Abstract: Black pigmented conidia of Aspergillus niger give rise to micro-colonies when incubated in liquid shaken medium. These micro-colonies are heterogeneous with respect to gene expression and size. We here studied the biophysical properties of the conidia of a control strain and of strains in which the fwnA, olvA or brmA gene is inactivated. These strains form fawn-, olive- and brown-coloured conidia, respectively. The ΔolvA strain produced larger conidia (3.8 μm) when compared to the other strains (3.2–3.3 μm). Moreover, the conidia of the ΔolvA strain were highly hydrophilic, whereas those of the other strains were hydrophobic. The zeta potential of the ΔolvA conidia in medium was also more negative when compared to the control strain. This was accompanied by the near absence of a rodlet layer of hydrophobins. Using the Complex Object Parametric Analyzer and Sorter it was shown that the ratio of individual hyphae and micro-colonies in liquid shaken cultures of the deletion strains was lower when compared to the control strain. The average size of the micro-colonies of the control strain was also smaller (628 μm) than that of the deletion strains (790–858 μm). The size distribution of the micro-colonies of the ΔolvA strain was normally distributed, while that of the other strains could be explained by assuming a population of small and a population of large micro-colonies. In the last set of experiments it was shown that relative expression levels of gpdA and AmyR and XhrR regulated genes correlate in individual hyphae at the periphery of micro-colonies. This indicates the existence of transcriptionally and translationally highly active and lowly active hyphae as was previously shown in macro-colonies. However, the existence of distinct populations of hyphae with high and low transcriptional and translational activity seems to be less robust when compared to macro-colonies grown on solid medium.

INTRODUCTION

Aspergillus niger is abundant in nature and an important industrial microorganism because of its ability to secrete large amounts of proteins and metabolites such as citric acid (Finkelstein et al. 1989, Conesa et al. 2001, Punt et al. 2002, Papagianni 2007, Andersen et al. 2011). Submerged growth of A. niger in liquid medium results in dispersed mycelium, in clumps or in micro-colonies known as pellets. The morphology of the mycelium impacts the production of enzymes and metabolites. For instance, micro-colonies are needed for the production of citric acid by A. niger (Gómez et al. 1988). It has also been shown that formation of large pellets coincides with increased extracellular glucoamylase activity and reduced extracellular protease activity (Papagianni & Moo-Young 2002). The mechanisms underlying the impact of morphology on productivity is not yet clear. Possibly, the effect of the fungal morphology on the viscosity of the medium plays a role (Bhargava et al. 2003). Large micro-colonies give rise to low viscosity, whereas dispersed mycelium results in a high viscosity. At the same time, the center of large pellets may experience oxygen starvation and other nutrients may also become limiting in this part of the mycelium (Gómez et al. 1988). These gradients are expected to be less pronounced during dispersed growth.

Conidia are used to inoculate liquid cultures of A. niger. Micro-colony formation is the result of a two-step aggregation process. First, conidia aggregate. This is followed by aggregation of germ tubes (Lin et al. 2008). Initial pH, agitation, and medium composition influence the degree of coagulation of conidia (Metz & Kossen 1977). Pellet formation can also be manipulated by changing the surface properties of the conidia. Formation of micro-colonies was affected in strains of Aspergillus nidulans in which either or both dewA and rodA were inactivated (Dynesen & Nielsen 2003). The effect was strongest when both hydrophobin genes were inactivated and this correlated with increased wettability of the mutant conidia. The pigment aspergillin that is contained in the cell wall of A. niger conidia may also directly or indirectly influence surface properties of the spore. Part of aspergillin is melanin. The pptA, fwnA, olvA and brmA genes have been shown to be involved in melanin synthesis in A. niger. Conidia of the ΔpptA strain are white due to the absence of phosphopantetheinyl transferase activity. This activity is required for activation of polyketide synthases (PKSs). In fact, inactivation of pptA abolishes synthesis of all polyketides and non-ribosomal peptides (Jørgensen et al. 2011). The phenotype of this gene can therefore be considered pleiotropic. Gene fwnA encodes a polyketide synthase. Inactivation of this gene results in fawn-coloured conidia. The ΔolvA and ΔbrmA strains produce olive-
and brown-coloured conidia, respectively. The function of \( \text{BrnA} \) is not yet known. The protein encoded by \( \text{olvA} \) is highly homologous to the \( \text{A. fumigatus} \) \( \text{Ayg1} \) protein. \( \text{Ayg1} \) converts the heptaketide naphthopyrone \( \text{YWA1} \) into 1,3,6,8 tetrahydroxynaphtalene, which is further modified in the DHN pathway to produce melanin (Fujii et al. 2004).

Micro-colonies formed by a wild-type strain of \( \text{A. niger} \) are not homogenous in size and gene expression (de Bekker et al. 2011b). Flow cytometry showed that a population of small and a population of large micro-colonies can be distinguished in a liquid culture. Similarly, populations of micro-colonies were detected that either highly or lowly express the glucoamylase \( \text{gpdA} \) gene. The population of pellets lowly expressing \( \text{gpdA} \) was over-represented and did only partly overlap with the population of small micro-colonies. It was also shown that zones within a micro-colony are heterogenic with respect to RNA content. The hyphae at the periphery of the colony would contain 50 times more RNA than those in the center of 1-mm wide micro-colonies (de Bekker et al. 2011a). Hyphae could even be heterogenic within a zone of a micro-colony. At least, this is the case at the periphery of macro-colonies of \( \text{A. niger} \). It was shown that in this zone two populations of hyphae could be distinguished. One population has a high rRNA content and highly expresses the glyceraldehyde-3-phosphate dehydrogenase gene \( \text{gpdA} \) and genes encoding secreted proteins. The other population is characterised by lower rRNA content and lowly expresses \( \text{gpdA} \) and genes encoding secreted proteins (Vinck et al. 2005, 2011). Recently it was shown by whole genome expression analysis that neighboring hyphae at the periphery of the colony are characterised by differences in their RNA profile (de Bekker et al. 2011a).

Here, the role of the conidial pigment in heterogeneity between micro-colonies was studied. Moreover, it was assessed whether hyphae at the periphery of micro-colonies are heterogenic with respect to expression of \( \text{gpdA} \) and genes encoding secreted proteins.

### MATERIALS AND METHODS

#### Strains and culture conditions

All strains used in this study are derivatives of \( \text{A. niger} \) N402 (Table 1). CB-A111.1 is a derivative of \( \text{A. niger} \) N593 (Goosen et al. 1987), which contains pGW635 (Goosen et al. 1989) resulting in uridine prototrophy. Cultures were grown at 30 °C. Conidia were isolated with saline Tween (0.5 % NaCl and 0.005 % Tween-80) from 3 day old cultures. The conidia of CB-A111.1 and the pigmentation mutant strains were isolated from cultures that had been grown on solid complete medium (MM (see below) with 2 g/L tryptone, 1 g/L casamino acids, 1 g/L yeast extract, 0.5 g/L yeast ribonucleic acids and 1 % glucose). Conidia of strains in which reporter constructs had been introduced were isolated from cultures grown on minimal medium (de Vries et al. 2004) containing 50 mM glucose (CB-A114.2, CB-A114.22, CB-A115.3, CB-A115.9, CB-A116.2 and CB-A116.11) or 200 mM xylose (CB-A117.1, CB-A117.5, CB-A118.24, CB-A118.28, CB-A121.4 and CB-A121.7) to prevent the conidia to become fluorescent. Liquid cultures used to assess heterogeneity had been inoculated with 1.5 × 10⁷ conidia and had been grown for 16 h at 250 rpm in 1 L Erlenmeyers in 250 mL transformation medium (TM) (Kusters-van Someren et al. 1991) with 25 mM of carbon source. Glucose was used to assess heterogeneity in micro-colony size and maltose (CB-A121.4 and CB-A121.7), xylose (CB-A114.2, CB-A114.22, CB-A115.3, CB-A115.9, CB-A116.2 and CB-A116.11) or a combination of xylose and maltose (CB-A117.1, CB-A117.5, CB-A118.24 and CB-A118.28) was used to assess heterogeneity at the hyphal level. To induce fluorescence of reporter proteins for heterogeneity studies, 5 mL of culture was transferred for 6 h to 50 mL minimal medium in 250 mL Erlenmeyers with the same carbon source as the preculture.

### Microbial adhesion to hydrocarbons (MATH) assay

Conidia were tested for hydrophobicity with the MATH assay as described (Smith et al. 1998). In short, the optical density (OD) was determined at 470 nm before and after extraction with hexadecane. The hydrophobicity index (HI) was calculated using the formula:

\[
\text{HI} = \frac{(\text{OD}_{\text{before}} - \text{OD}_{\text{after}})}{\text{OD}_{\text{before}}}
\]

#### Zeta-potential

The zeta potential of conidia was obtained by particulate micro-electrophoresis with a Lazer Zee meter 501 (PenKem, Bedford Hills, N.Y.). The micro-electrophoresis chamber was filled with 30 mL spore solution (10⁶–10⁸ conidia/mL TM or 100-times diluted TM) and a voltage difference of 150 V was applied. Conidia were detected by scattering of incident laser light. Image analysis revealed the velocity of conidia and zeta potentials were derived using the Smoluchowski equation (Hiemenz 1977).

Microscopy

GFP and dTomato expression was studied by confocal laser scanning microscopy (CLSM). Micro colonies were imaged with an inverted Zeiss LSM 5 system using a Plan-Neofluar 16x/0.5 oil immersion lens. GFP and dTomato were excited using a 488 nm and a 543 nm laser, respectively. GFP fluorescence was detected with a 505–530 nm band pass filter, while a 560 nm long pass filter was used in the case of dTomato. Under- and over-exposure was prevented by adjusting gain and amplifier offset settings. Images were captured as a z-stack of optical slices using the multi-track scanning mode (optimal interval 2.02 mm; 4x line average; 8 bit scan depth). Subsequently, the z-stack was projected with maximum intensity (1024 x 1024 pixels) using Zeiss software.

Image analysis

Hyphal fluorescence was quantified as described (Vinck et al. 2011). In short, the intensity of GFP was calculated with KS400 software by selecting hyphae in the green channel. The mask was copied to the red channel to determine the corresponding dTomato fluorescence. A custom Python script was used to correlate intensity of GFP and dTomato. Areas less than 100 mm² were discarded. For each channel the signal was normalised by dividing the hyphal fluorescence by the total green or red fluorescence for that picture. The Pearson correlation coefficient between GFP and dTomato was calculated for the normalised data.

Flow cytometry using the COPAS PLUS

Samples of 5 mL were taken from 16-h-old liquid shaken cultures and fixed for 20 min in 70 % ethanol (EtOH) in a final volume of 50 mL. The EtOH was removed by washing twice in excess PBS. Micro-colonies were allowed to settle in between the washing steps. Micro-colonies were analysed based on extinction (EXT) and Time of Flight (TOF) using a COPAS PLUS equipped with a 1 mm nozzle (Union Biometrica) and a 488 nm solid state laser. The TOF depends on the Feret diameter.

Electron microscopy

Cryoscanning electron microscopy was performed to determine the size and ornamentation of conidia. To this end, a 1 µL spore solution was dried on 4 % water agar. Small cubes (3 x 3 mm) of agar were excised and transferred to a copper cup for snap-freezing in nitrogen slush. Agar blocks were glued to the copper surface with frozen tissue medium (KP-Cryoblock, Klinipath, Duiven, Netherlands). Samples were examined in a JEOL 5600LV scanning electron microscope (JEOL, Tokyo, Japan) equipped with an Oxford CT1500 Cryostation for cryo-electron microscopy (cryoSEM). Ice was removed from the sample surface by sublimation at -85 °C. Electron micrographs were acquired from uncoated frozen samples using an acceleration voltage of 3 kV and 30 averaged fast scans (SCAN 2 mode). Rodlets were viewed with a field emission scanning electron microscope equipped with a through lens detector at 5 kV and a working distance of 3.5 mm (FEI, www.fei.com). To this end, fresh conidia were attached on a carbon adhesive stub and sputter coated with a 9 nm Pt/Pd layer.

Statistical analysis

A two-way ANOVA with Tukey post-hoc test (p < 0.05) was used to assess statistical significance of differences in hydrophobicity, zeta potential and diameter of conidia as well as differences in micro-colony heterogeneity. To assess whether distributions in size or fluorescence can be explained by a mixture of two normal distributions the data was modelled in the probability distribution \( \Phi : \Phi(x) = pN(x; \mu_1, \sigma_1) + (1-p)N(x; \mu_2, \sigma_2) \) (Vinck et al. 2005). In this model, \( \mu_1 \) and \( \mu_2 \), \( \sigma_1 \), and \( \sigma_2 \) represent the means of the populations, \( \sigma_1 \) and \( \sigma_2 \) their standard deviations and \( p \) the participation fraction. The five parameters in the model \( (\mu_1, \sigma_1, \mu_2, \sigma_2, p) \) were fit to empirical data by means of the maximum likelihood principle. 95 % confidence interval estimates were obtained by means of bootstrapping (1000 replicates) and refitting with the model using the open source Scilab language. The scripts of the Scilab functions are available at http://web.science.uu.nl/microbiology/links/index.html.

RESULTS

Surface characterisation of conidia of the wild-type strain and melanin mutants.

Hydrophobicity of the conidia of the control strain CB-A111.1 and the pigmentation mutant strains \( \Delta fwnA \), \( \Delta olvA \), and \( \Delta brnA \) was determined by the MATH assay. To this end, aqueous suspensions of conidia were extracted with hexadecane. The ratio of conidia in the aqueous solution before and after hexadecane extraction was determined by the \( \text{OD}_{470} \) resulting in a hydrophobicity index (HI) between 0–1. Values ≤ 0.7 are considered hydrophilic (Holder et al. 2007). Conidia of CB-A111.1 and the \( \Delta fwnA \) and \( \Delta brnA \) strains had a HI between 0.65 and 0.77. Their values were not significantly different (Fig. 1A). In contrast, the HI of conidia of the \( \Delta olvA \) strain was 0.13 showing that these spores were highly hydrophilic.

Surface charge, as assessed by the zeta potential, of the conidia of CB-A111.1, \( \Delta olvA \), and \( \Delta brnA \) ranged between -31 and -41 mV in 100-fold diluted TM medium. Their zeta potential was not significantly different. The conidia of the \( \Delta fwnA \) mutant had a zeta potential of -47 ± 0.7 mV. This value was significantly different from that of the conidia of the control strain but not from that of the other pigmentation mutant strains. Zeta potential of all conidia was at least 4-fold lower in TM medium (used to grow the strains). The zeta potential of the conidia of the control strain (6 ± 1.4 mV) was significantly different. The conidia of the \( \Delta fwnA \) mutant had a HI between 0.65 and 0.77. Their values were not significantly different (Fig. 1A). In contrast, the HI of conidia of the \( \Delta olvA \) strain was 0.13 showing that these spores were highly hydrophilic.

Scanning electron microscopy revealed that the diameter of conidia of 3 d old cultures of the control strain and the pigmentation mutant strains ranged between 3.2 and 3.8 µm. The conidia of CB-A111.1, \( \Delta brnA \), and \( \Delta fwnA \) (3.2–3.3 µm) were significantly smaller than those of \( \Delta olvA \) (3.8 µm). In all cases, the majority of the conidia lacked ornamentations with a width > 200 nm (Fig. 2).

High resolution scanning electron microscopy revealed large areas of 13–16 nm wide rosettes on conidia of all strains except for the \( \Delta olvA \) strain (Fig. 3). In the latter case some thin bundles of rosettes could be distinguished.

Fig. 2. Scanning electron microscopy of conidia from 3 d old colonies of strains CB-A111.1 (A), ΔbrnA (B), ΔolvA (C), and ΔfwnA (D). Bar represents 5 µm.

Fig. 3. Scanning electron microscopy of conidia of 3 d old colonies of strains CB-A111.1 (A, E), ΔbrnA (B, F), ΔolvA (C, G), and ΔfwnA (D, H). Bar represents 5 µm (A–D) and 500 nm (E–H). Rodlets are visible on the conidia of the control, ΔbrnA and ΔfwnA strains and are indicated by white arrows.
Culture profiling by flow cytometry

The control strain CB-A111.1 and the pigmentation mutant strains ΔfwnA, ΔolvA, and ΔbrnA were grown for 16 h in TM as liquid shaken cultures. The resulting micro-colonies were analysed on basis of their diameter as expressed as the time of flight (TOF) in milliseconds (Fig. 4). Individual hyphae were detected in the extinction range between 0–150, whereas micro-colonies were detected above 200. A mixture of hyphae and micro-colonies was observed in the range between 150–200 (Data not shown).

The percentage of events representing individual hyphae was not significantly different in the case of the CB-A111.1 and ΔfwnA strains. They were found to be 64 % and 39 %, respectively (Table 2). The number of individual hyphae was very low in the case of the ΔbrnA and ΔolvA strains (i.e. 6 % and 9 %, respectively). The percentage of events with an extinction between 150 and 200 was relatively low in all cases with a maximum of 6 % for the control strain. The percentage of events representing micro-colonies was 90–94 % in the case of the ΔbrnA and ΔolvA strains. This was statistically different from the values obtained with CB-A111.1 (30 %) and ΔfwnA (60 %) (Table 2). Also, the number of events of the ΔfwnA strain with an extinction > 200 was significantly different from that of the control strain. The average TOF of the micro-colonies (i.e. with an EXT > 200) produced by the control (821) was significantly different from that of the pigmentation mutant strains (1173–1321). Using the formula defined by de Bekker et al. (2011b), the average TOF value of the micro-colonies of the control strain corresponds to a diameter of 628, whereas that of the pigmentation mutants corresponds to 790–858 μm.

In the next step, we assessed whether the size distribution of the micro-colonies was normally distributed. To this end, the TOF of the events > 200 was divided by the mean TOF of the population to normalise the data. Mathematical modelling of the pooled data showed that the size distribution of the micro-colonies within liquid shaken cultures of the CB-A111.1, ΔbrnA, and ΔolvA strains can be explained by two normally distributed populations (Fig. 5 and Table 3). The population of large micro-colonies was underrepresented in the CB-A111.1 and ΔbrnA strains, whereas in the ΔolvA strain this population was over-represented. The ΔfwnA strain did not show a distribution of 2 populations. It should be noted that the average diameter of the two populations of strain CB-B111.1 differed almost 150 μm, whereas this was only 62 and 43 μm in the case of the ΔbrnA and ΔolvA strains. These data show that the ratio of individual hyphae and micro-colonies in liquid shaken cultures are different between the pigmentation mutants and the control strain. Moreover, the size distribution of micro-colonies of the pigmentation mutants is different when compared to the control strain.

Fig. 4. Distribution of diameter (time of flight in milliseconds x 0.4) and optical density (extinction in arbitrary units) of hyphae and micro-colonies of liquid cultures of pigmentation mutants of A. niger and the control strain CB-A111.1. The horizontal lines represent an extinction of 150 and 200. The grey dots in the graphs of the pigmentation mutants represent the events of the control strain.
Correlation of gene expression in *A. niger* strains

Relative expression levels of genes encoding secreted proteins correlate in hyphae at the periphery of macro-colonies (Vinck *et al.* 2011). This was shown by using strains expressing dTomato and GFP from promoters of genes that are regulated by the amylolytic regulator AmyR (*glaA* and *aamA*) and the xylanolytic regulator XlnR (*faeA* and *aguA*). In addition, it was shown that expression of the glyceraldehyde-3-dehydrogenase gene *gpdA* correlated with *faeA*. Here, it was assessed whether expression levels of *gpdA* and genes encoding secreted proteins also correlate in hyphae at the periphery of micro-colonies. To this end, fluorescence of GFP and dTomato was quantified in individual hyphae of strains expressing the reporter genes from the *gpdA* promoter and / or promoters of genes encoding secreted proteins. Expression of genes was not high enough in micro-colonies grown in TM, probably due to the presence of yeast extract. Therefore, fluorescence was induced for 6 h in MM. In general, GFP and dTomato expression resulting from the different promoters correlated in the individual hyphae at the periphery of micro-colonies (Table 4). The highest correlation was found between *faeA* driven GFP expression and *faeA* driven dTomato expression (correlation coefficient 0.8). The lowest correlation (but still highly significant) was found between *faeA* driven GFP expression and *glaA* or *aamA* driven dTomato expression (correlation coefficient of 0.64–0.65). Taken together, expression of *gpdA*, and AmyR and XlnR regulated genes correlate in individual hyphae of micro-colonies.

In the next analysis it was assessed whether the differences in fluorescence intensity of the reporters between the hyphae can be explained by assuming the existence of two distinct populations of hyphae; one highly and one lowly expressing the selected genes. The parameters obtained are the mean, standard deviation and participation fraction of the population lowly expressing GFP or dTomato (*µ*, *σ*, and *p*) and the mean and standard deviation of the population high expressing hyphae (*µ*₂, *σ*₂). The participation fraction of the second population is given by 1-*p*. Confidence intervals of the means were obtained by bootstrapping and refitting with the model. The data can be explained with a normal distribution if the confidence intervals of the means overlap. In the case of absence of overlap and when the CI of *p* is between 0.025 and 0.975, data can be explained by the presence of a bimodal distribution. In all cases, bimodal distributions were obtained (Table 5). However, fluorescence intensity distributions were skewed to the right (Fig. 6). Therefore, fluorescence data were log transformed followed by modelling the data assuming a bimodal distribution (see above). In this case, only 2 out of the 24 cases reporter expression was heterogeneous (Table 6).

**DISCUSSION**

Macro-colonies of fungi with a diameter > 5 cm have been shown to be heterogeneous with respect to gene expression, growth and secretion (Krijgsheld *et al.* 2013). Heterogeneity was not only observed between zones (Wösthen *et al.* 1991, Moukha *et al.* 1993a,b, Masai *et al.* 2006, Levin *et al.* 2007a,b) but even between neighboring hyphae (Moukha *et al.* 1993a, Teertstra *et al.* 2004, Vinck *et al.* 2005, 2011, Etxebeste *et
Heterogenic fungal micro-colonies in *Aspergillus niger*

Table 2. Fraction of individual hyphae and micro-colonies in *A. niger* cultures. Individual hyphae with occasional branches were observed at an extinction ≤ 150. A mixture of hyphae and micro-colonies was observed at an extinction between 150 and 200. Micro-colonies were observed at an extinction > 200. The average size of the micro-colonies (fraction with an extinction > 200) is indicated by the mean TOF. In all cases, standard deviation is indicated.

| Strains      | Events (%) ≤ 150 | Events (%) > 150 – ≤ 200 | Events (%) > 200 | mean TOF micro-colony fraction |

al. 2009, de Bekker *et al*. 2011a). Heterogeneity within a liquid shaken culture has been studied less. Recently, it was described that micro-colonies within a liquid culture of *A. niger* are heterogenic with respect to size and gene expression (de Bekker *et al*. 2011b). Moreover, it was shown that hyphae in the outer zone contain more RNA than hyphae in the central zone of the micro-colony (de Bekker *et al*. 2011b). Here we studied whether pigmentation of conidia, used to inoculate the cultures, impacts heterogeneity in a liquid shaken culture. Moreover, it was assessed whether neighboring hyphae within a liquid shaken culture are heterogeneous with respect to expression of genes encoding GpdA and secreted proteins.

Liquid shaken cultures of *A. niger* that have been inoculated with conidia consist of individual hyphae (either or not with occasional branches) and micro-colonies. In the case of TM medium, these micro-colonies are smaller than 1 mm (de Bekker *et al*. 2011b). The incidence of individual hyphae and micro-colonies was different in the control strain when compared to the pigmentation mutant strains ΔfwnA, ΔbrnA, and ΔolvA. The percentage of events representing micro-colonies was 90–94 % in the case of the ΔbrnA and ΔolvA strains, which was higher than that of ΔfwnA (60 %). All pigmentation mutant strains had a higher incidence of micro-colonies when compared to the control strain CB-A111.1 (30 %). These data show that the control strain forms relatively more single hyphae. This may be due to shearing or to conidia that have germinated later in the cultivation process. It should be noted that the biomass of an individual hypha is less than 0.1 % of that of a micro-colony (de Bekker *et al*. 2011b). Therefore, the biomass of the individual hypha represents maximally a few percent of the culture. This agrees with a study performed with *Aspergillus nidulans* (Dynesen & Nielsen 2003). At pH 5.8 only 0.1 % of the biomass of the culture consisted of free hyphal elements. The percentage increased by lowering the pH of the culture medium. For instance, more than 50 % of the biomass of *A. nidulans* was contained in free hyphae at pH 3.4. The percentage of biomass present in individual hyphae could also be increased by inactivating the hydrophobin genes rodA.
Table 5. Heterogenic gene expression in hyphae of micro colonies without log transformation of the fluorescence intensities of the individual hyphae. Heterogeneity is defined as non-overlapping confidence intervals (CI) of the mean of both populations ($\mu_1$ and $\mu_2$) and a CI of the participation fraction ($pf$) between 0.025–0.975.

and dewA. These mutant strains produce more wettable conidia. However, our results show that wettability of these asexual spores is not correlated per se with an increased incidence of hyphal elements in the liquid shaken culture. Strains ΔbrnA and ΔolvA formed a similar number of hyphal elements. Yet, the conidia of the ΔbrnA strain were hydrophobic, while those of the ΔolvA strain were highly hydrophilic.

The average size of the micro-colonies of the control strain was 628µm, while that of the pigmentation mutants was between 790–858µm. This is of interest for biotechnological applications because of the fact that mycelial morphology determines productivity of the bioreactor (Gomez et al. 1988, Papagianni & Moo-Young 2002, Bhargava et al. 2003). To optimally control productivity one would like to have a homogenous morphology of the mycelium. This is not the case in liquid shaken cultures of A. niger. Liquid shaken cultures of A. niger strains AR9#2 and UU-A005.4 consisted of two populations of micro-colonies. The population of large and small micro-colonies had an average diameter of 595 and 505µm, respectively. Here, we showed that cultures of the control strain CB-A111.1 are characterised by two populations with an average diameter of 608 and 755µm, respectively. The ΔbrnA and ΔolvA strains also formed heterogeneous cultures. However, the average diameter of the population of large and small micro-colonies was less distinct (i.e. 780 and 842µm and 825 and 868µm). The micro-colonies of the ΔfwnA strain were even normally distributed with an average diameter of 818µm. Taken together, the pigmentation mutants form larger and more homogenous micro-colonies than CB-A111.1 and the AR9#2 and UU-A005.4 strains.

The size of micro-colonies is influenced by aggregation of conidia and of germLings (Lin et al. 2008). This implies that the

**Fig. 6.** Representative fluorescence distributions before (A, C) and after (B, D) log transformation of hyphae at the periphery of micro-colonies of strain CB-A118.28 expressing GFP from the ffaA promoter (A, B) and dTomato from the glaA promoter (C, D). A, C and D show non-overlapping CI’s of the means. The scale of the Y-axis is set such that the surface area of the histogram equals 1.
size of micro-colonies depends on the surface properties of both conidia and hyphae. Whole genome expression analysis indicates that btmA, olvA, and fwaA are more than 8 times down-regulated in vegetative hyphae when compared to aerial structures (Bleichrodt et al. 2013). This indicates that the pigmentation genes can only affect the size of micro-colonies via their impact on surface properties of conidia. Conidia of the ΔbtmA and the ΔfwA strains were similar in size and displayed a similar hydrophobicity as the control strain. They did show a trend towards higher negative surface charge as indicated by the zeta potential. The rodlets were still present at the spore surface of these pigmentation mutants. The properties of the conidia of the ΔolvA strain were distinct from that of the control strain. In contrast to conidia of CB-A111.1, conidia of 3 d old cultures of the ΔolvA cultures were larger, more negatively charged, and highly hydrophilic. Moreover, rodlets formed by hydrophobins were almost completely absent. The latter is a remarkable finding. It may be that the pigment in the cell wall of the conidia affects assembly of hydrophobins. Assembly of the SC3 hydrophobin of Schizothyrium commune is promoted by glucan polymers in the cell wall (Scholtemeier et al. 2010). Spore pigments may do the same but the effect may also be indirect for instance by promoting the interaction between glucan and hydrophobin. The differences in biophysical and structural properties of the ΔolvA strain do not result in differences in incidence and size distribution of micro-colonies in the liquid shaken cultures when compared to the other pigmentation mutants. Previously, it has been shown that hydrophilicity of conidia and absence of the rodlet layer contributes to smaller micro-colonies in A. nidulans (Dyneisen & Nielsen 2003). This was not the case in A. niger. Possibly, different mechanisms underlie pellet formation in A. nidulans and A. niger. However, the differences may also be due to different growth conditions. It has been shown that the type and concentration of the carbon source, the levels of nitrogen and phosphate, trace elements, dissolved oxygen and carbon dioxide, as well as pH and temperature affect the morphology of the culture. Moreover, the geometry of the flask or bioreactor, the agitaiton system, the rheology and the type of culture (batch, fed-batch or continuous) impact the morphology of the mycelium (Papagianni 2004).

The periphery of macro-colonies consists of a population of hyphae that show a high transcriptional and translational activity and a population of hyphae that show a lower transcriptional and translational activity (Vinck et al. 2011). Similar results were obtained with micro-colonies formed within liquid cultures. By quantifying fluorescence of the reporters GFP and dTomato it was shown that relative expression levels of gpdA and genes encoding secreted proteins correlated in individual hyphae at the periphery of micro-colonies. As expected, the highest correlation was found when GFP and dTomato were expressed in the same strain from the same promoter (correlation coefficient 0.8). The correlation of expression of the XlnR regulated genes faeA and agraA and the AmyR regulated genes glaA and aamA were also highly significant and ranged between 0.56 and 0.8. Thus, relative expression of gpdA, and AmR and XlnR regulated genes correlate. The distribution of expression of genes encoding secreted proteins can be explained by the existence of two distinct populations of hyphae at the periphery of macro-colonies. The presence of such populations was also observed in micro-colonies. However, the distributions were skewed to the right (i.e. a relatively low number of highly fluorescent hyphae were observed). Log-transformation of the fluorescence intensities resulted in normal distributions of expression of the reporters in most of the cases. In contrast, bimodal distributions were still obtained after log-transformation of fluorescence intensities of individual hyphae at the periphery of macro-colonies of Aspergillus oryzae expressing GFP from the A. niger glaA promoter (G.J. van Veluw, R. Bleichrodt and H.A.B. Wösten, unpubl. results). This indicates that heterogeneity of expression of genes at the periphery of the micro-colonies is less robust as observed in macro-colonies. Possibly, signalling between hyphae is involved in promoting heterogeneity. In contrast to solid media, gradients of signalling molecules cannot be formed between hyphae that are grown in liquid shaken cultures. Growth of individual hyphae in micro-channels may give proof for a role of signalling molecules in heterogeneity of gene expression in aspergilli.
