Near-field engineering for boosting the photoelectrochemical activity to a modal strong coupling structure†

Yanfeng Cao, Xu Shi, Tomoya Oshikiri, Shuai Zu, Yuji Sunaba, Keiji Sasaki and Hiroaki Misawa

Near-field engineering is considered a significant strategy in constructing plasmonic nanostructures for efficient plasmonic chemistry. We demonstrate interfacial near-field engineering on a Au-NP/TiO2/Au-film (ATA) photoanode to improve the water oxidation efficiency. To tailor the near-field distribution, postdeposited Au on an ATA electrode (Au@ATA) is implemented using a facile constant potential electrolysis technique. As a result, the average photocurrent conversion efficiency of Au@ATA is approximately 1.3-fold higher than that of ATA.

Ultrahigh near-field enhancement is one of the most important properties in metallic nanostructures under the excitation of localized surface plasmon resonance (LSPR) and is widely demonstrated to play a crucial role in plasmonic chemical reactions. Especially in plasmonic electrochemical reactions, plasmon-induced electron transfer is known to enhance the visible light photoresponse of plasmonic metal nanoparticles deposited on typical n-type semiconductor electrodes. For the mechanism of electron transfer, it is considered that the hot electrons generated by the LSPR excitation transfer to the conduction band of the semiconductor, and the holes are captured in the surface states of the semiconductor and participate in the oxidation reaction. Because plasmon-induced hot-electron generation is strongly related to the nanoscale localization of the electromagnetic field near the metallic nanostructure, near-field engineering of the metallic nanostructures towards a strong and targeted near-field enhancement is very significant for photochemical and photocatalytic applications in which hot electrons play an important role.

To date, many studies have focused on evaluating Au-NP/TiO2 systems because of their unique properties, such as plasmon-enhanced photocurrent generation and photocatalytic reactions in the visible region. Recently, we reported a photoanode constructed with Au-NP/TiO2/Au-film (ATA), which shows enhanced water oxidation quantum efficiency due to modal strong coupling between the Fabry–Pérot nanocavity mode of TiO2/Au-film and LSPR of Au-NPs. In the ATA structure, Au-NPs are partially inlaid 7 nm inside TiO2 thin film to increase the interaction between LSPR and the nanocavity. According to a finite element method (FEM) simulation, the hot spot of the near-field enhancement is located at the bottom interface of Au-NPs embedded into TiO2 (see Fig. 1), indicating that hot electrons/holes are generated and separated at the inlaid interface of Au-NPs/TiO2 inside TiO2. For the photochemical reaction, the holes must migrate to the surface of TiO2 to drive the water oxidation reaction. This migration process of holes has an adverse effect on the photochemical reaction because of the increase in possible recombination with electrons. Therefore, a strategy of near-field engineering to create a strong near-field enhancement near the interface of the three-phase boundary between Au-NPs, TiO2 and aqueous solution is in high demand for improving the water oxidation efficiency of the ATA structure.

Morphology modulation is an efficient way to engineer the near-field spatial distribution on metallic nanostructures. Herein, we demonstrate a modulated ATA structure with electrochemically postdeposited Au, denoted as Au@ATA, in which the original Au-NPs are embraced by the postdeposited Au. The Au-NPs are partially inlaid in TiO2, which contributes to a strong light absorption similar to that of the original ATA structure. The postdeposited Au creates an interface between itself and TiO2 and thereby engineers the near-field spatial distribution on the surface of TiO2. Both parts should be indispensable to achieve high photoelectrochemical performances. The essential point of the morphology modulation is to selectively induce the near-field enhancement to the position near the three-phase boundary that is preferable for the water oxidation reaction.

Based on this concept, we first performed near-field simulations for the ideal models of ATA and Au@ATA structures.

solution when the postdeposited Au creates an interface with other shapes of the postdeposited Au, as presented in Fig. S1e, of Au@ATA, we also performed the near-field simulations using magnitude larger than that of Fig. 1c. Besides the ideal model the maximum of the scale bar of Fig. 1f being two orders of clearly apparent in Fig. 1e. Fig. 1f shows a more obvious near-field distribution under 650 nm irradiation calculated using an FEM simulation. Two near-field profile monitors were set in the xz- and xy-planes to visualize the near-field intensity, as shown by the blue and red dashed lines. (a) Simulation model, (b) side view (xz-plane), obtained by magnifying part of (a), and (c) top view (xy-plane) of ATA structures; (d) simulation model, (e) side view (xz-plane), obtained by magnifying part of (d), and (f) top view (xy-plane) of Au@ATA. The simulations were performed with a circularly polarized plane-wave light source in water.

Fig. 1 shows the side views and top views of the near-field distributions of ATA and Au@ATA under irradiation of 650 nm as simulated by a commercial finite element solver (COMSOL Multiphysics®), in which $E$ denotes the electric field amplitude. As shown in Fig. 1b and c, optical near fields with relatively high intensity are observed only at the Au-NP/TiO$_2$ boundary inside TiO$_2$. In contrast, for the Au@ATA structures, in addition to the strong near-field enhancement at the Au-NP/TiO$_2$ boundary inside TiO$_2$, a remarkable high-intensity near field at the edge of the interface between postdeposited Au and TiO$_2$ is clearly apparent in Fig. 1e. Fig. 1f shows a more obvious near-field enhancement at the edge of the postdeposited Au despite the maximum of the scale bar of Fig. 1f being two orders of magnitude larger than that of Fig. 1c. Besides the ideal model of Au@ATA, we also performed the near-field simulations using other shapes of the postdeposited Au, as presented in Fig. S1e, f, h and i (ESI†). All the simulation results suggest that the postdeposited Au can effectively tailor the near-field intensity near the three-phase boundary of postdeposited Au, TiO$_2$ and solution when the postdeposited Au creates an interface with the TiO$_2$ even the Au structure shows an anisotropic shape. In contrast, near-field distribution does not change dramatically when the postdeposited Au just propagate on Au-NPs in z-direction (Fig. S1k and l, ESI†). This strong near-field enhancement at the interface of the postdeposited Au and TiO$_2$ near the three-phase boundary is therefore expected to become primarily responsible for the efficient photochemical reaction.

According to the simulation results, we used a facile constant potential electrolysis (CPE) technique to postdeposit Au on an ATA electrode (Fig. S2, ESI†). The surface morphologies of ATA and Au@ATA were characterized via scanning electron microscopy (SEM). Fig. 2b–e displays typical top-view SEM images of ATA and Au@ATA structures with different reaction times. As displayed in Fig. S3a and c (ESI†), the average particle size of Au-NPs on ATA was estimated as 10 ± 6.7 nm. The surface morphology of ATA with an inlaid depth of 7 nm is shown in Fig. 2b. After electrodepositing Au on the ATA structure, as shown in Fig. 2c–e, the size of Au-NPs grew larger with increasing deposition time, indicating that the CPE method is successful and essential for electrodepositing Au. According to heterogeneous nucleation theory, the original Au-NPs on ATA structure can work as active centres to decrease the free energy of Au nucleating from the precursor solution, and the postdeposited Au prefers to be deposited on the original Au-NPs of the ATA structure. After appropriate deposition time such as 3 min, the postdeposited Au contact with the TiO$_2$ surface. When the deposition time increased, the oversized Au nanostructure merges to neighbouring Au-NPs, and the more prominent anisotropic structure is formed. In addition, according to the particle number distributions calculated using SEM images shown in Fig. S4 (ESI†), the total number of Au-NPs on the ATA structure decreased after postdepositing Au. The faradaic efficiency was calculated as 82.4% from number of postdeposited Au atoms obtained from Fig. S4 (ESI†) and the amount of electric charge obtained in Fig. S5 (ESI†), indicating that the reductive current is consumed for the postdeposition of Au on the original Au-NPs.

To observe the cross-section, characterization using scanning transmission electron microscopy (STEM) was performed, as shown in Fig. 2f and g. Before the postdeposition of Au, the Au-NP was partially inlaid as reported. After the postdeposition, the particle size of Au-NP was specifically increased on the top part of Au-NP, suggesting new Au was deposited on the original Au-NP. The energy-dispersive X-ray spectrometry (EDX) mapping in Fig. 2h and i further revealed the spatial configuration of Au-NPs and TiO$_2$ layer. Fig. 2i clearly indicates that the postdeposited Au closely touches on the TiO$_2$ surface and creates an interface. From a control experiment of depositing Pt on ATA using a similar CPE method (see Fig. S6, ESI†), we further determined that the postdeposited metal (Pt, Au) was intimately assembled on top of Au-NPs that were exposed to the aqueous
of TiO$_2$ was 28 nm. (b and c) are absorption spectra of ATA and Au@ATA structures, respectively, with various TiO$_2$ thin-film thicknesses. (d and e) are absorption spectra were obtained by measuring the transmittance $T$ and reflectance $R$ and calculating $-\log(T + R)$ as a function of wavelength. For all samples, absorption at wavelengths shorter than 500 nm can be primarily assigned to the interband transition of Au. At wavelengths longer than 550 nm, distinct dual bands were apparently observed, corresponding to the strong coupling-induced energy-level splitting into upper and lower modes. Additionally, the dual bands were almost maintained with increasing electrodeposition time of Au on the ATA structure. The absorption spectra were well reproduced using the peak fittings with three components (Fig. S7a, ESI$^\dagger$). The two components correspond to the upper and lower energy modes. The third component was also observed, which was considered to be the uncoupled Fabry–Pérot cavity mode, as reported.$^{11}$ Also, all absorption spectra with different deposition time were plotted together for better comparison in Fig. S7b, ESI.$^\dagger$ With increasing the deposition time, both absorption peaks of upper and lower modes shifted blue and the absorption intensity of lower energy mode decreased. The spectral changes are explained by the blue-shift of the LSPR band of Au-NPs due to the reduction of the inlaid ratio of Au nanostructure by high-refractive-index TiO$_2$ (Fig. S7c, ESI$^\dagger$).

To further understand the strong coupling properties of the ATA and Au@ATA structures, we fabricated ATA and Au@ATA structures with different TiO$_2$ thicknesses (19–44 nm) and then measured their absorption spectra (Fig. 3b and c). For the ATA structure, the inlaid depth of Au-NPs was maintained at 7 nm. When the TiO$_2$ thickness was thinner than 23 nm in both ATA and Au@ATA, the upper branch of the splitting absorption band was mainly affected by the interband transition of Au. As displayed in Fig. 3b, distinct dual bands were apparently observed at wavelengths longer than 550 nm, while the dual bands gradually disappeared and finally turned into an uncoupled LSPR band when the TiO$_2$ thickness was greater.$^{7}$ Nevertheless, after postdepositing Au on ATA structures, distinct dual bands were still apparently observed at wavelengths longer than 550 nm (Fig. 3c). The dispersion curves obtained by plotting the peak energy of the absorption spectra as a function of the energy of the cavity resonances are exhibited in Fig. 3d and e. The cavity resonance energies were obtained using the peak separation based on a Lorentz fitting because the cavity modes overlap the interband transition of Au occurring at wavelengths shorter than 500 nm. Using a coupled harmonic oscillator model,$^{7}$ the splitting energies of ATA and Au@ATA were calculated to be 340 $\pm$ 28 meV and 310 $\pm$ 30 meV, respectively. Because the splitting energies of Au@ATA and ATA are very close, the strong coupling behaviour of Au@ATA is considered similar to that of ATA structures.$^{7}$

Photoelectrochemical measurements were performed using a three-electrode system to evaluate the light-energy conversion efficiency (IPCE) action spectra of ATA and Au@ATA. The IPCE spectra were well reproduced using the peak fittings with two components, which correspond to the upper and lower energy modes (Fig. S8b, ESI$^\dagger$). Also, all IPCE action spectra with different deposition time were plotted together for better comparison in Fig. S8c, ESI.$^\dagger$ After postdepositing Au on the ATA structures, the IPCE of Au@ATA in the wavelength region of 500–900 nm gradually increased as the deposition time increased up to 3 min. Interestingly, the maximum IPCE value of Au@ATA with a 3 min deposition reaches to approximately 2.5%. To study the possible mechanism underlying the IPCE enhancement of Au@ATA, we first considered the size effect of Au-NPs. After postdeposition, the average size of Au-NPs increases from 10 nm on ATA to 12 nm on Au@ATA. From the control experiment using ATA with large Au-NPs, as shown in Fig. S9, (ESI$^\dagger$), we concluded that the size increase is not the main contribution to the IPCE enhancement. Because photocurrent generation at wavelengths longer than 500 nm can be attributed to plasmon-induced charge separation at the Au-NP/TiO$_2$ interface,$^6$ the three-phase boundary between Au-NPs, TiO$_2$ and aqueous solution plays an important role in the

On the original Au-NPs of ATA. The near-field enhancement at the interface of postdeposited Au and TiO₂ is crucial for boosting the photoelectrochemical activity. By comparing the photoelectrochemical activity of the Au@ATA electrode to that from ATA, an up to 1.3-fold higher average photocurrent conversion efficiency was observed from 500 nm to 900 nm. As a consequence, we can anticipate that this facile near-field engineering will lead to the development of more sophisticated photochemical systems, which can highly enhance the quantum yield of photochemical reactions, such as water splitting and carbon dioxide reduction. This work provides a facile and applicable approach to the further design of low-cost, feasible and prominent plasmon-enhanced energy conversion devices.
