium irradiation (to induce senescence) and cultured in a humidified incubator (maintained at 37 °C and 5% CO₂) for 20 d. SADS were visualized using confocal microscopy (Mayo Clinic Microscopy and Cell Analysis Core) as described16. The numbers of decondensed/elongated centromeres per osteocyte were quantified, as described16. We previously established a cut-off for defining cell senescence as ≥4 SADS per cell16.

Senescence-associated β-galactosidase (SA-β-gal) assay. Cellular SA-β-gal activity was measured to detect lysosomes in senescent cells42. Detailed methods for the SA-β-gal assay have been previously described3. Briefly, perigonadal adipose tissue samples or primary murine osteocytes were fixed with 2% (vol/vol) formaldehyde (Sigma–Aldrich) and 25% glutaraldehyde (Sigma–Aldrich) in PBS for 5 min. After washing with PBS three times, samples were incubated in SA-β-gal solution (pH 6.0) at 37 °C for 16–18 h. Ice-cold PBS was then used to stop the enzymatic reaction. In blinded analyses, for each sample, ten images were taken from random fields using Fluorescence Microscopy (Nikon Eclipse Ti). DAPI (Life Technologies) was used to stain nuclei for cell counting.

Skeletal phenotyping. All imaging was performed in a blinded fashion. Areal bone mineral density (aBMD; g/cm²) of the lumbar spine (L₁–L₄) was measured by dual-energy X-ray absorptiometry (DXA) using a Lunar PIXIms densitometer (software version 1.44.005; Lunar Corp., Madison, WI)42. Measures of total (metaphysis), trabecular (metaphysis), and cortical (midshaft diaphysis) volumetric BMD (vBMD; mg/cm³) at the tibiae were obtained using peripheral quantitative computed tomography (pQCT; Stratec XCT Research SA Plus, software v5.40, Nordland Medical Systems, Fort Atkinson, WI)42. Quantitative analysis of the lumbar spine (L₄–L₆) and distal femoral metaphysis were performed using the Viva Scan 40 µCT scanner (Scanco Medical AG, Basserdorf, Switzerland) with the following parameters: 55 kVp, 145 mA, high resolution, 25-mm voxel size, 300-ms integration time. Using two-dimensional (2D) data from scanned slices, 3D analysis was used to calculate morphometric parameters at both the lumbar spine (200 slices) and distal femoral metaphysis (100 slices) defining trabecular bone mass and microarchitecture, including trabecular bone volume fraction (BV/TV; %), trabecular number (Th.N; 1/µm), trabecular thickness (Th.Th; µm), trabecular...
MC3T3-E1 (subclone 4) cells were plated.

Nano-indentation was performed in a blinded fashion.

2-

Bone marrow adipocyte parameters have been described by our group previously. The determination of bone marrow adipocyte parameters has been described by our group previously.

Briefly, adipocyte number, adipocyte perimeter (mm), and adipocyte volume per tissue volume were measured by tracing out individual adipocytes in all the fields analyzed. All histomorphometric measurements and calculations were performed with the Osteomasure Analysis system (Osteometrics, Atlanta, Georgia).

Real-time quantitative polymerase chain reaction (RT–qPCR) analyses.

Targeted gene expression analyses were performed by RT–qPCR as described. Briefly, total RNA was isolated using QIAzol Lysis Reagent and RNeasy Mini Columns (QIAGEN, Valencia, CA). DNase treatment was applied to degrade contaminating genomic DNA using an on-column RNase-free DNase solution (QIAGEN, Valencia, CA). RNA quantity and purity were confirmed with a Nanodrop spectrophotometer (Thermo Scientific, Wilmington, DE). Reverse transcriptase was performed using the High-Capacity cDNA Reverse Transcription Kit (Applied Biosystems by Life Technologies, Foster City, CA). PCR reactions were run using the ABI Prism 7900HT Real Time System (Applied Biosystems, Carlsbad, CA) with either SYBR green (QIAGEN, Valencia, CA) or TaqMan (Applied Biosystems, Carlsbad, CA). Note that TaqMan assays (purchased from Thermo Fisher Scientific) were used to measure p16INK4a (Cdkn2a), EGFP, Sost, Opg (Tnfsf11), and Rankl (Tnfsf11) (normalized to Tbp or Actb), whereas all other genes (normalized to Tubα1) were measured using SYBR green. Murine primers for Trap (Acp5), Cathepsin K (Ctik), Oscar, Oc-stamp, and Tnfsf11a (Rank) were designed using Primer Express Software Version 3.0 (Applied Biosystems, Foster City, CA) according to the forward and reverse pair sequences:

Acp5: forward 5′-CCCTTTCAAAATTCAGCTACAA-3′ and reverse 5′-CAG CATCAGTTTGGTCCAGCAT-3′; Ctik: forward 5′-GGATTAAATCTCTGCGC GTTG-3′ and reverse 5′-GTTATGGCCAGAGTTCCT-3′; Oscar: forward 5′-CTCCTTCAAAAGTTGCGCTTGTCA-3′ and reverse 5′-GGAGAAGCTGACGCC AGCTTCA-3′; Oc-stamp: forward 5′-TGTAGGCTTGGGTCAGAGT-3′ and reverse 5′-GGTTGGTGGAGCAAGGAGG-3′; Tnfsf11a: forward 5′-ACTGA GGAGACCCCAAGAGG-3′ and reverse 5′-TGAAGAGGACGAGAAGATG-3′.

Conditioned medium generation.

Subcutaneous adipose tissue samples were collected from healthy, lean (BMI 26.6 ± 0.9 kg/m²) kidney donors aged 39 ± 3.3 years for isolation of primary human adipose-derived mesenchymal stem cells (AdMSCs) as described. The protocol was approved by the Mayo Foundation Institutional Review Board informed consent was obtained from all human subjects. Cellular senescence was induced in AdMSCs by 10 Gy of cesium irradiation as described. JAK inhibitor 1 (CAS 457081-03-7) was purchased from EMD Millipore (Billerica, MA). Ruxolitinib (INCB18424, CAS 941678-49-5) was purchased from ChemieTek (Indianapolis, IN). Conditioned medium (CM) was made of RPMI 1640 containing 1-mM sodium pyruvate, 2-mM glutamine, MEM vitamins, MEM nonessential amino acids, and antibiotic (Thermo Fisher Scientific). For collection, human nonproliferating control (CON) or senescent (SEN) AdMSCs cells were washed three times with PBS and cultured in CM for 24 h. For JAK inhibitor treatment, cells were treated with 0.6-µM JAK inhibitor 1 or DMSO in CM containing 10% FBS and antibiotic for 48 h. Cells were then washed three times with PBS and exposed to media containing JAK inhibitor or DMSO for another 24 h.

In vitro osteoblast differentiation.

MC3T3-E1 (subclone 4) cells were plated at a density of 1 × 10⁴ cells per cm² in α-MEM without ascorbic acid. After reaching confluence (~48 h), media was replaced and cells were cultured for an additional 72 h. Differentiation media consisted of α-MEM containing ascorbic acid with the addition of 50 µg/ml ascorbic acid and 10-mM beta-glycerophosphate. Cells were cultured in the presence of 20% control or senescent CM. Differentiation media and CM treatments were replaced every 3 or 4 days until day 21. Cells were fixed with 1% PFA, and stained with Alizarin Red S (Sigma-Aldrich) to assess osteoblast mineralization. Cultures were stained for 15 min, washed with H₂O, and dried before obtaining images. Alizarin Red stain was eluted with 10% cetylpyridinium chloride in NaP buffer and absorbance was assessed at 540 nm.

Osteoclast differentiation and quantification.

Following euthanasia, long bones were isolated from C57BL/6 mice, 5–8 weeks of age. As described above, bone marrow was washed with sterile PBS. Red blood cells (RBCs) were lysed using RBC lysis buffer (1 ×) (E Bioscience, San Diego, CA), and marrow counts were obtained. Equal cell numbers were cultured overnight in vehicle (negative...
control), 25 ng/ml rmM-CSF (positive control) (R&D Systems, Minneapolis, MN), control CM, senescent CM, or CM from senescent cells treated with the JAK inhibitor 1 (SEN/JAKi). CM treatments were 1:1 with α-Minimal Essential Medium (MEM, Invitrogen, Carlsbad, CA) with 10% FBS (FBS) and 1 x antibiotic/antimycotic. Negative and positive controls were 1:1 with control RPMI 1640 used for AdMSC culture. As a control for the presence of the JAK inhibitor 1, cells were treated with control CM or senescent CM with the addition of freshly added vehicle (DMSO) or JAK inhibitor 1 (0.3-µM final concentration). The nonadherent populations were collected 24 h after plating. Cell counts were obtained and viability was assessed with Trypan Blue. Equal cell numbers were then plated in osteostatation differentiation medium (α-MEM) with 10% FBS, 1 x antibiotic/antimycotic, 1:50 CMB 14-12 supernatant (source of M-CSF) and 200 ng/ml mouse receptor activator of NF-κB ligand (RANKL)-GST (generated using a recombinant RANKL expression construct provided by B. Lee, Ohio State University)). Osteostatation differentiation was carried out for 2–4 d, with differentiation media replaced on day 3. Mature osteoclasts formed on days 3 and 4.

Alternatively, mouse monocytes were isolated from mouse bone marrow by negative selection using the Mouse Monocyte Isolation Kit (Miltenyi Biotec, San Diego, CA) and magnetic activated cell sorting (MACS, autoMACS-Pro magnetic cell sort, Miltenyi Biotec, Inc.). Monocytes were cultured with CON or SEN CM overnight, as described above. Nonadherent populations were collected, counted, and plated at equal cell densities in osteostatation differentiation medium. To assess osteostatogenesis in vehicle or ruxolitinib (JAKi) treated mice, RBC-lysed marrow was plated directly in osteostatation differentiation medium. Osteostatation differentiation medium was replaced on day 3 and osteoclast cultures were fixed on day 4.

Mature osteoclast cultures were fixed in 1% PFA and osteostatation differentiation was assessed by TRAP activity (Acid Phosphatase, Leukocyte Kit, Sigma-Aldrich, St. Louis, MO). Osteoclasts were defined as TRAP-positive cells with greater than three nuclei.

Flow cytometry. Whole bone marrow was cultured overnight with CON or SEN CM as described above. The nonadherent cells were collected and counted. For each sample, 5 µl Fc Blocking Reagent was added to 1 x 10^6 cells in FACS buffer, and cells were stained with APC-conjugated anti-CD115 (eBio-Science) and PE-conjugated anti-RANK (ThermoFisher) in a total volume of 100 µl. Cells were washed and fixed with 1% PFA. Cells were sorted using FACS Calibur (BD Biosciences), and data were analyzed by FlowJo (FlowJo, LLC); gates were set according to unstained and single label controls for APC and PE, respectively.

Apoptosis. Apoptosis was assessed using ApoTox-Glo Triplex Assay (Promega, Madison, WI). Bone marrow or monocyte-enriched cultures (Mouse Mouse Isolation Kit, Miltenyi Biotec) were treated for 24 h with CON or SEN CM, and apoptosis was quantified. Alternatively, bone marrow was differentiated for 4 d into mature osteoclasts as described above. On day 4, mature osteoclast cultures were treated with vehicle or 10-nM AP20187 (the same in vitro dose used previously in fresh osteoclast differentiation media. Cells were incubated for 18 h followed by apoptosis quantification. Briefly, a luminogetic caspase-3/7 substrate was added to cells. Cultures were incubated for 30 min at RT, and luminescence was measured using the GloMax-Multi Detection System (Promega).

MethoCult assay. Bone marrow was plated in MethoCult GF 3434 Media (StemCell Technologies, Vancouver, BC, Canada). Each mouse was tested in duplicate. Cultures were incubated for 10 d and colonies were identified as monocyte/macrophage (M) or granulocyte-monocyte/macrophage (GM). Colony-forming units (CFU)-M and CFU-GM per plate were counted and averaged per mouse. Analyses were done in a blinded fashion.

Serum/plasma assays. Peripheral blood for serum/plasma measurements was collected from overnight fasted mice by cardiac puncture; samples were stored at ~80 °C in aliquots. Circulating plasma C-terminal telopeptide of type I collagen (CTXs) levels in young and old INK-ATTAC mice were measured by enzyme immunoassay (ELISA) (Immunodiagnostic Systems). Serum IL-6 and CXCL1 (IL-8) levels in JAKi-treated mice were previously measured using Luminex xMAP technology. Mouse ELISA kits (R&D Systems) were used to measure circulating plasma levels of IL-6, CXCL1 (mouse homolog to IL-8), and PAI-1 in all the other mice in Supplementary Figure 14. All assays were performed in a blinded fashion.

Cell-line identity. MC3T3-E1 (subclone 4) cells were obtained from the ATCC (ATCC CRL-2593) to assess the effects of senescent CM on osteoblast differentiation. This cell line is not listed in the database of commonly misidentified cell lines maintained by ICLAC. Given that these cells were freshly obtained from the ATCC, we did not perform testing for mycoplasma contamination. All other experiments were performed with primary cells.

Reagents. Antibodies and other reagents were purchased from commercial sources; details are available from vendors as indicated throughout the Methods.

Statistical analyses. Sample sizes were based on pilot or previously conducted and published experiments (for example, Syed et al. 42), in which statistically significant differences were observed on bone with various interventions in our laboratory. For each experiment, replicates are as noted in the figure legends. No samples were excluded from analyses. Investigators were blinded to allocation during experiments and outcome assessments, as noted specifically above. Data were checked for normality using histograms and all variables were tested for skewness and kurtosis. Analyses of differences between groups were performed by independent samples t-test, Wilcoxon rank–sum tests, one-way ANOVA, or repeated-measures ANOVA where justified as appropriate (see figure legends). Following ANOVA, the Bonferroni post hoc test was used to adjust for multiple comparisons. Data are presented as means ± s.e.m. (unless otherwise specified) with P < 0.05 (two-tailed) considered to be statistically significant. Statistical analyses were performed using the Statistical Package for the Social Sciences for Windows, Version 22.0 (SPSS, Chicago, IL).

Data availability. Data presented in this manuscript are available from the corresponding authors upon reasonable request. Source data are available for Figures 1–4.

Corrigendum: Host DNA released by NETosis promotes rhinovirus-induced type-2 allergic asthma exacerbation

Marie Toussaint, David J Jackson, Dawid Swieboda, Anabel Guédán, Theodora-Dorita Tsurouktsoglou, Yee Man Ching, Coraline Radermecker, Heidi Makrinioti, Julia Aniscenko, Michael R Edwards, Roberto Solari, Frédéric Farnir, Venizelos Papayannopoulos, Fabrice Bureau, Thomas Marichal & Sebastian L Johnston

Nat. Med. 23, 681–691 (2017); published online 1 May 2017; corrected after print 12 July 2017

In the version of this article initially published, Dr. Nathan W Bartlett was inadvertently omitted from the author list and the Contributions section. The errors have been corrected in the HTML and PDF versions of the article.

Corrigendum: The cold-induced lipokine 12,13-diHOME promotes fatty acid transport into brown adipose tissue

Matthew D Lynes, Luiz O Leiria, Morten Lundh, Alexander Bartelt, Farnaz Shamsi, Tian Lian Huang, Hirokazu Takahashi, Michael F Hirshman, Christian Schlein, Alexandra Lee, Lisa A Baer, Francis J May, Fei Gao, Niven R Narain, Emily Y Chen, Michael A Kiebish, Aaron M Cypess, Matthias Blüher, Laurie J Goodyear, Gökhans Hotamisligil, Kristin I Stanford & Yu-Hua Tseng

Nat. Med. 23, 631–637 (2017); published online 27 March 2017; corrected after print 23 August 2017

In the phrase, “Here we show that the lipid 12,13-dihydroxy-9Z-octadecenoic acid (12,13-diHOME) is a stimulator of BAT activity, and that its levels are negatively correlated with body-mass index and insulin sensitivity,” located in the abstract, the word “resistance” should take the place of the word “sensitivity”.

Also, the authors have clarified in more detail how the FATP1 oligomer density was quantitated in Figure 4f. This information can be found in the “Membrane Fractionation” section of the Online Methods: “To quantify FATP1 in scanned immunoblots, regions of interest of identical size were drawn in each lane at the same molecular weight, and integrated pixel density was measured using ImageJ software. For each independent experimental replicate, the integrated pixel density for each lane was expressed normalized to the control lane, or in the case of the experimental replicate with two control lanes, the integrated pixel density for each lane was expressed normalized to the average of both control lanes. The data are expressed as the average normalized value for each lane, with the error bars representing s.e.m.”

Corrigendum: Targeting cellular senescence prevents age-related bone loss in mice

Joshua N Farr, Ming Xu, Megan M Weivoda, David G Monroe, Daniel G Fraser, Jennifer L Onken, Brittany A Negley, Jag D Sfeir, Mikolaj B Ogrodnik, Christine M Hachfeld, Nathan K LeBrasseur, Matthew T Drake, Robert J Pignolo, Tamar Pirtskhalava, Tamara Tchkonia, Merry Jo Oursler, James L Kirkland & Sundeep Khosla

Nat. Med. 23, 1072–1079 (2017); published online 21 August 2017; corrected after print 11 October 2017

In the version of this article initially published, the representative images in Fig. 2n were inadvertently duplicated in Fig. 4h. A correct version of the images for Fig. 4h has been supplied. The authors wish to point out that this error did not affect the other data reported in the paper or the conclusions drawn. The error has been corrected in the HTML and PDF versions of the article.

Corrigendum: Genome-wide CRISPR screens reveal a Wnt–FZD5 signaling circuit as a druggable vulnerability of RNF43-mutant pancreatic tumors

Nat. Med. 23, 60–68 (2017); published online 21 November 2016; corrected after print 20 September 2017

In the version of this article initially published, duplicate panels in Figure 5e were incorrectly used in the assembly of the figure, for which all original panels are presented in Supplementary Figure 10. The errors in Figure 5e have been corrected in the HTML and PDF versions of the article.
Life Sciences Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form is intended for publication with all accepted life science papers and provides structure for consistency and transparency in reporting. Every life science submission will use this form; some list items might not apply to an individual manuscript, but all fields must be completed for clarity.

For further information on the points included in this form, see Reporting Life Sciences Research. For further information on Nature Research policies, including our data availability policy, see Authors & Referees and the Editorial Policy Checklist.

Experimental design

1. Sample size
   Describe how sample size was determined.
   Sample sizes were based on pilot or previously conducted and published experiments (e.g., J Bone Miner Res. 2005 Nov;20(11):1992-2001) in which statistically significant differences were observed on bone with various interventions in our laboratory.

2. Data exclusions
   Describe any data exclusions.
   No samples were excluded from analyses.

3. Replication
   Describe whether the experimental findings were reliably reproduced.
   No attempts at experimental replication failed.

4. Randomization
   Describe how samples/organisms/participants were allocated into experimental groups.
   For each study, all mice were randomly allocated into experimental groups.

5. Blinding
   Describe whether the investigators were blinded to group allocation during data collection and/or analysis.
   Investigators were blinded to allocation during experiments and outcome assessments (during both data collection and analysis), except for rare instances in which this was not possible.

Note: all studies involving animals and/or human research participants must disclose whether blinding and randomization were used.

6. Statistical parameters
   For all figures and tables that use statistical methods, confirm that the following items are present in relevant figure legends (or in the Methods section if additional space is needed).

   n/a

   Confirmed

   - The exact sample size \( n \) for each experimental group/condition, given as a discrete number and unit of measurement (animals, litters, cultures, etc.)
   - A description of how samples were collected, noting whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
   - A statement indicating how many times each experiment was replicated
   - The statistical test(s) used and whether they are one- or two-sided (note: only common tests should be described solely by name; more complex techniques should be described in the Methods section)
   - A description of any assumptions or corrections, such as an adjustment for multiple comparisons
   - The test results (e.g., \( P \) values) given as exact values whenever possible and with confidence intervals noted
   - A clear description of statistics including central tendency (e.g., median, mean) and variation (e.g., standard deviation, interquartile range)
   - Clearly defined error bars

See the web collection on statistics for biologists for further resources and guidance.

Nature Medicine: doi:10.1038/nm.4385
Software

Policy information about availability of computer code

7. Software

Describe the software used to analyze the data in this study.

Statistical analyses were performed using the Statistical Package for the Social Sciences for Windows, Version 22.0 (SPSS, Chicago, IL) or using GraphPad software (GraphPad Software, Inc., San Diego, CA, USA) (www.graphpad.com).

For manuscripts utilizing custom algorithms or software that are central to the paper but not yet described in the published literature, software must be made available to editors and reviewers upon request. We strongly encourage code deposition in a community repository (e.g. GitHub). Nature Methods guidance for providing algorithms and software for publication provides further information on this topic.

Materials and reagents

Policy information about availability of materials

8. Materials availability

Indicate whether there are restrictions on availability of unique materials or if these materials are only available for distribution by a for-profit company.

No unique materials were used for this study.

9. Antibodies

Describe the antibodies used and how they were validated for use in the system under study (i.e. assay and species).

RANK Monoclonal Antibody, PE: (9A725), ThermoFisher Scientific, MA1-41015, lot# SC2353362A. Species reactivity: Mouse, Human. Manufacturer provided intracellular flow analysis in RAW cells using 0.5ug of antibody vs isotype control, demonstrating the specificity of this antibody.

This antibody has previously been used for flow cytometry in the following publications: PMID 26329493, PMID 22531921. This antibody is also referenced in the Labome database of validated antibodies: https://www.labome.com/product/Invitrogen/MA1-41015.html

CD115 (CSF-1R) Antibody, APC: (AFS98) eBioscience, cat# 17-1152-82, lot# 4293537. Species reactivity: Mouse. Manufacturer provided intracellular flow analysis in peritoneal exudate cells using 0.03ug of antibody vs APC isotype control, demonstrating the specificity of this antibody. This antibody has been previously used in the following select publications:PMID 25503582, PMID 21654748. This antibody is also referenced in the Labome database of validated antibodies: https://www.labome.com/product/Invitrogen/17-1152-82.html.

10. Eukaryotic cell lines

a. State the source of each eukaryotic cell line used. MC3T3-E1 subclone 4 was obtained from ATCC (ATCC® CRL-2593™).

b. Describe the method of cell line authentication used. These cells were obtained and expanded directly from ATCC, within 30 days of receipt of the cell line. They exhibited mineralization activity consistent with what has been previously reported for this cell line.

c. Report whether the cell lines were tested for mycoplasma contamination. As these cells were freshly obtained from ATCC, we did not perform testing for mycoplasma contamination.

d. If any of the cell lines used are listed in the database of commonly misidentified cell lines maintained by ICLAC, provide a scientific rationale for their use. MC3T3-E1 (subclone 4) cells were obtained from ATCC. This cell line is not listed in the database of commonly misidentified cell lines maintained by ICLAC.

Animals and human research participants

Policy information about studies involving animals; when reporting animal research, follow the ARRIVE guidelines

11. Description of research animals

Provide details on animals and/or animal-derived materials used in the study.

Both sexes of C57BL/6 mice (Mus musculus) were studied. Female INK-ATTAC heterozygotes on the C57BL/6 background were used between the ages of 6-13.5 months (young) or 20-24 months (old). Male C57BL/6 mice between the ages of 7-9 months (young) or 20-24 months (old) were used for D+Q and JAK inhibitor studies. In addition, young C57BL/6 male mice aged 5-8 weeks were utilized to test the effects of senescent cell conditioned media on osteoclastogenesis in vitro.
12. Description of human research participants

Describe the covariate-relevant population characteristics of the human research participants.

Subcutaneous adipose tissue samples were collected from healthy, lean (BMI 26.6 ±0.9 kg/m²) kidney donors aged 39±3.3 years for isolation of primary human adipose-derived mesenchymal stem cells (AdMSCs). AdMSCs were utilized for generation of control and senescent cell conditioned media.
Flow Cytometry Reporting Summary

Form fields will expand as needed. Please do not leave fields blank.

Data presentation

For all flow cytometry data, confirm that:

1. The axis labels state the marker and fluorochrome used (e.g. CD4-FITC)
2. The axis scales are clearly visible
3. All plots are contour plots with outliers or pseudocolor plots
4. A numerical value for number of cells or percentage (with statistics) is provided

Methodological details

5. Describe the sample preparation. 1x10^6 cells were stained with APC-conjugated anti-Cd115 (eBioscience, AFS98, 0.25ug) and PE-conjugated anti-RANK (ThermoFisher Scientific, 9A725, 2ug) in 100uL volume for 30 minutes at 4oC, rotating. Cells were washed in FACS buffer, centrifuged, and resuspended in 500uL 1% paraformaldehyde.

6. Identify the instrument used for data collection. FACSCalibur, BD Biosciences

7. Describe the software used to collect and analyze the flow cytometry data. Data was collected with Cell Quest software. Data was analyzed using FlowJo (FlowJo, LLC).

8. Describe the abundance of the relevant cell populations within post-sort fractions. Not applicable. Flow cytometry was used for analysis only.

9. Describe the gating strategy used. Unstained and single stained controls were utilized to set gates for Cd115-APC positive vs negative and RANK-PE positive vs negative cell populations.

Tick this box to confirm that a figure exemplifying the gating strategy is provided in the Supplementary Information. □
