(Dated: June 12, 2009)

We present a solution of Kitaev’s spin model on the honeycomb lattice and of related topologically ordered spin models. We employ a Jordan-Wigner type fermionization and find that the Hamiltonian takes a BCS type form, allowing the system to be solved by Bogoliubov transformation. Our fermionization does not employ non-normal auxiliary degrees of freedom and the eigenstates we obtain are completely explicit in terms of the spin variables. The ground-state is obtained as a BCS condensate of fermion pairs over a vacuum state which corresponds to the toric code state with the same vorticity. We show in detail how to calculate all eigenstates and eigenvalues of the model on the torus. In particular, we find that the topological degeneracy on the torus descends directly from that of the toric code, which now supplies four vacua for the fermions, one for each choice of periodic vs. anti-periodic boundary conditions. The reduction of the degeneracy in the non-Abelian phase of the model is seen to be due to the vanishing of one of the corresponding candidate BCS ground-states in that phase. This occurs in particular in the fully periodic vortex-free sector. The true ground-state in this sector is exhibited and shown to be gapped away from the three partially anti-periodic ground-states whenever the non-Abelian phase is gapped.

I. INTRODUCTION

A combination of special properties has made Kitaev’s spin model on the honeycomb lattice4, a very popular subject of study in recent years. The model has a basic Hamiltonian with only nearest neighbour interactions, but nevertheless, extensions of the model with magnetic field like terms have both Abelian and non-Abelian topological phases. Moreover these extended models can still be exactly solvable, allowing in principle for direct study of both phases and of the phase transition.

In spite of the availability of what is by now a large collection of exact solutions,1,2,3,4,5,6,7,8,9,10,11,12,13,14,15 all based on fermionization techniques, the two types of phases of the system are generally understood through the use of different methods of analysis. On the one hand Kitaev showed3 using perturbation theory that the low energy effective theory of the Abelian phases is equivalent to his $Z_2$ toric code model16 and in the mean time, extensive further perturbative work on this phase has been done17,18,19,20,21. On the other hand, the non-Abelian phase is only understood using the fermionized exact solutions of the system. Its topological order is known to be described by the Ising model of topological field theory.

There have been a number of recent works linking the $Z_2$ toric code and Ising topological field theories directly. For example it was demonstrated that a $Z_2$ toric code theory could be formed by condensing bosonic excitations in a doubled Ising theory22,23. Also, excitations with properties of Ising anyons were constructed from superpositions of the electric and magnetic excitations of the toric code model24. In the present work, we want to explore the relationship between these two types of topological order within the context of the honeycomb model.

In order to do this, we introduce yet another solution of the model, but one which is particularly useful for studying the relation between the toric code and Ising type topological orders which exist in the model. Our solution is again by a Jordan-Wigner type fermionization, however, the Jordan-Wigner transformation we employ is closely linked to a choice of basis for the Hilbert space adapted to perturbative analysis of the Abelian, toric code type phase17,18,19. The fermions we use are also closely related to the deconfined fermionic excitations which were shown to occur throughout the phase diagram in ref.20 and which correspond to the fermionic excitations of the toric code in the Abelian phase. After fermionization, the model can be solved exactly and, as with other fermionization methods (cf. refs.5,9), the ground-state sector of the system can be transformed to that of a spinless p-wave superconductor, as analyzed by Read and Green in ref.26. The ground-state is thus a BCS type state27, and can be related to the $\nu = 5/2$ fractional quantum Hall state of Moore and Read28. With our method, we obtain a vacuum for the fermionized theory which is exactly defined in terms of toric code stabilizers and independent of the couplings of the model. The ground-state for the full system, valid for all parameter space, is in fact a BCS type condensate over the toric code ground-state. Because the vacuum is independent of the coupling parameters, the mechanism for switching between topological phases is contained exclusively within the BCS product. On the other hand, the topological degeneracies of the model are already present at the level of the toric code vacuum. The BCS product only lifts some of this degeneracy in the non-Abelian phase.

The structure of the paper is as follows: We start with a short review of the model and of the emergence of the toric code as an effective description of the Abelian phase. We give special attention to a description of the Hilbert space of the model in terms of hard core bosons and effective spins on a square lattice, as this is essential preparation for our fermionization scheme. In section III we fermionize and solve the model on the plane and give an explicit expression for the ground-state of the model in eq. (27). This expression in-
volve only the physical degrees of freedom of the model; no auxiliary variables are introduced anywhere in this work. In section [IV] we extend our fermionization method to the torus. We explain how to construct the eigenstates in any given vorticity sector and how to calculate their corresponding energy eigenvalues. Since the creation of an odd number of fermions does not preserve vorticity, certain low energy eigenvalues which might be expected do not occur in every vorticity sector. We give particular attention to the vortex free sector which we give a general discussion of Hartree-Fock-Bogoliubov theory with gauge violating fermions, which is used as background for the discussion in section [IV].

II. HONEYCOMB MODEL AND TORIC CODE

A. Spin Hamiltonian and loop symmetries

The system consists of spins on the sites of a hexagonal lattice. The Hamiltonian can be written as

\[ H_0 = - \sum_{\alpha \in \{x,y,z\}} \sum_{i,j} J_{ij} K_{ij}^{\alpha} \]

where \( K_{ij}^{\alpha} = \sigma_i^{\alpha} \sigma_j^{\alpha} \) denotes a directional spin exchange interaction occurring between the sites \( i, j \) connected by a \( \alpha \)-link as shown in FIG. 1. We define a the basic unit cell of the lattice with the two unit vectors \( n_x \) and \( n_y \) as shown in FIG. 1. By contracting each \( z \)-link to a single point we define the position vector labeling the \( z \)-dimers on a square lattice as \( q = q_x n_x + q_y n_y \).

Consider now products of \( K \) operators along loops on the lattice, \( K_{ij}^{(1)} K_{jk}^{(2)} \ldots K_{li}^{(m)} \), where \( \alpha^{(m)} \in x, y, z \). Any loop constructed in this way commutes with the Hamiltonian and with all other loops. The shortest such loop symmetries are the plaquette operators

\[ W_q = \sigma_i^x \sigma_j^y \sigma_k^z \sigma_l^y \sigma_i^z \sigma_j^x, \]

where the numbers 1 through 6 label lattice sites on single hexagonal plaquette, see FIG. 1. We will use the convention that \( q \) denotes the \( z \)-dimer directly below the plaquette. The fact that the Hamiltonian commutes with all plaquette operators implies that we may choose energy eigenvectors \( |n\rangle \) such that \( W_q |n\rangle = \langle n | W_q |n\rangle = \pm 1 \). If \( W_q = -1 \) then we say that the state \( |n\rangle \) carries a vortex at \( q \). When we refer to a particular vortex-sector we mean the subspace of the system with a particular configuration of vortices. The vortex-free sector for example is the subspace spanned by all eigenvectors such that \( W_q = 1 \) for all \( q \).

On a torus, the plaquette operators are not independent, as they obey \( \prod W_q = I \) where the product is over all \( q \). There are also two independent homologically non-trivial loop symmetries. To represent these we are free to choose any two closed loop operators that traverse the torus as long as they cannot be deformed into each other by plaquette multiplication. All other homologically non-trivial loop symmetries can be constructed from the products of these two operators and the \( N/2 - 1 \) independent plaquette operators, (cf. ref. 20). Note that when the torus is specified by periodic boundary vectors \( (x, y) \) which are integer multiples of the unit vectors i.e. \( x = N_x n_x \) and \( y = N_y n_y \), it is natural to use overlapping products of alternating \( z \) - and \( x \)-links \( (q_x^{(x)} = \prod K_{ij}^{x} K_{jk}^{y}) \) and alternating \( z \) - and \( y \)-links \( (q_y^{(y)} = \prod K_{ij}^{y} K_{jk}^{x}) \), as homologically non-trivial symmetries. We will generally use the operators \( L_x^{(x)} \) and \( L_y^{(y)} \) that run through the origin as the two independent symmetries.

The model contains 4 distinct phases. There are three gapped phases (1) \( A_x \) with \( J_x > J_y + J_z \), (2) \( A_y \) with \( J_y > J_x + J_z \) and (3) \( A_z \) with \( J_z > J_x + J_y \) with (4) a gapless \( B \) phase existing in the parameter space between the three \( A \) phases. As each \( A \) phase is related to the others by a lattice rotation we confine our analysis to the \( A_z \) and \( B \) phases with out loss of generality.

The Hamiltonian (1) is often extended to include perturbing terms \( H_1 \) that (i) are sums of \( K \) operator products (ii) open a gap in the \( B \)-phase (iii) break time-reversal symmetry (T-symmetry), (iv) \( H_1 \) and the fermionic string \( S \)

\[ H_1 = -\kappa \sum_q \sum_{l=1}^{6} P(q)^{(l)} \]

with the second summation running over the six terms

\[ \sum_{l=1}^{6} P(q)^{(l)} = \sigma_i^x \sigma_j^y \sigma_k^z + \sigma_i^y \sigma_j^x \sigma_k^z + \sigma_i^z \sigma_j^y \sigma_k^x + \sigma_i^y \sigma_j^z \sigma_k^x + \sigma_i^z \sigma_j^x \sigma_k^y + \sigma_i^x \sigma_j^z \sigma_k^y \]

Recently a third type of phase has been discovered in extended honeycomb models, featuring gapped Dirac fermions. The phase is opened by allowing the \( J_{\alpha} \) couplings to vary periodically on the lattice. Although we do not examine this phase in this paper, the methodology employed below can in principle be used.
B. The Toric Code as an effective system

The Hamiltonian (1) can be written in terms of hard-core bosons and effective spins of the z-dimers using the mapping:17

\[
| \uparrow \downarrow \rangle = | \uparrow, 0 \rangle, \quad | \downarrow \uparrow \rangle = | \downarrow, 0 \rangle
\]

The labels on the left hand side indicate the states of the z-dimer in the $S_z$ basis. The first quantum number of the kets on the right hand side represents the effective spin of the square lattice and the second is the bosonic occupation number. The presence of a boson indicates an anti-ferromagnetic configuration of the spins connected by a z-link.

In the $A_z$-phase, the dominance of the $J_z$ means that spins on a z-dimer tend to align in the same direction, and therefore in this limit the presence of bosons is energetically suppressed. A perturbative analysis for the low energy effective Hamiltonian in this regime shows that the first non-constant term, occurring at the 4th order, is

\[
H_{TC} = -J_{\text{eff}} \sum_q Q_q \otimes I
\]

with $Q_q = \tau^z_q - \tau^y_{q+n_x} \tau^y_{q+n_y} \tau^z_{q+n}$ where $\tau^a_q$ is the Pauli operator acting on the effective spin at position $q$ and $J_{\text{eff}} = \frac{J_1 J_2}{2b q_x + 1}$. This effective Hamiltonian, defined now on a square lattice, is unitarily equivalent to what is known as the toric code (TC).16

The operators $Q_q$, like the plaquette operators $W_q$, all commute with each other. The eigenvalues of each operator can therefore be used as quantum numbers to specify eigenstates of the system. We write $| \{ Q_q \} \rangle$ where $\{ Q_q \}$ is a full list of $Q_q$ eigenvalues. Excitations of the TC system are made/moved by applying $\tau^z$ and/or $\tau^y$ operators to a site. In the lattice orientation we use, $\tau^z_q$ changes the eigenvalues $Q_{q-n_x}$ and $Q_{q-n_y}$, while $\tau^y_q$ changes the eigenvalues $Q_q$ and $Q_{q-n_x+n_y}$. On even-even lattices, which can be bi-colored, the quasi-particle excitations occur in two types usually labeled $e$ and $m$. Excitations of the same type are mutually bosonic but excitations of different types display Abelian anyonic statistics. Importantly, pairs of $e$ and $m$ particles behave as fermions.

In the language of the stabilizer formalism, see37,38, we say that the TC states are stabilized by the operators $Q_q| \{ Q_q \} \rangle = Q_q| \{ Q_q \} \rangle$. On a plane for example, the TC ground-state is the state such that $Q_q| \{ Q_q \} \rangle = | \{ Q_q \} \rangle$ for all $q$. However, despite their simple description in terms of the stabilizer formalism, it is important to recognize that the TC states are structurally non-trivial and display unusual entanglement and geometric properties. It has been shown for example that the ground-state of the TC system is a Projected Entangled Pair State (PEPS) with virtual dimension $D=2$ (see for example ref. 40), and can also be described in terms of string-net condensates and loop models.41,42

C. Hard-core bosons and stabilizers

The basis (5) also describes anti-ferromagnetic configurations of the z-dimers through the bosonic occupation number and forms an orthonormal basis for the full honeycomb system. The Pauli operators of the original spin Hamiltonian can be written as (see references17,18,19):

\[
\begin{align*}
\sigma^x_q &= \tau_q (b_q^\dagger + b_q), \\
\sigma^y_q &= \tau_q (b_q^\dagger - b_q), \\
\sigma^z_q &= \tau_q I - 2b_q^\dagger b_q,
\end{align*}
\]

where $b^\dagger$ and $b$ are the creation and annihilation operators for the hard-core bosons. In this representation the Hamiltonian (1) becomes

\[
H_0 = -J_z \sum_q (b_q^\dagger b_q + b_q^\dagger b_{q+n_x} + b_{q+n_y}^\dagger b_{q+n_x} + b_{q+n_y}^\dagger b_q)
\]

\[
- J_y \sum_q i \tau^x_q (b_q^\dagger - b_q) (b_{q+n_y}^\dagger b_q + b_q b_{q+n_y}^\dagger)
\]

\[
- J_z \sum_q (I - 2b_q^\dagger b_q),
\]

with the perturbative term $H_1$ given pictorially in FIG. 3. The Hamiltonian (8) has been used in the gapped $A_z$ phase to perturbatively calculate effective Hamiltonians and other measures, to the 10th order in some cases.17,18,19. In the next section we will show how to fermionize this Hamiltonian by attaching string operators to the hard-core bosons. The procedure is much like other Jordan-Wigner type approaches but the operator strings that we choose, will be tailored for this system.

In this representation the plaquette operators (2) become

\[
W_q = (I - 2N_q)(I - 2N_{q+n_x})Q_q
\]

where $N_q = b_q^\dagger b_q$. This relation (9) is very useful because it allows one to write down an orthonormal basis for the full honeycomb system.32 The basis can be written as $| \{ W_q \}, \{ q \} \rangle$, where $\{ q \}$ lists the sites with non-zero bosonic occupation and the eigenvalues $\{ W_q \}$ determine the vortex sector. Note that to determine the structure of the state one still uses the effective operators $Q_q$ as the stabilizers with the eigenvalues reflecting the vorticity $\{ W_q \}$ through (9). In the special case where there are no broken dimers we have $| \{ W_q \}, \{ q \} \rangle \equiv | \{ Q_q \} \rangle$ with $W_q = Q_q$ for all $q$.

To specify a state on a torus we also give two additional quantum numbers associated with the holomorphically non-trivial loop symmetries. We can normally choose these to be the eigenvalues $l_0(x)$ and $l_0(y)$ of the independent operators $L_{0}^{(x)}$ and $L_{0}^{(y)}$ described above and the generic state in this case can be written as $| \{ W_q \}, l_0(x), l_0(y), \{ q \} \rangle$ where the list $\{ W_q \}$ contains $N_x N_y - 1$ independent $W_q$'s.

In the next section we will have cause to use a generalization of the expression (9) for products of plaquette operators. Of particular importance, because of the conventions...
used, will be the products arranged vertically on the effective lattice. We have in this case

$$X_{q_x,q_y} \equiv \prod_{q_y'=0}^{q_y-1} W_{q_x,q_y'}$$

$$= (I - 2N_{q_x,0})(I - 2N_{q_x,q_y}) \prod_{q_y'=0}^{q_y-1} Q_{q_x,q_y'}$$

and we see that only the bosonic occupation numbers at the upper and lower left corners of the plaquette product need to be taken into account.

**III. FERMIONIZATION**

We now show how to turn the hardcore bosons into fermions using a new Jordan-Wigner type transformation that is designed for this model and in particular for the basis $|\{W_q\},\{q\}\rangle$ described above. The procedure has a number of advantages over other fermionization techniques. For example, the method does not introduce additional un-physical degrees of freedom like the Majorana approach originally used to solve the problem, but still allows a transparent encoding of the vorticity within the fermionic Hamiltonian. In addition the procedure also reveals much more about the actual eigenstates of the system than previous fermionization methods. We will see for example, like Chen and Nussinov, that the ground-state of the system is a BCS type product acting on the vacuum. However, our vacuum will be exactly defined in terms of Toric Code stabilizers meaning that the eigenstates of the vacuum than previous fermionization methods. We will see for example, like Chen and Nussinov, that the ground-state of the system is a BCS type product acting on the vacuum. However, our vacuum will be exactly defined in terms of Toric Code stabilizers meaning that the eigenstates of the vacuum than previous fermionization methods. We will see for example, like Chen and Nussinov, that the ground-state of the system is a BCS type product acting on the vacuum. However, our vacuum will be exactly defined in terms of Toric Code stabilizers meaning that the eigenstates of the vacuum than previous fermionization methods.

The operators $S_q$ squares to unity while different operators $S_q, S'q$ anti-commute with each other. This leads us to identify the string $S_q$ with the following sum of fermionic creation and annihilation operators: $S_q = c_q^+ + c_q = (b_q^+ + b_q)^S$ where $S'q$ is simply the string $S_q$ but with the bosonic dependence of the end point $C$ removed, see TABLE I. Individually our fermionic canonical creation and annihilation operators are

$$c_q^+ = b_q^+ b_q'^+ \quad c_q = b_q b_q'^+$$

where the strings now insures that the operators $c_q^+$ and $c_q$ obey the canonical fermionic anti-commutator relations

$$\{c_q^+,c_q\} = \delta_{qq'}, \quad \{c_q^+,c_q^+\} = 0, \quad \{c_q,c_q^+\} = 0.$$

The operators $c_q^+$ and $c_q$ must both create/annihilate vortices at $-n_x$ and $-n_x - n_y$. We can therefore think of each fermion as being bound to a vortex pair at the origin. Remarkably, this vortex-pair can itself be thought of as a fermion and can even be moved without changing the energy of the system. Another interesting insight can be obtained by noting that the strings $S_q$, which we attach to the hard-core bosons to make them fermionic, change the eigenvalues of the $Q_q$ operators at $-n_x$, $-n_x - n_y$, $q$ and $q - n_y$. The creation of the $c_q^+$ fermions is thus reflected in the effective spins by the creation of two bound fermionic $e - m$ pairs. These associated states are structurally equivalent, up to the mapping $\mathbf{4}$, to the corresponding TC states.

**FIG. 2:** Bosonic and effective spin decomposition of the operator string $S$. B, (2) the turning point $B = (q_x,0)$, (3) the exclusive interval $BC$, and (4) the end point $C = (q_x,q_y)$, see FIG 2 and TABLE I.

| $S$ | $S_b \otimes S_b$ |
|-----|------------------|
| [A,B] | $\sigma^x\sigma^x\sigma^y - \tau^\parallel \otimes I - 2b^b$ |
| B | $\tau^\parallel \otimes I$ |
| (B,C) | $\tau^\parallel \otimes I$ |
| C | $\tau^\parallel \otimes b^b + b$ |

**TABLE I:** The string $S$ as four unique segments. While bosons are only created/destroyed at the endpoint $C$ of the string, the sites in the $[A,B]$ interval also have non-trivial bosonic dependence.

Explicitly we write

$$S_q \equiv \prod_{(q_x,q_y)} \prod_{(q_x,q_y-1)} \prod_{(q_x,q_y-2)} \prod_{(q_x,q_y-3)} \cdots \prod_{(1,0)} \prod_{(0,0)} \prod_{(0,0)} \cdots \prod_{(0,0)} \prod_{(0,0)} \cdots$$

Using the representation of $\mathbf{17,18,19}$ we can decompose $S_q$ into the effective spin and bosonic subspaces, i.e. $S = S_e \otimes S_b$. In this decomposition there are four different types of structures to observe on the effective lattice: (1) the line including the starting point $A$ up to, but not including, the turning point
FIG. 3: The Kitaev three body term in the effective-spin/hard-core boson and fermionic notation. On a torus the values of \(X\) and \(Y\) are as those for the basic two-body Hamiltonian described below, except for the terms \(P(q)\) and \(P(q)\) when \(q = N_y\).

If we invert (12) and substitute the relevant expressions into the Hamiltonian (8) we get
\[
H_0 = J_x \sum_q X_q (c_q^\dagger - c_q)(c_{q+n_x} + c_{q+n_y}) + J_y \sum_q Y_q (c_q^\dagger - c_q)(c_{q+n_y} + c_{q+n_y}) + J_z \sum_q (2c_q^\dagger c_q - I),
\]
(14)

where, in the plane, \(Y_q = I\) for all \(q\) and \(X_q\) is defined in (10). The fermionic representation of the perturbative term \(H_1\) is given in Fig. 3. We restrict the Hilbert space to the relevant vortex-configuration by replacing \(X_q\) by the eigenvalues \(X_q\) of that configuration. In the simplest case of the vortex free sector we have \(X_q = 1\) for all \(q\). This sector, because of a theorem by Lieb\(^\text{30}\) is known to contain the system ground-state and can be solved exactly in the thermodynamic limit by moving to the momentum representation with the Fourier transform
\[
c_q = M^{-1/2} \sum_k c_k e^{i k \cdot q}. \tag{15}
\]

After substitution into (14) and anti-symmetrization we have
\[
H = \sum_k \left[ \xi_k c_k^\dagger c_k + \frac{1}{2} (\Delta_k c_k^\dagger c_{-k}^\dagger + \Delta_k^* c_{-k} c_k) \right] - M J_z \tag{16}
\]
where
\[
\xi_k = \varepsilon_k - \mu \quad \Delta_k = \alpha_k + i \beta_k \tag{17}
\]
with
\[
\mu = -2 J_z \tag{19}
\]
\[
\varepsilon_k = 2 J_x \cos(k_x) + 2 J_y \cos(k_y) \tag{20}
\]
\[
\alpha_k = 4 \kappa (\sin(k_x) - \sin(k_y) - \sin(k_x - k_y)) \tag{21}
\]
\[
\beta_k = 2 J_x \sin(k_x) + 2 J_y \sin(k_y). \tag{22}
\]

where the extended Hamiltonian \(H_1\) is now fully contained within the \(\alpha_k\) term. The procedure also gives agreement with other fermionization techniques to analyse the extended model.\(^\text{31,32,33}\) We note in particular that the technique can be used to replicate the dispersion relations of \(E_k\) where the p-wave pairing can be tuned to have \(k_x + i k_y\) chiral symmetry thus allowing a direct link with the work of Read and Green\(^\text{26}\) and subsequent analysis\(^\text{30,31,32,33}\), relating the Pfaffian Quantum Hall states, p-wave superconductors and the Ising CFT model.

The Hamiltonian (16) is diagonalized by Bogoliubov transformation
\[
\gamma_k = u_k c_k - v_k c_{-k}^\dagger, \tag{23}
\]
where \(u_k\) and \(v_k\) satisfy \(|u_k|^2 + |v_k|^2 = 1\). We then have
\[
H = \sum_k E_k (\gamma_k^\dagger \gamma_k - I/2),
\]
with
\[
E_k = \sqrt{\xi_k^2 + |\Delta_k|^2} \tag{24}
\]
\[
u_k = \sqrt{1/2(1 + \xi_k/E_k)} \tag{25}
\]
The ground-state, annihilated by all \(\gamma_k\), and of energy \(E_{gs} = -\frac{1}{2} \int E_k d\kappa\), can be seen to be the BCS type state
\[
|gs\rangle = \prod_k (u_k + v_k c_{k}^\dagger c_{-k}^\dagger) | \{W_q\}, \{\emptyset\} \rangle. \tag{27}
\]

This expression is, to the best of our knowledge, the first closed form expression of the ground-state that does not require additional spectral projection. It is noteworthy because it combines two powerful wavefunction descriptors i.e. the BCS product and the Stabilizer formalism. In the expression, which is valid everywhere in the model’s parameter space, the fermionic vacuum is fixed to be the toric code ground-state. While this implies that any mechanism for switching between the Abelian and non-Abelian topological phases must
be contained exclusively within the BCS product, we should also recognize that the Abelian phase is $Z_2 \times Z_2$ because the fermionic vacuum is $Z_2 \times Z_2$ and not because of any mysterious property of the BCS product. To see this more clearly note that in the $A_x$ phase with $(J_x = 1, J_y = J_z = 0)$ we have $u_k \rightarrow 1$ and $u_k \rightarrow 0$ and the the ground-state of the full system $|gs\rangle \rightarrow |\{W_q\}, \{0\}\rangle \equiv |\{Q_q\}\rangle$, where $Q_q = 1$ and $W_q = 1$ for all $q$. This is of course what one expects from the perturbation theory, see for example 20,21.

IV. FERMIONIZATION ON A TORUS

The fermionization procedure above may be extended to systems that live on a torus. Going to the torus allows for the study of finite size systems without fixing boundary conditions. It also allows us to probe the topological order of the model’s A and B-phases directly. From the predictions of topological-QFT the ground-state degeneracy on a torus should be equal to the number of topological sectors, or quasiparticle types in the system. In the Abelian A-phase we should have a 4-fold degeneracy because we have $4$ distinct particle types: the trivial particle or vacuum, the $e$ particle, the $m$ particle, and the fermionic $e\cdot m$ composite, which as we have mentioned, corresponds to our $\gamma^G$ excitation. In the non-Abelian phase the theory predicts we have three distinct particle types with the distinction between $e$ and $m$ particle types no longer applicable. However, as far as we know, a direct analysis of the ground-state degeneracy in this phase has not been done. This may be because on the surface, it appears that the Read and Green’s analysis for $p$-wave superconductors in ref. 26 can be carried over directly to this model. However, we will show that this is not the case and that there are a number of subtle differences, the primary one being that our fermions do not preserve the gauge symmetries, i.e. the creation of a fermion changes the vorticity.

To proceed we first re-write the fermonic Hamiltonian as

$$H = \frac{1}{2} \sum_{q} \xi_{qq'} \begin{bmatrix} c^\dagger_q & c_q \end{bmatrix} \begin{bmatrix} \xi_{qq'} & \Delta_{qq'} \\ \Delta_{qq'} & \Delta_{qq'} \end{bmatrix} \begin{bmatrix} c^\dagger_{q'} \\ c_{q'} \end{bmatrix},$$

(28)

where for example with $H_0$ we have

$$\xi_{qq'} = 2J_x \delta_{q,q'} + J_x X_q \delta_{q,q'} \Delta_{qq'} + \delta_{n_x,q'} - \delta_{n_x,q'}$$

$$\Delta_{qq'} = J_x X_q \delta_{q,q'} \Delta_{qq'} + \delta_{n_x,q'} - \delta_{n_x,q'} + \delta_{n_x,q'}.$$  

(29)

and the non-zero entries of $H_1$ are given in FIG. 3. To specify the particular vortex configuration one, as before, replaces the operators $X_q$ and $Y_q$ by their eigenvalues in that configuration. On a torus, the $\xi$ and $\Delta$ given in (29) are modified to include the terms that connect both sides of the torus, i.e. the terms that connect the sites $(0, q_y)$ to $(N_x - 1, q_y)$ and $(q_x, 0)$ to $(q_x, N_y - 1)$. The values of $X_q$ and $Y_q$ in these terms depend on the arrangement of vortices and the quantum numbers $l_0(x)$ and $l_0(y)$ of the two independent homologically non-trivial loop symmetries $L_0^{(x)}$ and $L_0^{(y)}$ that run through the origin $(0, 0)$. The Hamiltonian for any sector on a torus can be now be generated by observing the following dependencies (see also FIG. 3):

$$X_{q_x,q_y} = \prod_{q_x=1}^{q_x-1} W_{q_x,q_y} (q_y \neq 0 \text{ and } q_x \neq N_x - 1)$$

$$X_{q_x,q_y} = 1 (q_y = 0 \text{ and } q_x \neq N_x - 1)$$

$$X_{q_x,q_y} = -l_0^{(x)} \prod_{q_y=0}^{q_y-1} W_{q_x,q_y} (q_y \neq 0 \text{ and } q_x = N_x - 1)$$

$$X_{q_x,q_y} = -l_0^{(x)} W_{q_x,q_y} (q_y = 0 \text{ and } q_x = N_x - 1)$$

(30)

$$Y_{q_x,q_y} = 1 (q_y \neq N_y - 1)$$

$$Y_{q_x,q_y} = -l_0^{(y)} (q_y = N_y - 1)$$

(31)

where $l_0^{(y)} = l_0^{(y)} \prod_{q_y=0}^{q_y-1} W_{q_x,q_y}. These values for $X_q$ and $Y_q$ can be used for the extended Hamiltonian $H_1$ shown pictorially in FIG. 3 except for $P(q)^{(5)}$ and $P(q)^{(6)}$ when $q_y = N_y - 1$. For $P(q)^{(5)}$, we have

$$X_{q_x,q_y} = l_0^{(y)} \prod_{q_y=0}^{q_y-1} W_{q_x,q_y} (q_y \neq N_x - 1)$$

$$X_{q_x,q_y} = l_0^{(y)} W_{q_x,q_y} (q_x = N_y - 1).$$

(32)

while for $P(q)^{(6)},$

$$X_{q_x,q_y} = l_0^{(x)} \prod_{q_x=1}^{q_x-1} W_{q_x,q_y} (q_x \neq N_x - 1)$$

$$X_{q_x,q_y} = l_0^{(x)} W_{q_x,q_y} (q_x = N_x - 1).$$

(33)

The system is diagonalized by solving the Bogoliubov-De Gennes eigenvalue problem

$$\begin{bmatrix} \xi & \Delta \\ \Delta^T & -\xi^T \end{bmatrix} = \begin{bmatrix} U & V^* \\ V & U^* \end{bmatrix} \begin{bmatrix} E & 0 \\ 0 & -E \end{bmatrix} \begin{bmatrix} U & V^* \end{bmatrix},$$

(34)

where the non-zero entries of the diagonal matrix $E_{nm} = E_n \delta_{nm}$ are the the quasi-particle excitation energies. The Bogoliubov-Valentin quasi-particle excitations are

$$\begin{bmatrix} \gamma^1, \ldots, \gamma^1 \gamma^1, \ldots, \gamma^M \end{bmatrix} = \begin{bmatrix} c^\dagger_1, \ldots, c^\dagger_M \end{bmatrix} \begin{bmatrix} U & V^* \end{bmatrix},$$

(35)

which after inversion and substitution into (28) give

$$H = \sum_{n=1}^{M} E_n (\gamma^\dagger_n \gamma_n - \frac{1}{2}).$$

(37)

A short review of the relevant theory of the eigenstates and eigenvalues of Hamiltonians obtained in this way, in particular the application of the Bloch-Messiah-Zumino theorem, is given in the appendix. Using the prescriptions described there we can calculate the eigenstates and energies in all vortex and homology sectors on tori containing a few thousand spins on a desktop computer. In the vortex free sector however, there
The allowed values of \( \theta_\alpha \) where the dispersion relation of size \( \pi \) is considerable advantage to be gained by working in the momentum representation. The Hamiltonian in this case can be written as

\[
H = \sum_{k_x, k_y} E_k (\gamma_{k_x}^+ \gamma_{k_y} - \frac{1}{2}),
\]

(38)

where the dispersion relation \( E_k \) is as given for the plane in [24]. The allowed values of \( k_\alpha \) in the various homology sectors on the torus are \( \theta_\alpha = 2\pi \frac{n_\alpha}{N_\alpha} \) for integer \( n_\alpha = 0, 1, \ldots, N_\alpha - 1 \), where the four topological sectors, \( (l_0^0, l_0^y) = (\pm 1, \pm 1) \), have values of \( \theta_\alpha \) given by \( \theta_\alpha = \left( \frac{l_0^x + 1}{2} \right) \frac{\pi}{N_\alpha} \). While it is simple to see that this expression is valid for the fully periodic sector with \( (l_0^x, l_0^y) = (1, -1) \), it is not so obvious how the general expression can be arrived at using the values for \( X_q \) and \( Y_q \) given above. One way to understand this jump is to imagine that the torus in question is doubled in period along the \( \alpha \) direction and the pattern of \( X \)'s and \( Y \)'s is repeated on the new part of the lattice, but with a \(-1\) phase. On this new lattice it is possible to define a fundamental domain of size \( N_x \times N_y \), such that all the values of \( X_q \) and \( Y_q \) are \(+1\). The periodic boundary conditions on the doubled torus now correspond to anti-periodic boundary conditions on the fundamental domain and we see that we can use the same dispersion relation as before, only with shifted momenta.

One would naively expect that the ground-states of the Hamiltonian be given by the four analogues of the planar ground-state [27] corresponding to the four ground-states of the toric code, and with energies \(-\frac{1}{2} \sum_k E_k \). These energies are not exactly equal for the four homology sectors on the torus, because the allowed momenta are different, but it is not difficult to see that, at least for the dispersion relations we have given, they approach each other rapidly as the system size is increased.

However, there are two situations where the true ground-state of a topological and vorticity sector on the torus may not be given by the BCS product. First of all, there is a connection between the number of vortices and the number of fermions on the torus. A configuration with an odd number of vortices of electric type can only exist if there are an odd number of broken dimers, i.e. an odd number of fermions. BCS products like eq. (27) have even fermion number parity and hence do not apply to vorticity sectors which have an odd number of electric (or in fact magnetic) vortices. Secondly, there are situations where the allowed momenta together with the values of \( u_k \) and \( v_k \) make the expression for the BCS product state vanish.

A particularly important example of this occurs in the vortex free sector with \( (l_0^x, l_0^y) = (1, -1) \). In the Abelian phase of the model, we can just use the BCS ground-state [27] as expected. However in the B-phase, we see that \( \Delta_{\pi,\pi} \) and \( \xi_{\pi,\pi}/\epsilon_{\pi,\pi} \) are \(-1\) implying that \( u_k = 0 \) and \( v_k \pi \). This cause the BCS state [27] to vanish because on a torus \( c_{\pi,\pi}^\dagger c_{\pi,\pi} = (c_{\pi,\pi}^\dagger)^2 = 0 \). It is important to note that this effect is not dependent on the B-phase being gapless, only requires that \( \xi_{\pi,\pi} \) is negative and \( \Delta_{\pi,\pi} = 0 \).

The vanishing of the BCS state is somewhat similar to what happens in Read and Green’s treatment of the spinless p-wave superconductor [28,29], but here, we cannot propose the expression in Eq. (A12) as an alternative because it has the wrong fermion number parity for the zero vortex sector. However, one sees that

\[
|\psi_{\pi,\pi}\rangle = \prod_{k, l \in (\pi, \pi)} (u_k + v_k c_{k-l}^\dagger c_{-k}) \{W_q\}_{l_0^x, l_0^y, \{0\}},
\]

(39)

with \( (l_0^x, l_0^y) = (1, -1) \) and \( Q_q = 1 \) for all \( q \), is an eigenstate with even fermion number, no vortex excitations and energy \(-\sum E_k / 2 + E_{\pi,\pi}\). As with the generic situation shown in the Appendix, all of the states \( |\psi_{k'}\rangle = \gamma_{\pi,\pi}^\dagger \gamma_{k'}^\dagger |\psi_{\pi,\pi}\rangle \) are also vortex-free eigenstates with energy \(-\sum E_k / 2 + E_{k'}\). The ground-state of the vortex free system in this topological sector is precisely the state in this family for which \( E_{k'} \) is minimal. If the system is gapped, then \( E_{k'} \) does not approach zero even in the thermodynamic limit, and the ground-state of \( (l_0^x, l_0^y) = (1, -1) \) is gapped away from the degenerate ground-states of the other three vortex free sectors.

Even more generally, we can say that if the B-phase is gapped and the conditions \( \xi_{\pi,\pi}/\epsilon_{\pi,\pi} = -1 \) and \( \Delta_{\pi,\pi} = 0 \) are fulfilled, the ground-state on a torus is three-fold degenerate, as expected from TQFT.
V. SUMMARY AND OUTLOOK

We have described a spin fermionization procedure for Kitaev’s honeycomb model and related spin models. Using this method we derived exact expressions for the ground-states and their associated eigenvalues. The derived ground-states are closed form expressions that do not require additional spectral projection. These expression combine two powerful wavefunction descriptors: the BCS product and the stabilizer formalism. The solution clarifies the nature of the topological phases of the model and the role the BCS product plays in determining them. It is clear now for example that the $\mathbb{Z}_2 \times \mathbb{Z}_2$ Abelian phase is determined from the fermionic vacuum, with the BCS product only adjusting this state slightly. As the vacuum is fixed and Abelian, the transition to the non-Abelian phase is therefore driven exclusively by the BCS product.

We also showed how to extend our fermionization procedure to handle general vortex configurations on a torus and we discussed how the additional constraints due to the interdependence of loop symmetries and fermions arise in the calculations. We closely examined the ground-state for the fully periodic vortex free sector, building on a more general discussion for arbitrary configurations given in the Appendix, and explained why the blocking mechanisms in the system dictate that the non-Abelian ground-state is three-fold degenerate, confirming the prediction from TQFT. We intend to use our fermionization to study degeneracies in systems with multiple anyonic excitations in the future and hope to elucidate the relation between the Abelian and non-Abelian anyons in the model.

While we have explicitly derived the relationship between the exact solution and the toric code ground-state we have not yet explored the relationship between the exact solution and its perturbative approximation. This now possible, at least in principle, as the BCS product and the Brillouin-Wigner perturbation expansion both start from the TC ground-state. At the very least, the comparison should reveal the precise determinants in the perturbative expansion and clarify how this expansion breaks down at the phase transition. More speculatively, it may also help to extend perturbative techniques beyond the phase transition. The ability to do so could provide a new perspective on the non-Abelian phase and would be extremely useful for other models which are not exactly solvable.

The results obtained on the torus highlight the connections between the blocking mechanisms, the ground-state degeneracy and the Abelian to non-Abelian phase transition. A more general analysis along these lines, which is not confined to a particular model would almost certainly be beneficial.

APPENDIX A: GROUND-STATE CONSTRUCTION

Here we review some of the relevant Hartree-Fock-Bogoliubov theory and discuss how to bring the ground-states of each vortex sector into a canonical form. We restrict ourselves, as in the main text, to situations where we have an even number of sites $M$ on the lattice, and therefore an even number of $\gamma^1$ excitations. For more details we refer the reader to ref. 43 on which much of the following is based.

The ground-state for a fermionic Hamiltonian $H$ can usually be written down as a Hartree-Fock-Bogoliubov (HFB) projection,

$$|gs\rangle = \prod_n \gamma_n |\text{vac}\rangle$$

(A1)

where the energy of this ground-state is $-\sum_n E_n/2$. However, sometimes the physical situation will demand that the ground-state has odd fermion number-parity $p$. In the honeycomb model for example the fermionic number parity is completely determined form the vortex configuration. Specifically we see that, because creating an e-m vortex pair excitation necessary means breaking a z-dimer, the fermionic number parity must be equal to the e-number parity and the m-number parity.

The procedure in this case is to redefine our choice of $\gamma^1$ and $\gamma$ such that the lowest energy odd parity state can be found. In practice we swap $\gamma^1_1 \leftrightarrow \gamma_1$ and then set $|gs\rangle_{odd} = \gamma_1 |gs\rangle$. This new state, annihilated by the annihilation operators, has odd fermion number parity but has energy $-\sum_n E_n/2 + E_1$ (Here our convention is to choose $E_1$ to be the smallest of the $E_i$).

While the above prescription handles a great many physical situations there are a number of reasons why it is not always sufficient. The first is simply that the method by which we construct the ground-state is projective and therefore in many cases the vacuum state is not uniquely defined. The second, and perhaps more important, is that physical situations do exist such that the calculated $\gamma$ fermions are such that $|gs\rangle$ and therefore $|gs\rangle_{odd}$ are already zero. A solution to both problems can be found by making use of the Bloch-Messiah-Zumino theorem 34,35.

In practice the theorem says that we can do a singular value decomposition of the $M \times M$ matrix $U$

$$U = D U C$$

(A2)

for unitary $C$ and $D$ such that the eigenvector matrix defining the $\gamma^1$ quasi-particle excitations, 35, can be decomposed into

$$\begin{pmatrix} U & V^* \\ V & U^* \end{pmatrix} = \begin{pmatrix} D & 0 \\ 0 & D^* \end{pmatrix} \begin{pmatrix} U & V \\ U & V \end{pmatrix} \begin{pmatrix} C & 0 \\ 0 & C^* \end{pmatrix}$$

(A3)

where $U$ and $V$ take block diagonal forms
where the ground-state, written in the canonical basis, is

$$|\text{gs}\rangle = \prod_{l} a_{l}^{\dagger} \prod_{k \neq l} (u_{k} + v_{k} a_{k}^{\dagger}) |\text{vac}\rangle,$$

(A12)

where the first product is over the $m$ occupied levels only and it is understood that all $u$'s in the second product are non-zero. The state is annihilated by all $\alpha_{k}$ and thus has an energy $-\sum_{n} E_{n}/2$. To see this first note that the state is annihilated by all $\alpha_{i}$ and then that each $\gamma_{l}$ is a linear superposition of these.

The fermion number-parity $p$ of the state is dictated by the number of occupied modes $m$. The appearance of an odd number of occupied modes implies that the final state is of different number parity to the vacuum. This is exactly the situation observed by Read and Green for the spinless $p$-wave superconductor on a torus. In the honeycomb lattice model on a torus, the situation is complicated slightly by the fact that the fermion number parity of an eigenstate is determined exclusively by the vortex configuration sector to which it belongs. This immediately implies that an odd (even) number of occupied modes is not allowed in a vortex sector with even (odd) e-number or m-number parity. When these situations occur we say that the state (A12) is blocked and we must re-arrange the eigenvector matrix, effectively switching the $\gamma_{i}^{\dagger}$ and $\gamma_{i}$, such that the eigenstate with the lowest energy is achieved. Below we discuss the four possible scenarios and describe how to construct the eigenstate in each case.

(A) Even $p$, Even $m$:

Here we may use (A12) with no modification. The ground-state energy is $E_{\text{min}} = -\sum_{n} E_{n}/2$. One encounters this situation in the vortex free sector in both the A-phase and the three partially/fully anti-periodic sectors of the B-phase.

(B) Even $p$, Odd $m$:

Here we also use (A12) but the singular value decomposition to calculate the $u$'s and $v$'s is performed after first switching columns $(U_{11}, V_{11}) \leftrightarrow (V_{11}^{\dagger}, U_{11}^{\dagger})$. Of course an initial singular value decomposition of the original $U$ matrix is first needed in order to determine the number of occupied modes $m$. The switching of columns of the matrix effectively changes an occupied mode for an empty one and the energy of the ground-state is therefore $E_{\text{min}} = -\sum_{n} E_{n}/2 + E_{1}$. We see that if the sector has even fermion parity and is gapped, an odd number of occupied modes $m$ implies a raising of the energy above what one might otherwise expect. We encounter this situation in the B-phase of the vortex-free sector with $(l_{0}^{(s)}, l_{0}^{(s)}) = (1, -1)$.

(C) Odd $p$, Even $m$:

This situation is again handled by switching occupied and empty modes $(U_{11}, V_{11}) \leftrightarrow (V_{11}^{\dagger}, U_{11}^{\dagger})$ and the energy of the ground-state is again $E_{\text{min}} = -\sum_{n} E_{n}/2 + E_{1}$. The vacuum in this case must be from the vortex sector such that the operation of the now odd number of $a_{k}^{\dagger}$'s gives the vortex and topological sector for which we calculated the $U$ and $V$ matrices.
(D) Odd \( p \), Odd \( m \).

The ground-state in this sector is given by \((A12)\) without modification and the ground-state energy is \(-\sum_n E_n/2\). Thus, if the sector is gapped, the energy of this ground-state is lower than what one might expect from an odd fermion number state. As in the previous case the vacuum must be defined so that operating with an odd number of \(a_i^\dagger\)'s gives the correct vortex and topological sector.

In all of the above situations, because the \(\gamma_i^\dagger\)'s do not com-
