(Dated: March 30, 2022)

Gamma-ray production cross sections have been measured for gamma-ray lines copiously emitted in the $^3$He bombardment of $^{16}$O nuclei: the 937, 1042 and 1081 keV lines of $^{18}$F and the 1887 keV line of $^{18}$Ne. Four Ge detectors with BGO shielding for Compton suppression were used to measure the angular distributions of the gamma-rays. The excitation functions have been obtained for $^3$He bombarding energies from 3.7 to 36 MeV. Total cross sections are tabulated for calculations relevant to gamma-ray astronomy. The importance of these lines as diagnosis for the presence and properties of accelerated $^3$He in solar flares is discussed in light of the measured cross sections.

PACS numbers: 25.20.Lj, 25.55.-e, 96.60.Rd, 96.40.Fg

I. INTRODUCTION

Solar flares have been historically divided into two classes, impulsive and gradual, based on the time duration of their soft X-ray emission (see [1]). They are, however, also well characterized by the abundances of the energetic particles accelerated in these events and detected in the interplanetary space. In particular, impulsive flares are generally associated with enormous enhancements of accelerated $^3$He: the measured $^3$He/$^4$He abundance ratios are frequently 3–4 orders of magnitude larger than the corresponding value in the solar corona and solar wind where $^3$He/$^4$He~5×10$^{-4}$ (see [2]). These solar energetic particle events have been the subject of many experimental and theoretical investigations aiming at the identification of the resonant acceleration mechanism causing the $^3$He enrichments (see [3] and references therein).

Independent information on the accelerated particle composition and energy spectrum, as well as on solar ambient abundances, density and temperature, can be obtained from observations of the gamma-ray line emission produced by nuclear interactions of the energetic particles with the solar atmosphere (see [4]). The recent launch of the RHESSI satellite offers, in particular, the possibility of high-resolution spectroscopic analyses of this emission [5]. Mandzhavidze et al. [6] pointed out that the reaction $^{16}$O$(^3$He,$p$)$^{18}$F$^*$ leads to strong line emission at 937, 1042 and 1081 keV, which can be used as diagnosis for the presence and properties of accelerated $^3$He. The 937 keV line, as well as a significant line feature at ~1.02 MeV have already been identified in data of the moderate-resolution gamma-ray spectrometers SMM/GRS and CGRO/OSSE [7]. Analysis of these detections suggested that the flare-averaged $^3$He/$^4$He abundance ratio could be ~0.1 and that in some flares $^3$He/$^4$He~1 [8,9]. However, these analyses were based on gamma-ray production cross sections evaluated from partial laboratory data (see [10]): excitation functions for the production of the 937, 1042 and 1081 keV lines from the reaction $^{16}$O$(^3$He,$p$)$^{18}$F$^*$ were measured for laboratory $^3$He energies ranging from 2.6 to 4 MeV only [10]; at higher energies, the gamma-ray cross sections were estimated from data on $^{18}$F total production, obtained through the detection of the $\beta^+$ decays of this isotope ($T_{1/2}$=109.77 m).

We have measured the cross sections for the production of the 937, 1042 and 1081 keV lines in $^3$He+$^{16}$O reactions, for 40 $^3$He energies ranging from 3.7 to 36 MeV. In addition, we have considered the production of the 1887 keV line from deexcitation of the first excited state of $^{18}$Ne, which is populated by the reaction $^{16}$O$(^3$He,n)$^{18}$Ne. Indeed, we suggest that the detection in solar flares of this relatively strong line could allow one to obtain valuable information on the energy spectrum of the accelerated $^3$He, by comparing its intensity to that of the 937 keV line. This is discussed in section IV, together with the overall relevance of these measurements for gamma-ray spectroscopy of solar flares. The experiment and the data analysis are described in sections II and III, respectively.

II. EXPERIMENTAL PROCEDURE

The experiment was performed at the Tandem accelerator of the IPN-Orsay. Together with the cross sections for gamma-ray production from $^3$He+$^{16}$O reactions, we studied in the same experiment the reaction $^{24}$Mg$(^3$He,$p$)$^{26}$Al, which is relevant to the production of $^{26}$Al in the early solar system [11]. The $^3$He-induced reactions on $^{16}$O and $^{24}$Mg were successively studied at each beam energy by means of a multiple target holder, which was shifted in the vertical direction with a geared engine.
FIG. 1: Observed gamma-ray spectra with the Ge detector at $\theta_{lab}=90^\circ$ for $^3$He-particle bombardments at $E_{beam}=4.75$ and 9 MeV of the tantalum-oxide target of 800 $\mu$g/cm$^2$ evaporated on a carbon foil of 90 $\mu$g/cm$^2$. Most of the lines arise from $^3$He-induced reactions on $^{16}$O and $^{12}$C target nuclei (see text). The most intense of these lines are labelled with their nominal energies and the excited nuclei from which the gamma-rays are emitted. Almost all of the unlabelled weak lines between 250 and 4000 keV are due to cascade transitions following the $^{16}$O($^3$He,$p$)$^{18}$F$^*$ and $^{12}$C($^3$He,$p$)$^{14}$N$^*$ reactions. The strong 511 keV line mainly arises from the $\beta^+$ decay of the $^{11}$C, $^{15}$O, $^{18}$F, $^{18}$Ne and $^{18}$O ground states. The background line at 1461 keV arises from the decay of ambient $^{40}$K ($T_{1/2}=1.3\times10^9$ y). The width of this line, 3.5 keV full width at half maximum, reflects the energy resolution of the detector. The line at 1779 keV is due to deexcitation of the first excited state of $^{28}$Si and is believed to arise from secondary-particle interactions in the aluminum walls of the reaction chamber.

remote-controlled from the data acquisition room. For each $^3$He energy, the beam position and spot size were first controlled optically with an alumina foil mounted on the target holder. Then, the magnesium- and oxygen-containing targets were successively placed in the beam. The gamma-ray production cross sections were measured for 40 beam energies, in small steps of 250 to 500 keV from 3.7 to 15 MeV and at 18, 20, 21, 25, 30 and 36 MeV. The beam current was integrated in a Faraday cup located 1.4 m behind the target. Typical beam intensities were 10-20 nA.

Several target foils were used for the $^3$He+$^{16}$O measurements. From $E_{beam}=3.7$ to 7.25 MeV and at 9 and 10 MeV, we used a tantalum-oxide target (chemical composition Ta$_2$O$_5$) of 800 $\mu$g/cm$^2$ evaporated on a carbon foil backing of 90 $\mu$g/cm$^2$. Above 7.25 MeV, we essentially used two Ta$_2$O$_5$ targets of 1.5 mg/cm$^2$ evaporated on carbon foils of 130 $\mu$g/cm$^2$, as well as two self-supporting Mylar foils (chemical composition C$_{10}$H$_8$O$_4$) of 3.213 mg/cm$^2$ (23 $\mu$m) for $E_{beam}=12.5, 18, 21, 25, 30$ and 36 MeV. The thicknesses of the Ta$_2$O$_5$ targets were chosen for the $^3$He energy loss in the targets to be similar to the beam energy steps of 250 keV below 10 MeV, in order to avoid significant gaps in the excitation functions. The reason of using Mylar targets instead of Ta$_2$O$_5$ targets at the highest energies was to avoid a too intense production of neutrons and gamma-rays from reactions with the Ta nuclei. Repeated measurements at the same energies allowed to ensure the stability of the various targets. After the experiment, the thickness of one of the Ta$_2$O$_5$ targets was checked by a Rutherford backscattering measurement performed at the ARAMIS accelerator.
The gamma-rays were detected with four large volume, high purity Ge detectors with BGO shielding for Compton suppression. The four detectors were placed horizontally in front of 2 mm-thick aluminum-windows of the reaction chamber and at the laboratory angles $\theta_{lab}=90^\circ$, 112.5$^\circ$, 135$^\circ$ and 157.5$^\circ$ with respect to the beam direction. The Ge crystals were located at about 37 cm far from the target. The detection efficiencies were measured at three different times by placing at the target position four radioactive sources calibrated in activities to 1.5%: $^{60}$Co, $^{88}$Y, $^{137}$Cs and $^{152}$Eu. These sources provide a dozen of gamma-ray lines of relatively high intensities from 122 to 1836 keV. The uncertainties in the absolute efficiencies were determined from these three measurements to be $\pm 7\%$ for the detectors at 112.5$^\circ$, 135$^\circ$ and 157.5$^\circ$, and $\pm 15\%$ for the detector at 90$^\circ$ due to an additional absorption of the gamma-rays in the target holder. The efficiencies at 1333 keV ($^{60}$Co) were $(1.67\pm0.25)\times10^{-4}$, $(2.28\pm0.16)\times10^{-4}$, $(1.90\pm0.13)\times10^{-4}$ and $(1.97\pm0.14)\times10^{-4}$, for the detectors at 90$^\circ$, 112.5$^\circ$, 135$^\circ$ and 157.5$^\circ$, respectively.

Conventional electronic and computing techniques were used to translate the detector output signals into pulse height spectra. The dead time of the system was precisely determined with a set of pulsers which were fed into the Ge detector preamplifiers and into a scaler that was triggered by the data acquisition system. We assessed an error of $\pm 3\%$ in the dead-time correction, which was $\sim 20\%$ for most of the measurements, but as high as $\sim 60\%$ for the highest beam energies.

Sample gamma-ray spectra are shown in Fig. 1 for the $^{12}$C($^{3}$He,$p\gamma$) target of 800 $\mu g/cm^{2}$ on the carbon backing. We see a variety of lines produced by $^{3}$He-induced reactions on $^{16}$O and $^{12}$C nuclei. For this target, the $^{16}$O-to-$^{12}$C number ratio is $N(^{16}O)/N(^{12}C)=1.2\pm0.2$, which is lower by a factor of $\sim 2$ than the corresponding abundance ratio in the solar atmosphere $[N(^{16}O)/N(^{12}C)]_{sol}=2.4$. The first and second escape peaks are almost invisible and the Compton background is strongly suppressed by the BGO anticoincidence system. For $E_{beam}=4.75$ MeV (lower spectrum in Fig. 1), all significant lines arise from the exothermic reactions $^{16}$O($^{3}$He,$p\gamma$)$^{18}$F, $^{12}$C($^{3}$He,$p\gamma$)$^{14}$N and $^{16}$O($^{3}$He,$\alpha\gamma$)$^{15}$O.

Apart from the strong 511 keV emission, the most intense line is at 937 keV and originates from the deexcitation of the first excited level in $^{18}$F (Fig. 2). This line is relatively narrow because the mean-life of the 937 keV state, $\tau=67.6\pm2.5$ ps, is greater than the slowing down time of the recoiling $^{18}$F ions in the target material, such that the gamma-ray emission happens predominantly near rest. The reaction $^{16}$O($^{3}$He,$p\gamma$)$^{18}$F also produces four lines, at 1020, 1042, 1054 and 1081 keV, which could contribute to the $\sim 1.02$ MeV line emission feature detected in solar flares with SMM/GRS and CGRO/OSSE.

The strongest lines from the reaction $^{12}$C($^{3}$He,$p\gamma$)$^{14}$N are at 2313, 1635 and 5105 keV. It was not possible to extract reliable cross section data for $^{3}$He$+^{12}$C reactions in this experiment, because the Ge detectors were not shielded enough from gamma-rays produced in the graphite material of the Faraday cup. In solar flares, these three lines are expected to be also significantly excited by inelastic scattering of protons and $\alpha$-particles on ambient $^{14}$N.

The most significant line from the reaction $^{16}$O($^{3}$He,$\alpha\gamma$)$^{15}$O is at 5240 keV corresponding to the deexcitation of the second excited level in $^{15}$O (Fig. 2). The line at 5182 keV from the first excited level in $^{15}$O was observed to be significantly weaker.

For $E_{beam}=9$ MeV, three additional reactions can be identified in the gamma-ray spectrum shown in Fig. 1: the reaction $^{16}$O($^{3}$He,$d\gamma$)$^{17}$F, the reaction $^{12}$C($^{3}$He,$\alpha\gamma$)$^{11}$C producing two broad lines at 2000 and 4318 keV and the reaction $^{16}$O($^{3}$He,$n\gamma$)$^{18}$Ne producing...
two narrow lines at 1489 and 1887 keV (Fig. 2). We see that the latter line is relatively strong, which motivated us to determine its production cross section. The relevance of this line for solar flare physics is discussed in section IV.

III. DATA ANALYSIS AND RESULTS

The cross sections for the production of the 937, 1042 and 1081 keV lines of $^{18}$F and the 1887 keV line of $^{18}$Ne have been derived from the yields of the full-energy peaks in the energy calibrated spectra. We used a Monte Carlo simulation of the gamma-ray line production in the targets (see [14]) to better estimate the peak shapes for the four detection angles. The background yields were determined by interpolation of the count rates below and above the peaks. For the 937 and 1887 keV lines, the systematic error due to the peak shape determination and the background subtraction was estimated to be comparable to the statistical error. For the weaker line at 1081 keV, this systematic error was typically 5% for the detectors at 90°, 112.5° and 135°, and 10-20% for the detector at 157.5°. Photopeak integrations were indeed more uncertain for this latter detector, because of a higher gamma-ray background induced by nuclear reactions in the Faraday cup. The case of the 1042 keV line was complicated by the proximity of the 1054 keV line (see Fig. 1). For $E_{beam}$>5 MeV, these two lines were not fully resolved from each other and we estimated their relative intensities from fits by two Gaussian shaped lines. The associated systematic error was 5-15% for 5<$E_{beam}$<12 MeV and 15-35% above 12 MeV, as the two lines were almost impossible to distinguish for the highest beam energies. The total error in the gamma-ray line yields was obtained from the linear sum of this systematic error with the usual statistical error.

Examples of measured angular distributions of gammarays are shown in Fig. 3. The 1042 and 1081 keV line emissions are isotropics, because the gamma-rays depopulate 0$^+$ and 0$^-$ levels, respectively. The 937 and 1887 keV lines are $E2$ transitions [11] and complete angular distributions were obtained by fitting the measured differential cross sections by the Legendre-polynomial expansion:

$$\frac{d\sigma}{d\Omega}(\theta_{lab}) = a_0 + a_2Q_2P_2(\cos \theta_{lab}) + a_4Q_4P_4(\cos \theta_{lab}) ,$$  

(1)

where $P_l(\cos \theta_{lab})$ is the Legendre polynomial of order $l$ and $Q_2$ and $Q_4$ are the attenuation coefficients, which can be calculated analytically from the geometry of the detection setup (see [16]). We have estimated the corrections arising from the laboratory-to-center-of-mass transformation and from the finite beam spot size to be negligible in this experiment. The total cross section is simply given by

$$\sigma = 4\pi a_0 .$$  

(2)

In Fig. 4-7, we show the excitation functions obtained from the fits of the measured differential cross sections. Energies at which cross sections and Legendre-polynomial coefficients are quoted are laboratory $^3$He energies at the middle of the targets, the horizontal error bars corresponding to the target thicknesses. Stopping powers were calculated with the computer code TRIM [17]. The vertical error bars correspond to the 1$\sigma$-errors in the coefficients of the Legendre-polynomial fits, except for the 1042 keV line for which we took into account an additional error due to the contribution of the reaction $^{16}$O($^3$He,$n$)$^{18}$Ne($^{\beta^+}$)$^{18}$F$^*$ (see below). In the determination of absolute cross sections, errors in the target thicknesses (10%), the beam current integration (5%) and the dead-time correction (3%) must also be included. The resulting overall uncertainties are 13-14% in $\sigma$(937 keV), 13-23% in $\sigma$(1042 keV), 14-16% in $\sigma$(1081 keV) and 13-17% in $\sigma$(1887 keV).
FIG. 4: Total cross section (panel a) and coefficients of the Legendre-polynomial fits to the angular distributions (panels b and c) for the reaction $^{16}$O($^3$He,$p$)$_{937}$F, as functions of the laboratory $^3$He energies at the middle of the targets. The horizontal error bars correspond to the target thicknesses. The vertical error bars are the errors in the Legendre-polynomial fits. The dotted line in panel (a) shows the polynomial fit to the data above $E_{lab}=$15 MeV used to calculate the average values of the cross section at high energies (see text).

We see that the excitation functions vary with energy in a relatively smooth fashion. Only the cross section for the ($^3$He,$n$) channel (Fig. 7) shows resonances corresponding to compound nuclear effects (see below). The lack of fine structures in the excitation functions is partly due to the use of relatively thick targets (160-330 keV thickness for $E_{beam}=$3.7-12 MeV).

The highest cross section is found for the reaction $^{16}$O($^3$He,$p$)$_{937}$F, which reaches a maximum of 216±28 mb at 7.3 MeV (Fig. 4). The angular distributions of the 937 keV gamma-rays were found to be slightly anisotropic (see also Fig. 3) and to have little dependence on the $^3$He bombarding energy: the $a_2/a_0$ coefficient ratio is nearly constant and slightly positive (its mean value is 0.14±0.12) whereas all values of $a_4/a_0$ are compatible with zero. Because the 937 keV level of $^{18}$F has a relatively long mean-life, $\tau_1=67.6$±2.5 ps, and high magnetic dipole moment, $\mu_1=+1.68$±0.15 $\mu_N$, it is possible that its nuclear alignment was partly lost by hyperfine interactions in the target prior to the gamma emission.

In solar flares, production of the 1042 keV line includes a contribution from the reaction $^{16}$O($^3$He,$n$)$_{1887}$Ne($\beta^+$)$^{18}$F$_{1042}$ for $^3$He energies above the reaction threshold $E_{\text{Thres}}=3.80$ MeV. For each $\beta^+$ decay of $^{18}$Ne, 0.0783±0.0021 gamma-rays of 1042 keV are emitted [14]. The half-life of $^{18}$Ne, $T_{1/2}=1672±8$ ms, is too short for the ($^3$He,$n$) and ($^3$He,$p$) channels to be distinguished in solar flares. In this experiment, however, a small correction of the 1042 keV data had to be made to take into account the nondetection of some ($^3$He,$n$) events due to the escape from the targets of some recoiling $^{18}$Ne ions prior to decay. To evaluate this correction, we first estimated the total cross section for the reaction $^{16}$O($^3$He,$n$)$_{1887}$Ne from the differential cross sections ($d\sigma/d\Omega_{cm}$) measured by Adelberger and McDonald [13] at $E_{lab}=$9.5, 10.5, 11.5 and 12.5 MeV, and by Nero et al. [15] at $E_{lab}=$13.8, 16.1 and 17.8 MeV, as well as from the $^{16}$O($^3$He,$p$)$_{1887}$F$_{1042}$ excitation function measured in this experiment (Fig. 7). From this estimate, we found that the contribution of $^{18}$Ne production to the total 1042 keV line emission is lower than 25%. We then used the measured differential cross sections ($d\sigma/d\Omega_{cm}$) [18, 19] to calculate the energy...
The coefficient ratios do not significantly vary with energy a deep for characteristic structure at 19 which could correspond to the 13.8 MeV level of E ≈ 16.4 MeV in the compound nucleus. This broad resonance has already been observed at E_{lab} ≈ 6.5 MeV, which could correspond to the 13.8 MeV level of 19Ne. The Legendre-polynomial coefficients show a characteristic structure at E_{lab} ≈ 7 MeV, with a significant deep for a_4/a_0. Above ∼8.5 MeV, the a_2/a_0 and a_4/a_0 coefficient ratios do not significantly vary with energy and their mean values are 0.40±0.17 and -0.15±0.23, respectively.

Heggie et al. 10 have measured the excitation functions for the production of the 937, 1042 and 1081 keV lines in the reaction 16O(^3He,p)18F* up to 4 MeV. Comparison of their results with the cross sections we obtained at the lowest energies shows an overall agreement of ∼20%. The results of our gamma-ray production measurements can also be compared with the cross section for 18F total production from 3He+16O reactions, which has been extensively studied by an activation method (see 20). The reported excitation function has a very similar overall shape to the one of the sum of the four excitation functions measured in our experiment and is ∼20% higher. The difference is due to the direct production of 18F and 18Ne in their ground states, as well as to their production in excited levels above 1081 keV (18F) and 1887 keV (18Ne) decaying directly to their ground states.

In order to provide data in a convenient form for gamma-ray astronomy, we have averaged the measured cross sections over 1-MeV energy intervals up to 15 MeV and over 5-MeV energy intervals at higher laboratory energies. The results are given in Table 1. Below 15 MeV, average values were generally obtained from linear interpolations between adjacent data points. At higher energies, average values were generally obtained from linear interpolations between adjacent data points.

The lowest cross section measured in this experiment is that of the reaction 16O(^3He, p)18F, which reaches a maximum of only 31±4 mb at 5.4 MeV (Fig. 6). The β⁺ decay of 18Ne also populates the 1081 keV state of 18F, but with a negligible branching ratio of (2.07±0.28)×10⁻⁶ 14.

Results for the 16O(^3He, n)18Ne reaction are shown in Fig. 7. A broad resonancelike structure dominates the excitation function at E_{lab}≈9.5 MeV, which corresponds to an excitation energy of ≈16.4 MeV in the compound nucleus. This broad resonance has already been reported in the yields of neutron production 13. A narrower resonance is also observed at E_{lab}≈6.5 MeV, which could correspond to the 13.8 MeV level of 19Ne 14. The Legendre-polynomial coefficients show a characteristic structure at E_{lab}≈7 MeV, with a significant deep for a_4/a_0. Above ∼8.5 MeV, the a_2/a_0 and a_4/a_0 coefficient ratios do not significantly vary with energy and their mean values are 0.40±0.17 and -0.15±0.23, respectively.

Heggie et al. 10 have measured the excitation functions for the production of the 937, 1042 and 1081 keV lines in the reaction 16O(^3He,p)18F* up to 4 MeV. Comparison of their results with the cross sections we obtained at the lowest energies shows an overall agreement of ∼20%. The results of our gamma-ray production measurement can also be compared with the cross section for 18F total production from 3He+16O reactions, which has been extensively studied by an activation method (see 20). The reported excitation function has a very similar overall shape to the one of the sum of the four excitation functions measured in our experiment and is ∼20% higher. The difference is due to the direct production of 18F and 18Ne in their ground states, as well as to their production in excited levels above 1081 keV (18F) and 1887 keV (18Ne) decaying directly to their ground states.

In order to provide data in a convenient form for gamma-ray astronomy, we have averaged the measured cross sections over 1-MeV energy intervals up to 15 MeV and over 5-MeV energy intervals at higher laboratory energies. The results are given in Table 1. Below 15 MeV, average values were generally obtained from linear interpolations between adjacent data points. At higher energies, average values were generally obtained from linear interpolations between adjacent data points.

*From Ref. [21], fig. 2. The error is $\sim$15%, including an uncertainty of 12% in the target thickness.

energies, we performed fits to the cross section data by polynomial or exponential curves (see Fig. 4-7). We estimated the uncertainty induced by this procedure to be generally negligible as compared with the overall errors in the measured cross sections, except for $\sigma$(1887 keV) at $E_{lab}=6$ and 7 MeV. For these two values, we quadratically added errors of 25% and 10%, respectively, due to the resonance at $\sim$6.5 MeV (Fig. 7).

IV. DISCUSSION

To discuss the expected emission of the $^3$He-produced lines in solar flares, we show in Fig. 8 two calculated gamma-ray line spectra, assuming an accelerated particle composition with or without $^3$He. We used the code developed by Ramaty et al. [8, 21], in which we incorporated the cross section values of Table 1. At higher $^3$He energies, we extrapolated the four cross sections assuming the same energy dependence as estimated by Kozlovsky et al. [8] for the $^{18}$O($^3$He,$p$)${}^{18}$F$^*$ reactions. In practice, we added two values for $\sigma$(937 keV), 3.4 mb at 60 MeV and 1.6 mb at 90 MeV, two values for $\sigma$(1042 keV), 3.6 mb at 30 MeV and 0.9 mb at 60 MeV, one value for $\sigma$(1081 keV), 1 mb at 30 MeV, and two values for $\sigma$(1887 keV), 2 mb at 60 MeV and 0.9 mb at 90 MeV. In Fig. 8, these extrapolations account for <3% of the $^3$He line strengths.

The calculations were performed in a thick target interaction model, in which the accelerated particles produce the nuclear reactions while they slow down in the solar atmosphere. Gamma-ray line spectroscopic analyses of solar flare emissions have shown that the composition of the gamma-ray production regions is generally close to coronal (see [22] and [23]): the abundances of the low FIP (first ionization potential) elements Mg, Si and Fe relative to the high FIP elements C and O are enhanced by a factor of 4–5 [22] in comparison with photospheric abundances. We took the coronal abundances from Ref. [22], except for He/H for which we adopted the helioseismological value He/H=0.084 [24]. For the accelerated particles, we used an impulsive-flare average composition obtained from solar energetic particle measurements [22], except for $\alpha/p$ for which we used an abundance ratio of 0.5. Such a relatively high concentration of accelerated $\alpha$-particles has been proposed to explain the intense $^3$He fusion lines observed in several flares (see [6, 8]). The two gamma-ray spectra shown in Fig. 8 were calculated for $^3$He/$\alpha=0$ (dotted line) and $^3$He/$\alpha=0.5$ (solid line). The latter value is typical of the $^3$He enrichment of the solar energetic particles accelerated in impulsive flares (see [23]). For the source energy spectrum of the fast ions, we took for all species a power law in kinetic energy per nucleon, $Q(E) \propto E^{-s}$, with $S=4$ (see [20]).

We see in Fig. 8 that the 937 keV line is relatively strong in comparison with other lines produced by accelerated protons and $\alpha$-particles. However, we also see from the gamma-ray spectrum calculated without accelerated $^3$He, that analysis of this line can be complicated by the proximity of another line at 931 keV, which is produced in the reaction $^{56}$Fe($p$,p)$^{56}$Fe$^*$ [8, 9]. In Fig. 9a, we show the fluence ratio of the 931 keV line to the 937 keV line, as a function of the power law spectral index of the accelerated particle energy spectrum. We used for $\sigma$(931 keV) the values supplied in table A3 of Ref. [8]. The relative contribution of the 931 keV line rapidly diminishes for increasing $S$, because this line is produced for proton energies above the reaction threshold $E_p=11.4$ MeV, whereas $\sigma$(937 keV) peaks at significantly lower $^3$He energy per nucleon, $E_{1\alpha}=2.4$ MeV/nucleon (see Table 1 and Fig. 4). Given the assumed coronal abundance ratio $^{56}$Fe/$^{16}$O=0.16 and the adopted accelerated particle composition with $^3$He/$p=0.25$, the 931 keV line fluence is <5% of that of the 937 keV line for $S=4$.

As shown in Fig. 8, the $^3$He line at 1042 keV can also be blended with another significant line, which is produced from the reaction $^{56}$Fe($\alpha$,$p\alpha$)$^{56}$Co [8, 9]. Fig. 9b illustrates that the 1049 keV line should generally be considered, especially if the accelerated particle spectrum is hard (i.e. low values of $S$). In addition, the analysis of the 1042 keV line can be complicated –as in this experiment– by the proximity of the 1054 keV line also produced in the reaction $^{16}$O($^3$He,$p$)$^{18}$F$^*$ (see Fig. 1 and § III).

The 1081 and 1887 keV lines are expected to be separated from other important lines (Fig. 8). They are, however, weaker than the 937 and 1042 keV lines. The 1887 keV line is broader than the three other $^3$He lines, because it is produced at higher $^3$He energies. Fig. 9c
FIG. 8: Calculated prompt gamma-ray line spectra in the 0.7–2 MeV region produced by accelerated particles (mainly protons, \(^{3}\)He and \(\alpha\)-particles) interacting with the solar atmosphere (see text). *Solid line*: accelerated \(^{3}\)He/\(\alpha\)=0.5; *dotted line*: \(^{3}\)He/\(\alpha\)=0. The fast particle source spectrum is \(Q(E) \propto E^{-S}\) with \(S=4\), normalized to 1 proton of energy \(E>30\) MeV. The 4 lines produced in \(^{4}\)He+\(^{16}\)O reactions, as well as the 4 strongest lines produced by accelerated protons and \(\alpha\)-particles are labelled with the excited nuclei from which the gamma-rays are emitted.

\[\begin{align*}
F_{\gamma}(\text{photons MeV}^{-1}) \\
0.8 & 1 & 1.2 & 1.4 & 1.6 & 1.8 & 2 \\
\end{align*}\]

\[\begin{align*}
\text{Ambient} = \text{coronal} \\
\alpha / p = 0.5 & & S = 4 \\
\end{align*}\]

shows the fluence ratio of the 1887 keV line to the 937 keV line, as a function of the spectral index \(S\). We see that the calculated ratio decreases by one order of magnitude, from 0.4 for \(S=2\) to 0.04 for \(S=6\). Since both lines are produced from \(^{3}\)He-induced reactions on the same \(^{16}\)O target, this ratio is independent of the ambient medium and accelerated particle compositions. It depends only on the accelerated \(^{3}\)He energy spectrum, which is important in understanding the acceleration mechanism in impulsive solar flares (see [3]).

It is noteworthy that a significant synthesis of \(^{18}\)F nuclei in solar flares could also be identified through the characteristic, long living, 511 keV emission expected from the \(\beta^{+}\) decay of this isotope (\(T_{1/2}=109.77\) m). The detection of this delayed emission, maybe with the RHESSI satellite, would furthermore provide a new insight into mixing and transport processes in the solar atmosphere.

In summary, the four cross sections measured in this experiment could allow one to determine with a good accuracy the abundance of \(^{3}\)He accelerated in solar flares and interacting in the solar atmosphere. The strongest of the gamma-ray lines from \(^{3}\)He-induced reactions is the one at 937 keV from the reaction \(^{16}\)O(\(^{3}\)He,\(p\))\(^{18}\)F*, which however, can overlap with a line at 931 keV, produced in the reaction \(^{56}\)Fe(\(p,\gamma\))\(^{55}\)Fe*. If observed, the 1887 keV line from the reaction \(^{16}\)O(\(^{3}\)He,\(n\))\(^{18}\)Ne* would furthermore provide unique information on the energy spectrum of the accelerated \(^{3}\)He.

FIG. 9: Calculated line fluence ratios in a thick-target interaction model as a function of the power-law spectral index of the accelerated particles. The lines at 931 keV (a) and 1049 keV (b) are produced by proton and \(\alpha\)-particle reactions on \(^{56}\)Fe, respectively. The 937 and 1887 keV lines are both produced by \(^{3}\)He reactions on \(^{16}\)O.

\[\begin{align*}
\text{Power Law Spectral Index, } S \\
1 & 2 & 3 & 4 & 5 & 6 & 7 \\
\end{align*}\]
Acknowledgments

We would like to thank the operator crew of the Orsay Tandem accelerator for their engagement in the preparation of the experiment, as well as Frédéric Garrido, Claire Boukari, Jacques Chaumont and Catherine Clerc for their assistance in the RBS measurements.
