CPEB regulation of human cellular senescence, energy metabolism, and p53 mRNA translation

David M. Burns and Joel D. Richter1

Cytoplasmic polyadenylation element-binding protein (CPEB) stimulates polyadenylation and translation in germ cells and neurons. Here, we show that CPEB-regulated translation is essential for the senescence of human diploid fibroblasts. Knockdown of CPEB causes skin and lung cells to bypass the M1 crisis stage of senescence; reintroduction of CPEB into the knockdown cells restores a senescence-like phenotype. Knockdown cells that have bypassed senescence undergo little telomere erosion. Surprisingly, knockdown of exogenous CPEB that induced a senescence-like phenotype results in the resumption of cell growth. CPEB knockdown cells have fewer mitochondria than wild-type cells and resemble transformed cells by having reduced respiration and reactive oxygen species (ROS), normal ATP levels, and enhanced rates of glycolysis.

p53 mRNA contains cytoplasmic polyadenylation elements in its 3′ untranslated region (UTR), which promote polyadenylation. In CPEB knockdown cells, p53 mRNA has an abnormally short poly(A) tail and a reduced translational efficiency, resulting in an ∼50% decrease in p53 protein levels. An shRNA-directed reduction in p53 protein by about 50% also results in extended cellular life span, reduced respiration and ROS, and increased glycolysis. Together, these results suggest that CPEB controls senescence and bioenergetics in human cells at least in part by modulating p53 mRNA polyadenylation-induced translation.

Initiation is the rate-limiting step for translation of most eukaryotic mRNAs and requires both a 5′-methylated guanosine cap \( \text{[m}^\text{G}\text{][5′]}\text{pp}[5′]\text{N} \) and a 3′ poly(A) tail. The ends of the RNA are brought into close proximity by a protein–protein–protein bridge composed of eIF4E (the cap-binding factor), eIF4G, and poly(A)-binding protein (PABP) (Tarun and Sachs 1996; Tarun et al. 1997; Wells et al. 1998). PABP may facilitate the interaction of eIF4G with eIF4E, which is necessary for initiation since eIF4G, via the multisubunit eIF4F, positions the 40S ribosomal subunit on the 5′ end of the mRNA (Sonenberg and Hinnenbusch 2007). One mode of translational control that is particularly important for germ cell development is the abrogation of this 5′–3′ protein bridge by the near absence of the poly(A) tail [and hence PABP] and by the association of a specialized eIF4E-binding protein with some mRNAs. These inert [masked] mRNAs are activated by subsequent poly(A) tail growth, the binding of PABP to poly(A), and the replacement of the eIF4E-binding protein with eIF4G. The cytoplasmic polyadenylation element [CPE] controls poly(A) tail length; it resides in mRNA 3′ untranslated regions (UTRs) and serves as the binding site for CPE-binding protein [CPEB], a factor that associates with Gld2, a poly(A) polymerase (Barnard et al. 2004); PARN, a deadenylating enzyme (Kim and Richter 2006); ePAB, a PABP (Kim and Richter 2007); Maskin, an eIF4E-binding protein (Stebbins-Boaz et al. 1999; Cao et al. 2006); CPSF, a multisubunit RNA-binding complex (Mendez et al. 2000; Dickson et al. 2001); and symplekin, a probable scaffold or assembly protein (Barnard et al. 2004). In response to developmental cues, CPEB becomes phosphorylated, causing the expulsion of PARN from the RNP complex and results in Gld2-catalyzed polyadenylation (Mendez et al. 2000; Kim and Richter 2006). The newly elongated poly(A) tail is bound by ePAB that in turn binds eIF4G, this complex displaces Maskin from eIF4E, thus circularizing the RNA and promoting initiation (Barnard et al. 2005; Cao et al. 2006; Kim and Richter 2006).

CPEB-controlled translation has also been found to modulate neuronal synaptic plasticity (Klann and Richter 2007; Richter 2007) and cellular senescence in murine embryonic fibroblasts [MEFs] (Groisman et al. 2006). Like apoptosis, senescence is a mechanism that prohibits unrestricted cell proliferation. DNA damage, nutrient

deprivation, improper cell contacts, and oncogenic signaling all converge on the p53 and/or retinoblastoma (Rb) tumor suppressor pathways to initiate cell cycle arrest and entry into senescence (Lowe et al. 2004; Campisi and d’Adda di Fagagna 2007). While senescence is usually examined in cultured cells, recent studies in animals have demonstrated that it is an important barrier to malignant transformation (Braig et al. 2005; Chen et al. 2005; Collado et al. 2005; Michaloglou et al. 2005).

The bypass of senescence, or immortalization, is required for, but does not necessarily lead to, cellular transformation. Although both phenomena are often studied in mouse and human cells, there are a number of differences between the two organisms, indicating the complexity of molecules that influence these processes. For example, cultured mouse cells are relatively easy to transform, requiring the addition of only one or two oncogenes (Drayton and Peters 2002). Normal diploid human cells, however, are more refractory and require the inactivation of the p53 and Rb proteins, as well as the activation of the catalytic subunit of the telomerase, hTERT. In addition, mouse telomeres are typically 25–60 kb in length while those in humans are much shorter, ~10–15 kb; thus, telomere erosion is not necessarily essential for senescence in mouse cells while it is in human cells (Chin et al. 1999). Moreover, murine cells senesce abruptly in culture five to 10 times faster than human cells. These and other differences between mouse and human cells notwithstanding, it is increasingly evident that in both species, cellular and replicative senescence are not only triggered by cellular perturbations that generate a DNA damage response, such as oncogene expression and cell culture stress (Lee et al. 1999; Wu et al. 2004), but that senescence onset and maintenance requires a sustained DNA damage response (Hemann and Narita 2007).

While comparing rates of mitosis between MEFs derived from wild-type and CPEB knockout (KO) mice, we made the startling observation that the KO MEFs did not senesce as did wild-type MEFs, but instead were immortal [Groisman et al. 2006]. Reintroduction of CPEB into early passage KO MEFs induced them to senesce; reintroduction of CPEB into late passage KO MEFs [i.e., those that had gone through several passages beyond when wild-type MEFs senesce] did not. CPEB-mediated senescence required the tumor suppressors p53 and p19ARF; conversely, Ras-induced senescence required CPEB. Myc protein levels were elevated in the KO MEFs and more myc mRNA was found on polysomes compared with wild-type MEFs. Most importantly, shRNA knockdown of myc in the KO MEFs caused them to become senescent. These data indicated that in mouse cells, the removal of CPEB-inhibited myc RNA translation led to immortalization.

Here, we investigate the importance of CPEB for senescence of normal human diploid fibroblasts. While wild-type and mock-infected human foreskin fibroblasts senesced after ~70 population doublings, those infected with a lentivirus harboring a shRNA against CPEB did not; the life span of these cells was extended by nearly fivefold. A second infection of these knockdown cells with a retrovirus expressing murine CPEB restored a senescence-like phenotype in early but not late passage cells. Human WI-38 lung fibroblasts also bypassed senescence when CPEB levels were reduced. As expected, CPEB knockdown cells that bypassed senescence retained long telomeres. Interestingly, promotion of the senescence-like phenotype by over expressed CPEB could be reversed when the levels of this protein were reduced. CPEB knockdown cells had abnormally low levels of mitochondria; they also resemble transformed cells in that they had reduced respiration, but an elevated rate of glycolysis presumably to maintain homeostatic ATP levels. CPEB knockdown cells contained ~50% reduction of p53, and p53 mRNA had a shorter poly(A) tail and a reduced translational efficiency compared with p53 mRNA in wild-type cells. An ~50% reduction of p53 levels in cells containing normal levels of CPEB also bypassed senescence and had reduced mitochondrial mass and respiration. We propose that the senescence bypass and change in energy metabolism observed in CPEB knockdown cells is due at least in part to dysfunctional p53 mRNA polyadenylation and translation.

Results

CPEB is required for senescence in primary human cells

To determine whether primary human cells require CPEB to become senescent, human diploid foreskin fibroblasts were, in two separate occasions, infected at passage eight with a lentivirus expressing one of two different shRNAs against CPEB RNA [shCPEB] as a control for possible off-target effects. As an additional control, the cells were also infected with an empty lentivirus or one expressing shRNA against mRNA encoding the tetracycline resistance gene [shTETR]. The lentivirus vector also expressed GFP, which indicated that ~70% of cells were infected with the virus. The cells were analyzed for growth and morphology without drug selection.

The efficiency of the CPEB knockdown was monitored by both RT–PCR of RNA [data not shown] and by Western analysis [Fig. 1A]. CPEB was reduced by >80% compared with the control shTETR knockdown; the top band in Figure 1A might represent phosphorylated CPEB. After ~68 population doublings, the mock-infected and shTETR-infected cells stopped dividing and assumed a flat senescent-like morphology. These cells also stained for β-galactosidase activity at acidic pH, a common marker for senescence [Fig. 1D; Itahana et al. 2007; data not shown]. The shCPEB-infected cells, however, continued to grow, did not undergo a morphology change, and did not stain for β-galactosidase activity [Fig. 1A,D]. Additionally, while mock-infected and shTETR-infected cells expressed high levels of p21CIP1 and p16INK4A, which is consistent with entry into senescence, the cells...
panied by telomere loss, we measured telomere length in Because senescence in human cells is generally accom-
maintenance CPEB is required for the suppression of telomere
fore, CPEB must bind RNA to induce the senescence-
addition to containing two RNA recognition motifs, is
enter senescence. Thus, at least two human cell types require CPEB to
passages.

We also assessed whether CPEB is required for senes-
cence in WI-38 human lung fibroblasts. These cells were
with the same lentiviruses used for the foreskin
fibroblasts; while the mock-infected or control-infected
cells entered senescence after an additional 10 popula-
tions doublings, none of these events took place. Thus, the
reintroduction of CPEB into knockdown cells induces a
senescence-like state at early and middle, but not late,

Finally, the zinc finger of CPEB was deleted, which in
addition to containing two RNA recognition motifs, is
required for CPE binding [Hake et al. 1998]. This mutant
protein was unable to restore senescence [a mock infec-
tion also did not rescue senescence] [Fig. 1C–E]. Therefore, CPEB must bind RNA to induce the senescent-

CPEB is required for the suppression of telomere mainte-

Because senescence in human cells is generally accom-
panied by telomere loss, we measured telomere length in
cells infected with shCPEB by a telomere oligonucleo-
tide ligation assay (T-OLA) [Stewart et al. 2003] and by
fluorescence in situ hybridization (FISH) [Henegariu et
al. 2001]. The T-OLA assay [Fig. 2A, B] shows that, as
expected, the telomeres of wild-type or shTETR-infected
cells eroded as the cells entered senescence. While the
shCPEB-infected cells also underwent some telomere shortening [e.g., at 90 d post-infection], the erosion was not as severe as with the control cells. This maintenance of telomere length was also evident by FISH for the telo-
meric region [Fig. 2C], that is, at 90 d post-infection with
shCPEB, there was clearly hybridization to the telomeric region. In contrast, cells infected with shTETR under-
went extensive telomere erosion as evidenced by the lack of a FISH signal to this same region. As expected, wild-type cells also lacked a FISH signal due to telomere shortening. These data indicate that CPEB is required, directly or indirectly, for telomere erosion.

The CPEB-induced senescence-like arrest is reversible

Two approaches were used to determine whether the
CPEB-induced senescence-like phenotype is reversible.
First, wild-type fibroblasts were infected with lentivirus
expressing human HA-CPEB on day one, which was fol-
lowed 2 d later by the infection of another lentivirus
expressing shRNA against this same CPEB; the cells
were analyzed 4 d later (Fig. 3A). Western analysis shows that the shRNA efficiently knocked down HA-CPEB
expressing human HA-CPEB on day one, which was fol-

Figure 1. CPEB is necessary for cellular senescence. (A) Human foreskin fibroblasts were infected with a lentiviruses encoding shRNA targeting CPEB mRNA [shCPEB], or the tetracycline resistance mRNA [shTETR], as a control. Additional cells were mock in-
fected with an empty lentivirus. Population doublings were then determined by counting cells with a hemo-
cytometer. Some cells were also infected with a retro-
virus expressing mouse CPEB [because of differences in the primary sequence, mouse CPEB mRNA is not a tar-
et of the shCPEB], followed by cell counting. The inset
shows a Western blot probed for CPEB and actin; these
extracts were prepared from cells 40 d post-lentivirus
infection. (B) Human lung fibroblasts [WI-38] were in-
fected with lentiviruses targeting CPEB or, as a control
GFP; mock refers to infection with an empty virus. The
cells were counted as in A. (C, D) Foreskin fibroblasts
previously infected with shCPEB were also infected with retroviruses expressing wild-type CPEB or a CPEB
lacking a zinc finger, which renders the protein inca-
pable of RNA binding. Some cells were also mock in-
fected. The cells were then stained for β-galactosidase at
acidic pH and were counted (C), and visualized by bright-
field microscopy 3 d after retrovirus infection (D).
cells returned to prolific cell division once CPEB was knocked down by the lentivirus-expressed shCPEB (Fig. 3C).

In a second approach to address reversibility, sequences encoding a CPEB-GFP fusion protein were cloned into a vector containing the tetracycline response element. Following infection and antibiotic selection, the cells were infected with a lentivirus encoding the tetracycline repressor (TetR); several days later, the cells were incubated with doxycyclin (DOX), which represses the expression of CPEB. The cells were then split; some were further incubated with DOX, while others were transferred to DOX-free medium (−DOX). The cells were analyzed 4 and 8 d later (Fig. 3D). Figure 3E demonstrates that CPEB (−DOX) inhibited cell division; conversely, the subsequent down-regulation of CPEB expression (+DOX) allowed the cells to continue to divide. Finally, CPEB-GFP was readily detected in cells incubated in the presence, but not the absence, of DOX (Fig. 3F). These results demonstrate that the CPEB-induced senescence-like phenotype is reversible.

**CPEB is necessary for stress-induced cellular senescence**

Cellular senescence is generally thought to be a response to stresses that induce telomere shortening, oncogene activation, reactive oxygen species (ROS), etc. [Ben-Porath and Weinberg 2005]. In MEFs, at least one inducer of senescence, constitutively active Ras, requires CPEB [Groisman et al. 2006]. This is also the case with human fibroblasts that have reduced CPEB levels (Supplemental Fig. 1). Also, as in CPEB KO MEFs, Ras failed to induce senescence in human fibroblasts with reduced CPEB [Supplemental Fig. 1]. Because Ras is involved in modulating levels of ROS [Irani et al. 1997; Archer and Bar-Sagi 2002], we used two approaches to examine whether ROS was also involved in the CPEB-induced senescence-like phenotype. First, wild-type fibroblasts were treated with 200 µM N-acetyl-cysteine (NAC), an oxygen free-radical scavenging agent, followed by infection of a retrovirus expressing CPEB. While CPEB strongly induced senescence in untreated cells, its ability to do so in NAC-treated cells was substantially reduced (Supplemental Fig. 2A). Moreover, fibroblasts treated with hydrogen peroxide to increase the ROS concentration readily senesced, but did not do so when they had reduced CPEB levels [Supplemental Fig. 2B].

While indirect, these results suggest some connection between CPEB and ROS, and possible changes in cellular bioenergetics. To examine bioenergetics directly, we measured mitochondrial respiration in two CPEB knockdown cell lines; Figure 4A shows that relative to wild-type or shTETR control cells, mitochondrial respiration in these cells was reduced by ∼50%. To investigate the origin of this reduced respiration, we stained wild-type, shTETR, and shCPEB cells with Mitotracker, which reflects mitochondrial mass, followed by stacking of confocal images. These images indicate that shCPEB caused a reduction of mitochondrial number (Fig. 4B); the quantification of the Mitotracker fluorescent signal indicates that there was nearly eightfold fewer mitochondria (Fig. 4C). This decrease was confirmed by a Western blot for cytochrome C, a mitochondrial marker (Fig. 4D).

Because mitochondrial oxidative phosphorylation generates most of the cell’s ATP, it might be inferred that the CPEB knockdown fibroblasts contain less ATP than wild-type cells. However, the level of ATP was nearly identical between wild-type and shCPEB cells (Fig. 4E). Transformed cells also have reduced respiration but maintain relatively normal levels of ATP by increasing glycolysis [Bensaad and Vousden 2007]. To determine whether this is also the case with CPEB knockdown cells, the amount of lactate, an indicator of glycolysis, was determined. Indeed, the CPEB knockdown cells produced about five times more lactate than did wild-type cells (Fig. 4F), indicating a substantial up-regulation of glycolysis. Finally, CPEB knockdown cells were also found to have a decrease in ROS levels (Fig. 4G), as might be expected from the reduction in mitochondrial respiration.
CPEB-induced senescence requires p53

In MEFs, CPEB requires p53 to induce senescence (Groisman et al. 2006). To determine whether this is also the case with human cells, fibroblasts were infected with a retrovirus encoding GSE-22, a p53 dominant-negative peptide that inhibits p53 activity (Beausejour et al. 2003). Two days later, the cells were infected with a virus expressing CPEB; the cells were then analyzed for growth and p21, a target gene of p53 (Figs. 5A–C). While CPEB induced senescence in cells lacking GSE-22, they were unable to do so if they contained the inhibitory peptide. Moreover, GSE-22 prevented p21 expression, thus demonstrating that it indeed inhibited p53 activity. These results indicate that CPEB-induced senescence requires p53 in human cells.

CPEB control of p53 mRNA translation

Several senescence-related proteins were analyzed in extracts derived from wild-type, shTETR, and shCPEB cells. p53 as well as K382-acetylated p53 were reduced by ~50%–60% in shCPEB-containing cells; the cell cycle inhibitory proteins p21\textsuperscript{CIP1} and p16\textsuperscript{INK4A} were also reduced, consistent with the bypass in senescence (Fig. 6A). Because p53 mRNA levels were not commensurately lower with the p53 protein levels (Fig. 6B), we
of synthesis and destruction, we sought to determine which of these processes was controlled by CPEB. Wild-type and shCPEB-infected fibroblasts were first starved of methionine and cysteine, then pulsed with 35S-methionine and 35S-cysteine, followed by a chase with radio-inert methionine and cysteine. p53 was then immunoprecipitated and the decay of this protein was monitored by SDS-PAGE and phosphorimaging. While shCPEB had no effect on the decay rate of general cellular proteins, there was a stabilizing effect on p53 [Fig. 7A,B]. This result, however, is complicated by the fact that p53 is a positive regulator of the human homolog of mdm2, the E3 ligase that controls ubiquitin-mediated p53 destruction [Fig. 7C]. In other words, elevated p53 levels induce mdm2 transcription, which in turn leads to p53 destruction. Consequently, we used alternative approaches to determine why p53 levels are reduced in CPEB knockdown cells. First, wild-type and shCPEB-infected cells were pulsed with 35S-methionine and 35S-cysteine in the presence of the proteasome inhibitor MG132, followed by p53 immunoprecipitation. Compared with total protein, the rate of p53 synthesis was ∼50% lower in the shCPEB-infected cells compared with wild type [Fig. 7D,E].

The translational efficiency of p53 mRNA was determined by polysome sucrose density centrifugation of extracts from wild-type and shCPEB-infected cells. The gradients were fractionated and following RNA extraction, p53 mRNA was assayed by quantitative RT–PCR (qRT-PCR) using GAPDH mRNA as an internal standard. Figure 7F demonstrates that in shCPEB-infected cells, there was a shift in the sedimentation profile of p53 mRNA from heavy to lighter polysomes, consistent with a reduction in translational efficiency.

Senescence bypass and alteration in bioenergetics in p53 knockdown cells

We next investigated whether the ∼50% reduction in p53 in CPEB knockdown cells is sufficient for the senescence bypass and change in bioenergetics [Fig. 8A]. To do so, we stably expressed a p53 shRNA via lentiviral gene transfer, which reduced p53 protein levels by ∼50% [Fig. 8B]. As expected, expression of p21, a p53 target gene, was also inhibited [Fig. 8B]. The 50% reduction of p53 induced senescence bypass, as did expression of the GSE-22 dominant-negative p53 peptide [Fig. 8C]. The 50% reduction of p53 also resulted in reduced mitochondrial respiration [Fig. 8D] and ROS [Fig. 8E], and stimulated a greater than sixfold increase in lactate production, indicating substantial up-regulation of glycolysis [Fig. 8F]. To assess what factors might be downstream from CPEB and p53 that influences the change in bioenergetics, we determined the levels of synthesis of cytochrome oxidase 2 (SCO2), which has been reported to modulate the Warburg effect in a p53-dependent fashion [Matoba et al. 2006]. Figure 8F demonstrates that SCO2 levels were reduced in cells in which either CPEB or p53 were knocked down, suggesting that the influence of CPEB on bioenergetics occurs via p53 mRNA translation and SCO2.
Response to chemical carcinogen in CPEB KO mice

Based on the results of Groisman et al. [2006] and this study that describe the importance of CPEB in cell growth and metabolism in vitro, we initiated studies to examine the relative importance of CPEB in aging and malignant transformation in mice. CPEB KO mice have ~2- to 2.3-yr life spans that are virtually indistinguishable from those of wild-type animals; they also display no unusual proclivity for tumor formation (data not shown). However, CPEB KO mice do form papillomas at a significantly faster rate than wild-type animals in a two-step DMBA-TPA carcinogenesis assay (Supplemental Fig. 3). Thus, CPEB does appear to offer some protection against at least one type of induced tumor formation and perhaps other induced stresses as well.

Discussion

We demonstrate that reduced levels of CPEB cause a bypass of senescence in primary human cells. While these cells have a nearly fivefold extended life span, their rate of cell division eventually begins to slow and they cease to divide after ~93 population doublings. While mouse cells [MEFs] that lack CPEB also bypass senescence, they do not begin to slow even after ~40 passages and are immortal [Groisman et al. 2006]. In both mouse and human cells lacking [or with reduced] CPEB, the reintroduction of CPEB at early passages restores a senescence-like phenotype; a similar reintroduction of CPEB into late passage cells, however, has little effect on cell division. While it is unclear why only early passage cells respond to exogenous CPEB, such experiments do demonstrate that it is CPEB and not another factor that is responsible for the senescence bypass. In both MEFs and human fibroblasts, p53 is required for CPEB-induced senescence, while CPEB is required for Ras-induced senescence [Fig. 5; Supplemental Fig. 1; Groisman et al. 2006]. These similarities between mouse and human cells notwithstanding, CPEB-controlled senescence in MEFs is mediated at least in part by myc, while in human cells one key factor is p53. In MEFs containing or lacking CPEB, there is no detectable change in the amount of p53 over many cell passages, while myc protein is elevated in CPEB KO MEFs [Groisman et al. 2006]. Myc mRNA is also translated more efficiently in the KO MEFs and is at least one factor that mediates immortalization when CPEB is absent since a knockdown of myc in CPEB KO MEFs causes a cessation of cell division [Groisman et al. 2006]. In human skin fibroblasts, there is no evidence for CPEB control of myc translation that contributes to senescence. On the other hand, CPEB mediates poly[A] tail length of p53 mRNA in wild-type and shCPEB knockdown cells.
similar to that which occurs in vertebrate germ cells (Tay and Richter 2001; Tay et al. 2003; Barnard et al. 2004; Kim and Richter 2006, 2007; Richter 2007). If this is the case, then other factors such as Gld2 and PARN, which mediate CPEB-directed polyadenylation in oocytes, may have the same function in human fibroblasts, and a reduction in their steady state levels might modulate senescence.

In response to DNA damage, ribosomal protein L26 (rpL26) has been reported to stimulate p53 mRNA translation, while nucleolin inhibits it (Takagi et al. 2005). p53 mRNA translation in also enhanced by the RNA-binding protein HuR in response to UV irradiation (Mazan-Mamczarz et al. 2003). While we have no evidence that CPEB regulates p53 mRNA translation in response to DNA damage, it appears to regulate steady state translation by insuring that the p53 poly(A) tail is the proper length. Polyadenylation is a complex process regulated in both the nucleus and cytoplasm. For example, both nuclear pre-mRNA and cytoplasmic mRNA polyadenylation can be regulated during the cell cycle (Colgan et al. 1996; Groisman et al. 2006) and in response to certain signaling events [Wu et al. 1998; Mellman et al. 2008]. Moreover, poly(A) dynamics are also regulated by environmental stress [Hilgers et al. 2006] and by miRNAs [Wu et al. 2006]. We speculate that CPEB activity may be necessary for maintaining steady state p53 levels under normal conditions where it has important functions in cellular aging and energy metabolism [Bensaad and Vousden 2007].

Reversible CPEB-induced senescence-like phenotype

The observation that the CPEB-induced senescence-like phenotype was reversible was surprising because senescence is generally considered to be an irreversible process. On the other hand, there have been reports of senescence reversibility under particular circumstances. For example, Macip et al. (2006) have shown that in p53-null cells, a ROS-induced senescence-like phenotype is reversible. This type of senescence reversibility may not be directly related to that described here since oxidative stress of CPEB knockdown cells does not readily induce senescence (Supplemental Fig. 2). Moreover, Beausejour et al. (2003) have shown that senescence accompanying telomere shortening can also be reversed. While the nature of the CPEB reversibility of senescence requires further investigation, it is clear that cells’ entry into senescence is particularly sensitive to the amount of this protein; that is, in human cells, a knockdown of CPEB, either endogenous or exogenous to ∼20% of normal levels results in senescence bypass. In MEFs, cells heterozygous for CPEB also bypass senescence (Groisman et al. 2006). Conversely, cells containing relatively low amounts of exogenous CPEB require several passages before they senesce, whereas cells containing high levels...
senesce much faster. We speculate that the amount of CPEB is important for the relative translational efficiency of p53 mRNA, which in turn could be responsible for the rate, or timely onset, of senescence.

CPEB, p53, and energy metabolism

CPEB knockdown fibroblasts have nearly eightfold fewer mitochondria compared with wild-type cells and overall, respire about half as well. This startling observation suggests that these cells have reduced ATP levels and thus would probably divide more slowly than wild-type cells. Such is not the case, however, because knockdown cells have a very high rate of glycolysis; normal levels of ATP are therefore generated and the cell division rate at early passages is indistinguishable from wild type. The so-called “Warburg effect” of reduced oxygen consumption and elevated glycolysis was recognized many years ago as a hallmark of cancer cells (Shay and Wright 2000; Gatenby and Gillies 2004; Bensaad and Vousden 2007). Based on the Warburg effect, it might be inferred that CPEB knockdown skin fibroblasts are transformed; this is unlikely to be the case, however, because they are contact inhibited (data not shown). Moreover, the CPEB KO MEFs do not grow in reduced serum, do not show significant anchorage independent growth, and do not form tumors when injected into nude mice (Groisman et al. 2006). In the human CPEB knockdown fibroblasts, it

Figure 8. p53 regulation of senescence and bioenergetics. (A) Proposed pathway in which CPEB, at least in part, influences senescence, telomere maintenance, and bioenergetics. (B) Western blot showing a shRNA-directed ∼50% knockdown of p53, which inhibits the expression of p21. (C) Growth curves of wild-type cells or cells infected with shp53 or GSE-22. (D) Oxygen consumption in cells infected with a nonsilencing shRNA, shp53 RNA, or GSE-22, a p53 inhibitory peptide. (E) Relative ROS levels in wild-type or shp53-infected cells. (F) Levels of lactate in wild-type and shp53 knockdown cells. (G) Western blot of SCO2 in CPEB and p53 knockdown cells.
seems likely that the Warburg effect is due to reduced levels of p53 [Fig. 8; Matoba et al. 2006]. In p53-null or even hypomorphic cells, aerobic respiration is reduced and glycolysis is elevated. One downstream gene whose expression was recently reported to be regulated by p53, synthesis of cytochrome oxidase 2 [SCO2], may be responsible for several of these changes in energy metabolism [Matoba et al. 2006]. This protein is necessary for assembly of the multiprotein cytochrome C oxidase (COX) complex, which forms the molecular foundation for oxidative phosphorylation. Indeed, SCO2 is reduced in CPEB as well as p53 knockdown cells [Fig. 8], which probably is responsible for the lowered respiration and elevated glycolysis. However, there are likely to be a number of mRNAs whose translation is misregulated in cells that lack CPEB, some of which are likely to contribute to the senescent bypass and/or the Warburg effect. In this vein, Wajapeyee et al. (2008) recently identified a growth factor, IGFBP7, and 16 additional factors that control BRAF-induced senescence. In MEFs, CPEB is necessary for Ras and probably BRAF-induced senescence, suggesting that mRNAs encoding some of these factors might be under the translational control of CPEB. We are presently investigating whether the translational regulation of other mRNAs modulates senescence.

Materials and methods

Cells and culture conditions

Primary human foreskin fibroblasts were obtained from the Cell Culture Core Facility of the Yale University Skin Disease Research Center and cultured as described (Rangarajan et al. 2004) in Dulbecco’s Modified Eagle’s Medium (DMEM) containing 10% fetal calf serum. About 10⁶ cells, counted with a hemocytometer following treatment with trypsin blue, were passaged every 3 d. Human lung WI-38 fibroblasts were cultured in a 5% CO₂ atmosphere for 8–12 h with viral supernatants using Lipofectamine 2000 (Invitrogen). Human cells at 50% confluency were infected for 8–12 h with viral supernatants containing 7 µg/mL polybrene. Typically 70–90% infection efficiency was achieved as assessed by using a GFP-encoding plasmid. The concentration of lactate in 40,000 cells was measured as described by Chang et al. (1992); the NADH produced by the reaction was measured by the procedure can be found in the supplemental Material.

Virus production, infection, and cell lines

Amphotrophic retroviruses and lentiviruses were produced by transient transfection of 293T cells with a transfer vector and amphotrophic packaging plasmids encoding VSV-G and gag-pol using Lipofectamine 2000 [Invitrogen]. Human cells at 50% confluency were infected for 8–12 h with viral supernatants containing 7 µg/mL polybrene. Typically 70–90% infection efficiency was achieved as assessed by using a GFP-encoding viral gene or by immunostaining cells using anti-HA (Covance). Metaphase chromosomes from wild-type, shTETR-, and shCPEB-infected cells were prepared as described [Henegariu et al. 2001] and blocked with COT1 DNA and hybridized with 50 ng of a locked nucleic acid (LNA) probe [5’TAGGGTTAGGGT TACGG; locked nucleotides are underlined] that was 3’-end-conjugated with Cy3.

RNA analysis

To examine the p53 mRNA poly[A] tail, total RNA (300 ng) was preannealed with 5’-phosphorylated oligo d[T]₉ [20 ng/mL] followed by RT with an oligo d[T]₉ anchor primer [5’-GCTTCA GATCAAGGTTAGGGGTTAGGG; locked nucleotides are underlined] that was 3’-end-conjugated with Cy3.

Analysis of p53

Control and shCPEB-infected fibroblasts were cultured in methionine and cysteine-free media [Invitrogen] for 45 min and then cultured in media containing 140 µCi [³⁵S] methionine and ³⁵S cysteine (ProMix, Amersham) for 30 min. The cells were then washed and cultured in fresh DMEM supplemented with 2 mM each methionine and cysteine for the times indicated. The cells were then frozen and stored until they were lysed and used to immunoprecipitate p53 [DO-1 antibody, Neomarkers], which was analyzed by SDS-PAGE and PhosphorImaging. Details of the procedure can be found in the supplemental Material.

Bioenergetics

To measure oxygen consumption, ~4 x 10⁵ cells were washed and resuspended in 200 mL of Krebs-Ringers solution plus HEPES (125 mM NaCl, 1.4 mM KCl, 20 mM HEPES at pH 7.4, 5 mM NaHCO₃, 1.2 mM MgSO₄, 1.2 mM KH₂PO₄, 1 mM CaCl₂) containing 1% BSA. Cells from each condition were aliquoted into a BD Oxygen Biosensor System plate (BD Biosciences) in triplicate. Plates were assayed on a SAFIRE multimode microplate spectrophotometer [Tecan] at 1-min intervals for 60 min at an excitation wavelength of 485 nm and emission wavelength of 630 nm.

Lactate assay

The concentration of lactate in 40,000 cells was measured as described by Chang et al. (1992), the NADH produced by the
conversion of lactate to pyruvate by lactate dehydrogenase was measured at 340 nm using a SAFIRE multimode spectrophotometer (TECAN).

ATP
ATP concentrations were determined using a CellTiter-Glo Luminescent Cell viability assay kit (Promega) by first plating ~40,000 cells in 96-well format plate and following the manufacturer’s instructions.

Mitochondria
Images were obtained from live cells plated on coverslips after incubating them with 500 nM Mitotracker-Red (Molecular Probes). Cells were stained cells for 20 min in 10% FBS, DMEM, 5% CO2 using a Zeiss AxioVert 200M Confocal with a PerkinElmer UltraView Spinning Disc. Images were analyzed with Metamorph and Imaris software, similar to Kang et al. (2007).

ROS
ROS levels in 80,000 cells were determined by using 10 µM CM-H2DCFDA (dichlorodihydrofluorescein diacetate) (Invitrogen) in Krebs-Ringer bicarbonate buffer (Sigma-Aldrich). Using a Tecan plate reader, CM-H2DCFDA was excited at 485 nm and detected at 530 nm with a 4 x 4 pattern reader.

Detailed procedures
Details of all procedures are found in the Supplemental Material.

Acknowledgments
We thank Richter laboratory members—in particular, Stephanie Nottrott, Kiran Padmanabhan, Jongsun Lee, Maryia Iyshima—for discussions and technical advice. Additionally, we thank Alen Lofsky, Kenkichi Masutomi, Mark Riddle, Chun Ting Chen, Sambra Redick, Xiarong Shi, Pedia Sekaric, and the Craig Peterson and Silvia Corvera laboratories for sharing equipment and protocols. Special thanks are given to Eric Campeau for his expert technical advice and generosity in sharing reagents. We thank Ittai Ben-Porath, Kenkichi Masutomi, Jack Rosa, Chun Ting Chen, Zhiyong Gao, and Maryia Iyshima for providing antibodies. We thank Richard Rosen for sharing equipment and protocols. This work was supported by NIH grant AG03032. Additional core support from the Diabetes and Endocrinology Research Center Program Project (DK32520) is gratefully acknowledged.
