Received 27 August 2010/Returned for modification 4 October 2010/Accepted 5 January 2011

The objective of this study was to observe early markers of cell-mediated immunity in naïve calves infected with *Mycobacterium avium* subsp. *paratuberculosis* and how expression of these markers evolved over the 12-month period of infection. Groups for experimental infection included control (noninfected), oral (infected orally with *M. avium* subsp. *paratuberculosis* strain K-10), oral/DXM (pretreatment with dexamethasone before oral inoculation), intraperitoneal (i.p.) inoculation, and oral/M (oral inoculation with mucosal scrapings from a cow with clinical disease) groups. One of the earliest markers to emerge was antigen-specific gamma interferon (IFN-γ). Only i.p. inoculated calves had detectable antigen-specific IFN-γ responses at 7 days, with responses of the other infection groups becoming detectable at 90 and 120 days. All infection groups maintained robust IFN-γ responses for the remainder of the study. At 1 month, calves in the oral and oral/M groups had higher antigen-stimulated interleukin-10 (IL-10) levels than calves in the other treatment groups, but IL-10 secretion declined by 12 months for all calves. T-cell activation markers such as CD25, CD26, CD45RO, and CD5 were significantly upregulated in infected calves compared to noninfected controls. Oral inoculation of calves resulted in significantly increased antigen-specific lymphocyte proliferation at 9 and 12 months, as well as inducible nitric oxide synthase (iNOS) secretion at 6 and 12 months. These results demonstrate that infection of naïve calves with *M. avium* subsp. *paratuberculosis* invoked early immunologic responses characterized by robust antigen-specific IFN-γ responses and induction of CD25 and CD45RO expression on T-cell subsets. These were followed by antigen-specific lymphocyte proliferation, iNOS secretion, and expression of CD26 and CD5°bright markers in the latter part of the 12-month study.

Deciphering host immune responses upon exposure to *Mycobacterium avium* subsp. *paratuberculosis*, differentiating the responses due to exposure from true infection, and then further characterizing responses at different stages of infection have been daunting and complex tasks that remain elusive. Early measures of host immune responses to infection with mycobacteria, including *M. avium* subsp. *paratuberculosis*, have been dominated by a strong bias toward Th1-mediated gamma interferon (IFN-γ) production. Higher levels of antigen-specific IFN-γ secreted by peripheral blood mononuclear cells (PBMCs) have been reported for animals in the early stages of *M. avium* subsp. *paratuberculosis* infection, whether it be natural or experimental infection (11, 18, 22, 24). Since IFN-γ is a key effector cytokine involved in the activation of T cells and macrophages, maturation of dendritic cells, upregulation of major histocompatibility complex (MHC) class I and II molecules, and production of reactive oxygen and nitrogen species by macrophages, it is purported to be not only an immune response variable but also a correlate of immune protection (7, 16). However, it is unlikely that the paradigm of host immune responses in the early stages of infection and subsequent resistance to infection is quite so simplistic. Rather, a complex coordination of immune responses is more probable, with these responses shifting as the host transitions through the different stages of infection and disease (subclinical to clinical).

Animal infection models are useful because they can provide a more insightful examination of responses of the naïve host to a singular pathogen. Two recent reviews summarized the efficacy of animal models for paratuberculosis in a wide range of species, including cattle, sheep, goats, deer and other wildlife, and rodents such as mice, rats, and rabbits (2, 8). The majority of experimental models for ruminants have utilized oral inoculation of live *Mycobacterium avium* subsp. *paratuberculosis* in order to establish infection, thereby mimicking the fecal-oral route of transmission generally observed in the field. Many of these studies utilized laboratory-adapted strains of *M. avium* subsp. *paratuberculosis* in the inocula, while a few studies demonstrated more effective results with clinical isolates of *M. avium* subsp. *paratuberculosis* (21, 23). Establishing a reproducible and effective challenge model for cattle, with well-defined host immune responses, is key to the interpretation of future work evaluating vaccines or therapeutics.

In the present study, we compared the effectiveness of oral suspensions of a clinical isolate of *M. avium* subsp. *paratuberculosis* and a low-passage laboratory strain. We further sought to evaluate the potential of dexamethasone (DXM) administration as an immunosuppressant to enhance infectivity in calves. Lastly, we adapted an intraperitoneal (i.p.) challenge model to neonatal calves and compared it to traditional oral inoculation methods. Although oral inoculation is the most favored mode of infection for *M. avium* subsp. *paratuberculosis* challenge models in ruminants, intraperitoneal inoculation has been used successfully in murine models (10). In addition,
recent studies that involved surgical intervention to introduce \textit{M. avium} subsp. \textit{paratuberculosis} directly into the ileum resulted in colonization of tissues both locally and systemically (1, 25). We desired to mimic this effect without surgery by inoculating \textit{M. avium} subsp. \textit{paratuberculosis} directly into the peritoneal cavity. In the present study, measurements of the host cell-mediated immune responses to \textit{M. avium} subsp. \textit{paratuberculosis} infection were performed to ascertain the nature and vigor of responses shortly after exposure and over a protracted infection period. The upregulation of these early response variables was correlated with the degree of infectivity in the calves, as determined by the number of positive tissue sites.

**MATERIALS AND METHODS**

**Animals.** Neonatal Holstein dairy calves were obtained from herds in Minnesota at 1 to 2 days of age. The farms were status level 4 herds enrolled in the Voluntary Bovine Johne’s Control Program, with no reportable incidence of Johne’s disease in the last 4 to 5 years and a 99% probability that they were free of paratuberculosis. Calves were housed in biosecurity level 2 containment barns for the duration of the study, with control calves housed in a barn separate from the experimentally infected animals. Calves were allowed to acclimate to their environment for 1 week prior to the initiation of the study. Standard commercial milk replacer (Land O’ Lakes, Shoreview, MN) was fed to calves twice per day at 10-h intervals during the acclimation and experimental infection periods. At 6 weeks of age, calves were weaned onto calf starter (Kent Feeds, Muscatine, IA) and then gradually switched over to a mixed pelleted ration for the remainder of the study. Blood and fecal samples were collected on 2 consecutive days prior to initiation of the study, followed by sampling on days 7, 14, and 28 and monthly thereafter for 12 months. All calves, regardless of inoculation route, were confirmed to be infected by culture of intestinal tissues and associated lymph nodes, as well as the spleen and liver, taken at necropsy (21).

**Experimental infection of calves.** At 1 week of age, calves were assigned to the following treatment groups: (i) control noninfected (control) group (n = 4), (ii) oral group (n = 4), (iii) oral/DXM group (n = 4), (iv) i.p. group (n = 4), and (v) oral-mucosal (oral/M) group (n = 3). On day 0 of the study, the oral group was fed milk replacer containing, on average, 1 x 10^11 live \textit{M. avium} subsp. \textit{paratuberculosis} organisms of low-pass-strain K-10, twice per day for 14 consecutive days. The oral/DXM group was treated similarly, except that the calves were administered 0.25 mg of DXM/kg of body weight (Axera; Schering Corp., Kenilworth, NJ) intravenously (i.v.) for 3 days prior to the first bacterial challenge on day 0 and then administered the same dosage of DXM on days 28 and 56 of the study. Intrapерitoneal inoculation of calves was performed on days 0, 7, 14, and 21 of the study. Inoculation of a 1-ml volume of \textit{M. avium} subsp. \textit{paratuberculosis} (10^11 bacteria) was performed through a 3-mm incision in the right flank of each calf with a 25-gauge needle containing sterile Anitserum (Bayer Animal Health, St. Joseph, MO) as previously described (21). Calves in the i.p. group were fed milk replacer twice per day without bacteria and were weaned onto solid diets at the same time points as calves in other treatment groups. The oral/M group calves were inoculated by being fed milk replacer containing 2.6 x 10^11 live \textit{M. avium} subsp. \textit{paratuberculosis} organisms obtained by scraping the ileal mucosa of a clinically infected cow. Calves were dosed on days 6, 7, and 14 of the study. All procedures performed on the animals were approved by the Institutional Animal Care and Use Committee of the National Animal Disease Center (NADC), Ames, IA.

**Bacteria.** As previously described (21), \textit{Mycobacterium avium} subsp. \textit{paratuberculosis} strain K-10 was used for the inoculums for the oral, oral/DXM, and i.p. treatment groups. Calves in the oral/M treatment group were administered a clinical isolate of \textit{M. avium} subsp. \textit{paratuberculosis} obtained by scraping the ileal mucosa of a naturally infected cow in end-stage disease (cow 509). Aliquots of the mucosa (20 g) were dispensed into 50-ml sterile conical tubes and either directly into the ileum (20 g) were dispensed into 50-ml sterile conical tubes and either

**PBS, followed by plating onto Herrold’s egg yolk medium (HEYM; BD) in duplicate and culturing for 12 weeks at 39°C. Total colony counts were performed for each dilution, and the average count obtained for the highest dilution showing viable \textit{M. avium} subsp. \textit{paratuberculosis} cells was used to calculate the final concentration of the stock bacteria. Counts of viable bacteria recovered on HEYM from the inoculum preparations (6 for strain K-10 and 3 for the clinical isolate) averaged between 1 x 10^9 and 1 x 10^11/ml for both the K-10 strain and the clinical isolate. Based upon average recovery of \textit{M. avium} subsp. \textit{paratuberculosis} by culture, approximate dosages of viable \textit{M. avium} subsp. \textit{paratuberculosis} during the study were 3.6 x 10^11 for oral and oral/DXM group calves, 4 x 10^11 for i.p. group calves, and 8 x 10^12 for oral/M group calves.

**Blood collection and culture conditions.** Blood was collected from the jugular vein in 2 x acid-citrate-dextrose (ACD; 1:10). For each animal, blood was collected on 2 consecutive days prior to initiation of the study, followed by sampling on days 7, 14, and 28 and monthly thereafter for 12 months. PBMCs were isolated from the buffy coat fractions of blood. PBMCs were resuspended in complete medium (RPMI-1640 [Gibco, Grand Island, NY] with 10% fetal calf serum [Atlanta Biologics, Atlanta, GA], 100 U of penicillin G sodium [Gibco] per ml, 100 mg of streptomycin sulfate [Gibco] per ml, 0.25 mg of amphotericin B [Gibco] per ml, and 2 mM L-glutamine [Gibco]). Cells were cultured at 2.0 x 10^7/ml in replicate 48-well flat-bottomed plates (Corning Incorporated, Corning, NY) at 37°C in 5% CO2 in a humidified atmosphere. Plates for each animal for each in vitro treatment. In vitro treatments consisted of no stimulation (NS; medium only), concanavalin A (ConA) (10 mg/ml; Sigma Chemical Co., St. Louis, MO), and a whole-cell sonicate of \textit{M. avium} subsp. \textit{paratuberculosis} (MPS; 10 mg/ml). After 24 h, one set of plates were removed and centrifuged at 400 x g for 5 min. Supernatants were removed without disturbing the cell pellet, and culture and were stored at -20°C prior to cytokine measurement. The replicate set of plates was incubated for 6 days, and cells were harvested for flow cytometric analyses.

**Cytokine and inducible nitric oxide synthase (iNOS) analyses.** Blood IFN-γ was measured by using a Bovigam test kit (Prionics, La Vista, NE) as described by the manufacturer. A standard curve was generated using recombinant bovine IFN-γ (3.12 to 100 ng/ml; Thermo Scientific, Rockford, IL). Bovine interleukin-10 (IL-10) was quantified by coating MaxiSorp microtiter plates (Nunc, Rochester, NY) with mouse anti-bovine IL-10 (MCA2110; Serotec, Raleigh, NC) in coating buffer (15 mM sodium carbonate, 34 mM sodium bicarbonate, pH 9.6; 100 µl per well at 2 µg/ml) overnight at room temperature (RT). Plates were washed 5 times with PBS containing 1% Tween 80 (washing buffer). The samples and serial 2-fold dilutions of a bovine IL-10 standard (0.3125 to 20 ng/ml) (a generous gift from Jayne Hope, Compton, United Kingdom) were added to duplicate wells and incubated at RT for 1 h. Plates were then washed 5 times with washing buffer before being incubated with the detection antibody, mouse anti-bovine IL-10-biotin (MCA2111B; Serotec, Raleigh, NC). Plates were washed 5 times with washing buffer, 100 µl of avidin-horseradish peroxidase (HRP) conjugate (diluted 1:800) (Pharmingen, San Diego, CA) was added to each well, and the plates were incubated for 45 min at RT. After another wash cycle, plates were incubated with substrate solution (40 mM ABTS [2,2′-azino-di(3-ethylbenzthioleozolino)]/H2O2, pH 4.8; 50 µl of substrate and 40 µl of 30 mM hydrogen peroxide as a 1:30 dilution). Color development was quantified after 30 min by measuring the absorbance at 405 nm with a Wallac Victor 1420 multilabel counter plate reader (Perkin-Elmer, Gaithersburg, MD).

To determine the amount of nitric oxide produced (NO), the stable oxidation product nitrite was quantitated. For this analysis, 24-h cell culture supernatants from NS and ConA and MPS-stimulated PBMCs were evaluated. The samples and serial 2-fold dilutions of sodium nitrate standard (0.028 to 18 µM) were added in duplicate to a 96-well round-bottom plate (Corning, Corning, NY). The culture supernatant (100 µl) was mixed with 100 µl of Greiss reagent (0.5% sulfanilamide; Sigma Chemical Co., St. Louis, MO) in 2.5% phosphoric acid (Mallinckrodt Chemical Inc., Hazelwood, MO) and 0.005% N-(1-naphthyl)ethylenediamine dihydrochloride (Sigma Chemical Co., St. Louis, MO). The mixture was allowed to incubate at RT for 10 min, and color development was measured at 505 nm. The concentration of nitrite in the supernatant was quantified by linear comparison with absorbance values of sodium nitrite standards within a linear curve fit.

**Lymphocyte blastogenesis.** Peripheral blood mononuclear cells were plated at a density of 2 x 10^5 cells/well in 96-well tissue culture plates in complete culture medium alone (NS) or containing 10 µg of ConA or MPS as described above. Plates were incubated for 72 h, and then [3H]thymidine (5 µCi/well) was added for an additional 18 h. Cells were harvested on filter mats by use of a Tomtec harvester (Tomtec, Orange, CT) and were counted on a Wallac 1450 Microbeta Plus liquid scintillation counter (Wallac, Gaithersburg, MD). Results are expressed in counts per minute (cpm).
Generally, the immune parameters measured. However, oral/M group calves did have more robust responses for some immune markers. However, due to the number of treatment groups and time points within the study, it was not possible to depict or discuss all of these data, and the focus here is primarily on antigen-specific responses. However, due to the number of treatment groups and time points within the study, it was not possible to depict or discuss all of these data, and the focus here is primarily on antigen-specific responses.

### RESULTS

Previously, our laboratory published data from this study demonstrating that the route of experimental inoculation with *M. avium* subsp. *paratuberculosis* (oral versus intraperitoneal) and the strain of *M. avium* subsp. *paratuberculosis* used for inoculation (laboratory strain versus clinical isolate) impacted the degree of tissue colonization over a 12-month infection period (21). In that paper, we reported that calves orally inoculated with a clinical isolate of *M. avium* subsp. *paratuberculosis* (oral/M group) had the largest number of positive tissue sites (15/22 sites), whereas i.p. group calves had the smallest (5/22 sites) (Table 2). For the most part, bacterial burdens within tissues were low, with the exception of 1 oral/M group calf who had a large number of *M. avium* subsp. *paratuberculosis* organisms. Interestingly, calves treated with dexamethasone prior to oral inoculation with *M. avium* subsp. *paratuberculosis* (oral/DXM group) had the largest numbers of tissues with lesions, followed by oral and oral/M group calves and, lastly, i.p. group calves. Since the degree of tissue pathology was fairly minor in this study, it did not appear to influence the immune parameters measured. However, oral/M group calves did have more robust responses for some immune mea-

**TABLE 2. Average numbers of tissues positive by culture and histopathology among tissues obtained from calves at necropsy 12 months following oral or intraperitoneal challenge with live *Mycobacterium avium* subsp. *paratuberculosis***

| Tissue† | % Positive tissues for treatment group (unless stated otherwise) |
|---------|---------------------------------------------------------------|
|         | Oral | i.p. | Oral/DXM | Oral/M |
| Jejunum + LN (proximal, mid-, and distal)a | 54 | 25 | 42 | 67 |
| Ileum + LN (proximal, mid-, and distal)a | 17 | 25 | 17 | 50 |
| Duodenum + LN | 50 | 50 | 38 | 50 |
| Ileocecal valve | 50 | 100 | 50 | 67 |
| Ileocecal LN | 25 | 50 | 0 | 33 |
| Spleen | 50 | 100 | 50 | 33 |
| Iliac LN | 75 | 50 | 50 | 33 |
| Spiral colon + LN | 63 | 25 | 38 | 50 |
| Descending colon + LN | 13 | 13 | 25 | 50 |
| Avg no. of positive tissue sites | 10.3 | 8.5 | 9.5 | 15 |
| Avg no. of tissues with lesions | 19 | 8 | 31 | 15 |

* The total number of tissue sites sampled per calf was 22.
† Three sections of the jejunum (proximal, mid-, and distal sections) plus three associated lymph nodes (n = 6) were sampled.
* Three sections of the ileum (proximal, mid-, and distal sections) plus one associated lymph node (n = 4) were sampled.
* Tissue + LN, the lymph node (LN) associated with that tissue site was also collected (n = 2 tissue sites).

---

**Flow cytometric analysis.** Briefly, 6-day culture plates were centrifuged at 1,500 rpm for 5 min, and the supernatant was decanted. Cells were gently resuspended in 300 µl of PBS (0.15 M, pH 7.4). In 96-well round-bottom plates (Corning Incorporated, Corning, NY), 50 µl of the cell suspension was added to wells containing 50 µl of primary monoclonal antibody (MAb) to CD4, CD8, γδ, CD25, CD26, CD5, or CD45RO (Table 1). All wells received 10 µg/ml of DAPI (4′,6-diamidino-2-phenylindole; Sigma) to differentiate live from dead cells and allow gating on viable cells. Cells were then incubated at 4°C for 30 min. After incubation, plates were centrifuged at 1,250 rpm for 2 min at 4°C and the supernatants were decanted, and cells were washed once with PBS and resuspended in 200 µl of medium (Caltag Laboratory, Burlingame, CA) for 15 min at room temperature in the dark. After incubation and one wash with PBS, cells were incubated with fixation buffer (4°C, 20 min). Supernatants were decanted, and cells were washed once with 200 µl of PBS. Cells were then incubated with 50 µl of secondary antibody (fluorescein-conjugated goat F(ab)2 anti-mouse IgG2a (Southern Biotech, Birmingham, AL), or peridinin-chlorophyll-protein complex-conjugated rat anti-mouse IgG1 (Becton Dickinson, San Jose, CA), diluted 1:312, 1:625, and 1:342, respectively, in PBS with 1% fetal calf serum and 0.04% sodium azide, was then added to designated wells, and the plate was centrifuged again at 1,250 rpm for 2 min at 4°C. The cells were then suspended in 200 µl of BD FacsLyse (BD Biosciences, San Jose, CA) for immediate flow cytometric analysis. Samples were evaluated using 30,000 events per sample on a FACSscan flow cytometer with Cell Quest software (Becton Dickinson). Analysis was conducted by gating on mononuclear cells, based on forward and side scatter characteristics (FlowJo; Tree Star, Inc., San Carlos, CA). The percentages of CD4-, CD8-, γδ-, CD25-, CD26-, CD45RO-, and CD5 bright-positive cells were determined and are presented for MPS-stimulated PBMCs. Marker expression was fairly consistent for NS and ConA-stimulated PBMCs, regardless of infection group, so these data are not presented.

For intracellular IFN-γ and IL-10 analyses, PBMCs were incubated as described above with medium only, ConA, or MPS for 18 h. Cells were then centrifuged at 1,250 rpm for 2 min. Intracellular cytokine staining was performed with a commercial kit (Caltag Laboratories, Burlingame, CA) following the manufacturer's protocol.
sures, suggesting that the degree of tissue infectivity had a demonstrable effect on host response.

A temporal analysis of secreted IFN-γ after stimulation of cells with medium alone (NS), ConA, or MPS is presented in Fig. 1. Secretion of IFN-γ was negligible for NS cultures at all time points, regardless of treatment group (Fig. 1A), whereas responses to ConA stimulation were robust for all treatment groups throughout the study (Fig. 1B). Early time points were
included within these analyses to demonstrate the rapidity of
PBMC responses to antigen stimulation. Infection of calves by
the i.p. route led to the earliest detection of antigen-specific
IFN-γ responses, with significantly more ($P < 0.01$) IFN-γ
secretion beginning on day 7 for i.p. group calves than for
control calves, an effect that continued throughout the 12-
month study (Fig. 1C). Responses for oral/M group calves
began to emerge by day 90 ($P < 0.01$), with other treatment
groups following this trend by day 180 and continuing to re-
main at this high level of responsiveness ($P < 0.01$) throughout
the study. Overall, a highly significant ($P < 0.01$) day effect was
noted for infected calves during the experimental period. As
expected, antigen-specific IFN-γ responses were negligible for
control calves.

Differences in intracellular IFN-γ within T-cell subpopu-
lations (CD4, CD8, and γδ T cells) due to
$M. \text{avium}$ subsp. $paratuberculosis$ infection were variable until 12 months (Fig.
2). Oral/M group calves had the most consistent ($P < 0.05$)
responses for all T-cell subsets. Increased ($P < 0.05$) intracel-

FIG. 2. Percentages of IFN-γ+ T cells among PBMCs isolated from
control noninfected calves and calves infected with
$Mycobacterium \text{avium}$ subsp. $paratuberculosis$ by the following methods: oral, intraperitoneal, oral
with dexamethasone administration, and oral with mucosal scrapings from a
cow with clinical disease. Percentages of IFN-γ+ T cells were determined at
12 months for CD4, CD8, and γδ T-cell subpopulations stimulated with a
whole-cell sonicate of $Mycobacterium \text{avium}$ subsp. $paratuberculosis$ (MPS).
Data are expressed as means ± SEM. Significant differences between control
and infection groups within the 12-month time point are represented by
asterisks ($*, P < 0.05$).

FIG. 3. Secretion of IL-10 (U/ml) at 1 month (A) and 12 months (B) by PBMCs isolated from control noninfected calves and calves infected with
$Mycobacterium \text{avium}$ subsp. $paratuberculosis$ by the following methods: oral, intraperitoneal, oral with dexamethasone administration, and oral with
mucosal scrapings from a cow with clinical disease. Note that the scales on the x axes in panels A and B are different. PBMCs were nonstimulated (NS)
or stimulated with ConA or a whole-cell sonicate of $Mycobacterium \text{avium}$ subsp. $paratuberculosis$ (MPS). Data are expressed as means ± SEM.
Significant differences between control and infection groups within given time points are represented by asterisks ($**, P < 0.01$; $*, P < 0.05$).
lular IFN-γ in CD4 and CD8 cells was also observed for oral/DXM group calves at 12 months, whereas it was decreased (P < 0.05) for oral and i.p. group calves.

Inoculating calves with a clinical isolate of M. avium subsp. paratuberculosis (oral/M group) invoked more (P < 0.01) IL-10 secretion than infection with the laboratory strain (Fig. 3). IL-10 secretion was more robust in the early time points of the 12-month study, with reductions of almost 90% between 1 and 12 months for most treatment groups, regardless of in vitro stimulant (Fig. 3). For the most part, intracellular IL-10 responses for infected calves were not different from those for controls during the study (Fig. 4). Although effects were noted for other infection groups, oral/M group calves had more consistent responses, with moderate increases in intracellular IL-10 noted at 6 months (data not shown) and significantly (P < 0.01) higher intracellular IL-10 for CD4, CD8, and γδ T cells at 12 months (Fig. 4). Interestingly, the trend for declining IL-10 observed for oral/M group calves paralleled the increase in antigen-specific IFN-γ responses between 1 and 12 months of the study (Fig. 5).

Secretion of iNOS by MPS-stimulated PBMCs was elevated for infected calves at 6 months compared to control calves, but this was significant only for oral/DXM group calves (Fig. 6). By 12 months, iNOS secretion was higher for all orally inoculated calves, but this was significant only for oral (P < 0.01) and oral/DXM (P < 0.05) group calves. Earlier time points did not yield any definitive effects due to infection, and therefore these data are not shown. Antigen-specific lymphocyte proliferation responses to MPS were not observed until day 270 and were significantly (P < 0.01) higher for oral, oral/DXM, and oral/M group calves than for control calves (Fig. 7C). By 360 days, proliferation responses had declined for oral/DXM group calves at 12 months (Fig. 4). Interestingly, the trend for declining IL-10 observed for oral/M group calves paralleled the increase in antigen-specific IFN-γ responses between 1 and 12 months of the study (Fig. 5).

Secretion of iNOS by MPS-stimulated PBMCs was elevated for infected calves at 6 months compared to control calves, but this was significant only for oral/DXM group calves (Fig. 6). By 12 months, iNOS secretion was higher for all orally inoculated calves, but this was significant only for oral (P < 0.01) and oral/DXM (P < 0.05) group calves. Earlier time points did not yield any definitive effects due to infection, and therefore these data are not shown. Antigen-specific lymphocyte proliferation responses to MPS were not observed until day 270 and were significantly (P < 0.01) higher for oral, oral/DXM, and oral/M group calves than for control calves (Fig. 7C). By 360 days, proliferation responses had declined for oral/DXM group calves at 12 months (Fig. 4). Interestingly, the trend for declining IL-10 observed for oral/M group calves paralleled the increase in antigen-specific IFN-γ responses between 1 and 12 months of the study (Fig. 5).
calves but continued to increase for oral, i.p., and oral/M group calves, with oral/M group calves having the highest ($P < 0.01$) responses to MPS.

An upregulation of CD25 expression on CD4, CD8, and γδ T-cell subpopulations in *M. avium* subsp. *paratuberculosis*-infected calves was observed by 1 month (Fig. 8A, B, and C). CD25 expression on CD4 T-cell subpopulations was significantly ($P < 0.01$) higher only for oral/M group calves at 1 month but was highly upregulated on CD8 and γδ T cells for other infection groups (Fig. 8A, B, and C). A similar pattern of upregulation of CD25 on CD4, CD8, and γδ T cells was observed for infected calves at 6 and 12 months, but expression had begun to decline at 12 months for i.p. group calves compared to other infection groups (Fig. 8). Expression of CD26 was also determined within T-cell subsets, but due to technical difficulty, the earliest reportable time point was 3 months (Fig. 9). At 3 months, expression of CD26 was relatively low (<20% of cells) but was consistently higher ($P < 0.01$) for i.p. group calves across all T-cell subsets. Following 6 months of infection, CD4 and CD26 expression was highly ($P < 0.05$) upregulated for all infected calves compared to controls. More robust CD26 responses were noted at 12 months, with consistent upregulation noted on CD4, CD8, and γδ T-cell subpopulations for oral, oral/DXM, and oral/M group calves but not i.p. group calves.

Expression of CD45RO on total PBMCs after stimulation with MPS also proved to be a useful marker of infection in calves at points as early as 1 month (Fig. 10A). Similar trends for upregulated CD45RO expression on MPS-stimulated PBMCs from infected calves compared to control calves were observed on other sampling dates as well (data not shown). The majority of these responses can be credited to a similar increase in expression of CD45RO on the γδ T-cell subpopulation (Fig. 10B), whereas variable responses were noted on CD4 and CD8 T cells (data not shown). Expression of the CD5$^{\text{bright}}$ marker was also upregulated on MPS-stimulated PBMCs from infected calves compared to control calves throughout the 12-month study (Fig. 11). The percentage of CD5$^{\text{bright}}$ cells in the total PBMC population increased over the period of the study, ranging from 2.7 to 18.2% at 1 month to 8.6 to 48.7% at 12 months. This increase in CD5$^{\text{bright}}$ expression on total PBMCs paralleled an increase in the CD4 subpopulation for infected calves (Fig. 11B). The upregulation of CD5$^{\text{bright}}$ on CD4 cells was most significant ($P < 0.01$) at 6 and 12 months.

**DISCUSSION**

The early acquisition of antigen-specific IFN-γ responses by calves in the present study clearly demonstrated the utility of using secreted IFN-γ as an indicator of infection with *M. avium* subsp. *paratuberculosis*. Antigen-specific IFN-γ responses were robust for all infected calves, regardless of treatment group, by 6 months of infection. This suggests that bacterial load is not a major factor in the elicitation of an IFN-γ response, since tissue infectivity was higher for oral/M group calves. Previously, it was demonstrated that antigen-specific IFN-γ responses could be useful to differentiate early (paucibacillary) and late (multibacillary) stages of paratuberculosis in older cows ranging from 3 to 9 years old (17). In the present study, calves were deemed infected if there was recovery of viable *M. avium* subsp. *paratuberculosis* from at least one tissue, and all calves fit this criterion, regardless of inoculation route (21). This did not allow the interpretation of IFN-γ responses after “exposure” of calves to *M. avium* subsp. *paratuberculosis* without actual infection, as it is thought that exposure may invoke similarly robust but more transient IFN-γ responses (5). The appearance of IFN-γ responses on day 7 for i.p. inoculated calves was surprising and suggests that a peripheral signal to *M. avium* subsp. *paratuberculosis* was stimulated appropriately through draining lymph nodes in the peritoneal cavity. Although there was no indication at the end of the 12-month study that i.p. group calves had greater colonization in the draining lymph nodes than calves in the other treatment groups, effects may have been transient. In addition, any impact due to potential differences in virulence between the K-10 strain and the clinical isolate of *M. avium* subsp. *paratuberculosis* used for the inoculums was not detected in the degree of IFN-γ responses between treatment groups. Overtly, there was no significant correlation between host
immune responses and tissue pathology in individual calves. A moderate correlation seemed apparent for IFN-γ responses, but since few calves had marked pathological lesions, it was difficult to discern if this effect was real.

An upregulation of intracellular IFN-γ within CD4+ T cells was shown previously for experimentally infected calves (24), but in the present study, it was also noteworthy for CD8+ T cells, suggesting that these subpopulations may be key responders for IFN-γ secretion in active *M. avium* subsp. *paratuberculosis* infection. Overall, intracellular
FIG. 8. Percentages of CD25⁺ T cells among PBMCs isolated from control noninfected calves and calves infected with *Mycobacterium avium* subsp. *paratuberculosis* by the following methods: oral, intraperitoneal, oral with dexamethasone administration, and oral with mucosal scrapings from a cow with clinical disease. Percentages of CD25⁺ T cells during the 12-month study were measured within CD4 (A), CD8 (B), and γδ (C) T-cell subpopulations stimulated with a whole-cell sonicate of *Mycobacterium avium* subsp. *paratuberculosis* (MPS). Data are expressed as means ± SEM. Significant differences between control and infection groups within given time points are represented by asterisks (**, *P < 0.01; *, *P < 0.05*).
FIG. 9. Percentages of CD26⁺ T cells among PBMCs isolated from control noninfected calves and calves infected with Mycobacterium avium subsp. paratuberculosis by the following methods: oral, intraperitoneal, oral with dexamethasone administration, and oral with mucosal scrapings from a cow with clinical disease. Percentages of CD26⁺ T cells during the 12-month study were measured within CD4 (A), CD8 (B), and γδ (C) T-cell subpopulations stimulated with a whole-cell sonicate of Mycobacterium avium subsp. paratuberculosis (MPS). Data are expressed as means ± SEM. Significant differences between control and infection groups within given time points are represented by asterisks (**, P < 0.01; *, P < 0.05).
IFN-γ did not appear to have tremendous value as an early indicator of M. avium subsp. paratuberculosis infection, as it was variable throughout the study.

An upregulation of antigen-specific iNOS has been associated with subclinical M. avium subsp. paratuberculosis infection in cattle (12), and iNOS was upregulated in infected calves in the latter part of the present study. As a product of activated macrophages, the iNOS response aligned itself with the robust IFN-γ responses noted for infected calves after 180 days, suggesting that these two markers may be induced to activate macrophages and control M. avium subsp. paratuberculosis replication within the host. A concurrent decline in IL-10 responses was noted for all calves by 12 months, including a lesser decline for control calves; however, the degree and the somewhat linear manner in which IL-10 declined for oral/M group calves suggest that this effect was due to the method of inoculation rather than to an age-related effect. During the transition from subclinical to a more advanced clinical state of paratuberculosis, a switch from Th1- to Th2-mediated immune responses, characterized by increased Th2 cytokines (IL-4 and IL-10), is generally noted (6, 11). Although IL-10 is known to inhibit IFN-γ production through a negative-feedback mechanism designed to limit proinflammatory tissue damage, conversely, IFN-γ is also an effective inhibitor of IL-10 (9). Interestingly, the paradigm demonstrating robust protracted IFN-γ responses and transient IL-10 responses in this study (Fig. 4) is paralleled for IFN-γ and IL-4 responses in calves infected with M. bovis (14).

Despite the fact that some nontraditional modes of experimental infection were attempted in this study, we were still skeptical that infected calves would transition to an advanced disease state within the 12-month period. Not surprisingly, all infected calves remained asymptomatic during the study, shedding very little M. avium subsp. paratuberculosis in their feces, and very small numbers of M. avium subsp. paratuberculosis were recovered from tissues at necropsy. Whether IFN-γ was a factor in the maintenance of the experimental calves in an asymptomatic state is unknown. Regardless, the cumulative results of increased antigen-specific IFN-γ, iNOS, and lymphocyte proliferative responses
suggest that T cells were highly activated, promoting subsequent activation of monocyte/macrophage populations.

This was further evidenced by the upregulation of activation markers on T-cell subsets after stimulation of cells with antigen. Increased expression of CD25, CD26, and CD45RO on CD4+ T cells has been demonstrated previously for naturally infected cattle and for experimentally infected calves (13, 19, 24), and this effect was repeated in this study. We also demonstrated a significant presence of CD4 CD5bright cells in infected calves, particularly toward the latter part of the study. Previously, we had shown that the CD5 activation marker was able to delineate between stages of disease in naturally infected cattle, with greater expression noted for subclinically infected cattle (20). In the present study, we also observed dominant populations of memory CD8 and γδ T cells, an effect that contrasted with those for other experimental *M. avium* subsp. *paratuberculosis* infection models (25). Overall, CD25 was the most prolific marker present on all T-cell subsets, with substantial upregulation in infected calves throughout the study. Although this could be indicative of regulatory T-cell populations, the fact that we observed declining antigen-specific IL-10 responses during the study indicates otherwise. In a recent study evaluating host immune responses for naturally infected sheep in different stages of disease, it was noted that sheep with paucibacillary disease had larger numbers of CD25 cells in the blood than asymptomatic sheep (culture positive and histopathology negative) and sheep with multibacillary disease (7a). This would align itself with the histopathologic results obtained for calves in the present study, as we were able to demonstrate lesions in all infection groups but not in all calves within each group. Perhaps the frequency of CD25 expression within CD4, CD8, and γδ T cells indicates a phenotype suggestive of an activated immune response that is helpful in limiting disease within the host but is disassociated from IL-10 responses.

It is interesting that we observed CD26 expression much later
in the study than CD25 expression and that this expression aligned itself most closely with CD4+ T cells. CD26 has a known function as an activation marker for T cells, B cells, NK cells, and macrophages but has also been cited as a maturation marker for T lymphocytes (4). Upon stimulation of Th1 and Th2 cell lines, it was demonstrated that CD26 expression was 3- to 6-fold higher on Th1 cells, which further correlated with higher intracellular IFN-γ levels (4). This association of CD26 expression with IFN-γ production was also noted for tissue biopsy specimens from patients with tuberculosis leprosy but not for those from patients with lepromatous leprosy, indicating that CD26 is a marker of early stages of M. leprae infection, much like the case reported here (15).

Another interesting note was the predominant expression of the CD45RO marker on the γδ T-cell subset, rather than the previously described CD4 marker. Although limited information is available for cattle, it appears that CD45RO is primarily a marker of antigen memory on CD4 and CD8 T cells and may act more like an activation marker on γδ T cells (3). Additionally, the γδ CD45RO+ cell population decreased over the study, an effect that is in agreement with a previous report that this phenotype is most notable in neonates and declines with age (3). In the present study, the experimental methods of infection resulted in an asymptomatic state, with tissues positive for M. avium subsp. paratuberculosis and lesions characteristic of granulomatous disease. Activation of host immune responses occurred in all infected calves, regardless of experimental route, but occurred more frequently in calves orally inoculated with M. avium subsp. paratuberculosis, with oral/M group calves maintaining the most comparable responses across CD4+, CD8+, and γδ T-cell subsets. Early immunologic responses included robust antigen-specific IFN-γ responses as well as induction of antigen-specific CD25 and CD45RO expression. In contrast, immune responses such as antigen-specific lymphocyte proliferation, iNOS secretion, and expression of CD26 and CD56bright markers were upregulated in the latter part of the 12-month study. These data indicate that introduction of naïve animals to M. avium subsp. paratuberculosis may invoke very specific markers of early immune responses that can potentially be used for diagnosis of infection. A clear statement of how host immunity was affected by the M. avium subsp. paratuberculosis burden within tissues cannot be made based upon this study alone. It is highly likely that even a short-term study of 12 months resulted in animals that were transiently infected and perhaps cleared the infection or were able to reduce the burden in specific tissues. This theory suggests that more intensive studies need to be performed to evaluate host immune responses and correlate them to temporal changes in tissue infectivity over a protracted experimental period.

ACKNOWLEDGMENTS

We thank Trudy Tatum, Tonia McNunn, Megan Parlett, and Margaret Walker for their excellent technical assistance, as well as Paul Amundson and Jerri Grove for their excellent care of the animals in this study. This study was supported by a USDA-NRICAP (Johne’s Disease Integrated Program) grant.
