INTRODUCTION

The primate fronto-striatal system, which plays an important role in temporal coordination of goal-directed behavior, consists of a network of neuronal circuits that integrate spatial and timing information for behavioral purpose (Alexander and Crutcher 1990; Hoshi and Tanji, 2000; Staddon 2001; Miller and Phelps, 2010). Previous studies have demonstrated that pre-movement firing in fronto-parietal cortex and basal ganglia mediates preparation and initiation of both sensory guided and self-initiated movements (Horak and Anderson, 1984; Gardiner and Nelson 1992; Romo et al., 1992; Turner and Anderson, 1997; Lee and Assad 2003; Churchland et al., 2006a; Tsujimoto et al., 2010). In particular, it has been suggested that basal ganglia modulate motor performance (“dynamics” or “movement vigor”) under the effect of motivational factors quantified as context-specific cost/reward functions (for review see Hayden et al., 2008; Turner and Desmurget, 2010). Motor planning involves programming of the direction of movement, the kinematics, and the goal of movement (Kalaska and Crammond, 1995; McCoy and Platt, 2005; Platt and Huettel, 2008; for review Ong and Bruce, 2005). Motor areas of the brain also specify movement vigor which is overtly represented by the reaction time (RT) and the speed with which a movement is performed. The choice of these behavioral parameters is mediated by the activation of midbrain's dopaminergic projections to fronto-parietal cortex and dorsal striatum that track successful and erroneous behaviors and the contingencies between the behaviors and rewards (Romo and Schultz, 1990; Gaspar et al., 1992; Kiyatkin, and Rebec, 1996; Fiorillo et al., 2003).

Although reward probability is an important factor that shapes animal’s behavior, it is not well understood how the brain translates reward expectation into the vigor of movement [reaction time (RT) and speed]. To address this question, we trained two monkeys in a RT task that required wrist movements in response to vibrotactile and visual stimuli, with a variable reward schedule. Correct performance was rewarded in 75% of the trials. Monkeys were certain that they would be rewarded only in the trials immediately following withheld rewards. In these trials, the animals responded sooner and moved faster. Single-unit recordings from the dorsal striatum revealed modulations in neural firing that reflected changes in movement vigor. First, in the trials with certain rewards, striatal neurons modulated their firing rates earlier. Second, magnitudes of changes in neuronal firing rates depended on whether or not monkeys were certain about the reward. Third, these modulations depended on the sensory modality of the cue (visual vs. vibratory) and/or movement direction (flexions vs. extensions). We conclude that dorsal striatum may be a part of the mechanism responsible for the modulation of movement vigor in response to changes of reward predictability.

Keywords: basal ganglia, primate neostriatum, movement planning, decision making, reward, uncertainty, hand movements, movement vigor

Although reward probability is an important factor in shaping animal’s behavior (Herrnstein, 1961; Sugrue et al., 2004), it is not well understood how the cortico-striatal circuits translate reward probability into the vigor of movement. We hypothesized that the dorsal striatum (Putamen and Caudate Nucleus) of primates is part of the system that modulates the movement vigor (i.e., RT and speed), depending on the probability of the expected reward. This hypothesis is supported by the finding that changes in dorsal striatal activity occur shortly after go-cues and clearly earlier than the movements (100–200 ms before movements). Therefore, it is possible that changes in reward expectation are processed by the neostriatum (NS), which biases both motor planning and preparation (Mirenowicz and Schultz 1994; Shidara et al., 1998; Lauwereyns et al., 2002; Simmons and Richmond 2008). Dorsal striatum may be responsible for enhancing movement vigor when rewards are certain and decreasing the vigor when rewards become uncertain (Seideman et al., 1998; Ditterich, 2006; Wittmann et al., 2008; Van der Meer and Redish, 2009; Machens et al., 2010).

To elucidate NS modulations that putatively mediate the translation of reward probability into the changes of movement vigor, we trained two rhesus monkeys in a RT task in which they produced wrist flexions or extensions in response to vibratory and visually cues (Lebedev and Nelson 1999). Trial outcome was made uncertain by rewarding the monkeys for correct performance only in 75% of the trials. Monkeys were uncertain about an upcoming reward in all trials except for the trials that immediately followed withheld rewards. In these trials the monkeys were certain about the outcome because they were always rewarded. Given these trial to trial changes
in reward probability, we determined if the activity of dorsal striatal neurons that was associated with motor preparation, varied as a function of reward expectation and whether it was correlated with changes in movement timing and wrist kinematics.

MATERIALS AND METHODS

EXPERIMENTAL APPARATUS AND BEHAVIORAL PARADIGM

Two adult male rhesus monkeys (Macaca mulatta; E, N) were trained to make wrist flexion and extension movements in response to vibratory or visual go-cues (Lebedev and Nelson 1995, 1999; Liu et al., 2008). The monkeys were cared for in accordance with the National Research Council Guide for the Care and Use of Laboratory Animals. Experimental protocols were approved by the Animal Care and Use Committee of The University of Tennessee Health Science Center, Memphis. Detailed descriptions of the experimental apparatus have been provided elsewhere (Lebedev and Nelson, 1995, 1999; Liu et al., 2005). A brief description is provided below.

Experimental apparatus

Each monkey sat in an acrylic monkey chair, with its right palm on a movable plate. One end of the plate was attached to the axle of a brushless D.C. torque motor (Colburn and Evarts, 1978). A load of 0.07 Nm was applied to the plate. The load assisted wrist extensions and opposed wrist flexions. Feedback of current wrist position was provided by a visual display consisting of 31 light-emitting diodes (LEDs), located 35 cm in front of the animal. The middle, red LED corresponded to a centered wrist position. Yellow LEDs above and below the middle LED indicate successive angular deviations of 1°. Two instructional LEDs were located in the upper left corner of the visual display. When the first, red LED was illuminated at the start of a trial, it indicated that extension movements should be made; otherwise flexions were required. When the second, green LED was illuminated, it informed the monkey that the go-cue for that trial would be palmar vibration; otherwise, the go-cue was the illumination of one of two LEDs which were each 5° from the center. Neuronal activity was triggered by vibratory cues at 57 Hz or by visual go-cues.

Behavioral task

The behavioral paradigm is illustrated schematically in Figure 1A. Monkeys made vibratory and visually cued wrist flexion and extension movements after holding a steady position during an instructed delay period lasting 0.5–2.0 s. Wrist movements were guided by either vibratory cues (VIB-trials) or visual cues (VIS-trials). For vibratory stimulus (VIB) trials, movements were triggered by vibration to the monkey’s palm. For the visual stimulus (VIS) trials, movements were initiated by the appearance of a visual target that indicated the movement endpoint. Trials began when the monkey centered the plate. Each task trial had three basic phases: the instructed delay phase, reaction phase (partition of RT is shown in Figure 1B) and movement phase. Correct performance in the task was rewarded pseudo-randomly in only 75% of the trials, with the unrewarded trials never being imposed sequentially.

Our pseudo-random reward schedule used the following types of trials: (i) unrewarded trials, (ii) trials immediately following the unrewarded ones called after trials ("A" trials), and (iii) rewarded trials, for which the current and the preceding trial were rewarded, called regular (R) trials. We grouped individual trials by the number of previously rewarded trials that preceded each trial in the group, as well as, by the direction of the movement made in that trial. In some instances there were trials in which the animal failed to perform properly (i.e., made a movement in the wrong direction). These error trials are conceptually different from the A trials since rewards were withheld because of incorrect performance rather than arbitrarily. These were marked separately in the data stream, not being under consideration here. For analyses of sequential effects, we required that each group from the records of a neuron have at least four valid trials. If any single group of records had fewer than four trials, the data from that group were not included in the analyses.

Reward probability

The probability of reward was not indicated to the animal except via prior experience. The key manipulation in the task was to distinguish between “certain” rewards that occurred only in trials following withheld rewards (25% of trials), and the “uncertain” rewards occurring in the subsequent 50% of the trials. In Figure 2A we show two blocks of trials with unrewarded (U) and rewarded (“A” being the first rewarded trial and R the subsequent rewards) trials. The unrewarded U trial acts as a cue indicating a certain reward, coded...
as “A” trial. In order to properly address the temporal aspect of movement planning under certain vs. uncertain reward, trials were re-coded to reflect the number of previously rewarded trials that occurred, in sequence, prior to the trial in question. Trials belonging to these groups had been preceded by none, one, two, or three previously rewarded trials in sequence (“A,” S-1, S-2, or S-3). The next trial groups in the sequence usually contain less than four trials, that are not enough to be considered for statistical analyses Thus, as it is shown in Figure 2B (depicting the probability of reward in each group), reward was certain in group “A,” and uncertain in the groups S-1 to S-3 (with reward uncertainty increasing as trials advanced from group S-1 to S-3).

**RESULTS**

A total of 236 neurons were recorded, of these 149 (~63%) were selected for further analysis, because each neuron: (i) had pre-movement activity (PMA) changes following the vibratory or visual go-cue onset and prior to MOS, (ii) had a PMA firing rate that was at least 3 SDs different from the baseline firing rate, and (iii) was held long enough to record at least 25 trials for each movement direction. Of these, 99/149 (~66%) also had a complete set of recordings during visually cued trials. Of the selected NS neurons, 104/149 (~70%) neurons were located in Putamen, 20/149 (~13%) in the Caudate Nucleus, 18/149 (~12%) in the cellular bridges in between these structures and 7/149 neurons were localized in the nearby regions. The total number of neostriatal cells categorized by the cue modality to which they responded (vibratory, VIB; visual, VIS), movement direction (flexions, Flex, extensions, Ext) and reward sequence (A, S-1, S-2, S-3) is shown in Table 1.

**NEOSTRIATAL CELL FIRING FOR CERTAIN AND UNCERTAIN REWARDS**

A significant proportion of neurons in dorsal striatum modulated their firing during this task. Figure 3A shows an example of a striatal neuron with increased modulations in trials with certain rewards (“A” trials). This neuron was recorded from the cellular...
bridge between caudate and putamen. Pre-movement firing is illustrated for vibratory cued trials. The PETHs and spike rasters are aligned on MOS. COS are indicated by blue dots, and reward delivery by red dots. Wrist flexion trials with certain rewards (“A” trials) and the subsequent trials with uncertain rewards (S-1 to S-3) are shown. The PEHs indicate that this neuron’s activity was modulated during both the RT epoch (from COS to MOS) and during movements. Wrist trajectories are shown in Figure 3B. It can be seen that in “A” trials the monkey initiated flexions earlier and moved faster and that the activity of the illustrated neuron was higher during these trials.

Modulation of pre-movement activity by reward uncertainty

It has been suggested that reward probability biases neural activity by altering either the rate or the duration of cell firing (Lauwereyns et al., 2002). Figure 4 illustrates these features for our experiment. Average RT was the shortest for “A” trials, and as the RT “rubber-band” (Renoult et al., 2006) got shorter, so did the timing of the illustrated striatal neuron. For the illustrated striatal neuron, the duration of PMA (i.e., the interval between activity onset, AOS, and MOS) decreased, from 147, 139, and 157 ms in S-1, S-2, and S-3 trials, respectively, to 102 ms in “A” trials. Thus, the change in movement vigor manifested itself as change in RT and wrist velocity and accompanying changes in the timing of a striatal neuron's activity. Note also that the slope of rate change in the striatal neuron increased in “A” trials (compare with similar

Table 1 | Neurons having sufficient trials for timing and activity analyses as a function of reward (un)certainty.

| Sensory modality | Movement direction | Reward | Certain | Uncertain |
|------------------|--------------------|--------|---------|-----------|
|                  |                    | A      | S-1     | S-2       | S-3       |
| VIB              | Flex               | 147    | 149     | 140       | 117       |

FIGURE 3 | Example of dorsal striatal cell recorded under unpredicted reward schedule. (A) Each peri-event histogram illustrates neuronal activity expressed as mean firing rate (in spikes/s), together with raster displays aligned on MOS. The left panel display the NS activity during certain reward trials and the next panels represent the activity during uncertain reward trials. In the raster display, rows represent individual trials, dots represent single spikes, while the left and right bold dots represent vibratory cue onset and reward delivery, respectively. Bin width was equal to 5 ms. (B) Wrist position traces for each flexion trial are presented at the bottom of each panel.

FIGURE 4 | Movement plans as a function of the probability of expected reward. Smoothed peri-event histograms (on the left), aligned on movement onset, represent the pre-movement activity epochs (from the yellow line corresponding to activity onset to MOS) as a function of reward probability (with the certain reward A on top and the sequence of uncertain rewards S-1 to S-3 following below). On the right we show hand position trajectories and movement velocity profiles (averaged across trials) that depict the vigor of movements when reward is certain (top traces) and when reward becomes uncertain (bottom). Abbreviations: MOS, movement onset; AOS, activity onset; COS, cue onset; and MOF, movement offset.
findings in Lebedev et al., 2008). When the reward was certain, RT shortened, wrist velocity increased, the duration of striatal pre-movement firing contracted and the slope of pre-movement modulation increased in the striatum.

**Changes in activity onset time**

We observed several types of neuronal modulations. To describe these types of neuronal patterns, neuronal responses of each cell were sorted by activity onset time (see **Figure 1B**) and grouped into three categories: short, normal and long latencies. In **Figure 5** we compared pre-movement and baseline firing of each latency group for certain (“A” trials) and uncertain rewards (S-1 trials). The short latency group responded with higher pre-movement firing rate (Resp) under VIB and VIS conditions (p < 0.01 for “short” latency and p < 0.05 for “normal” latencies; post hoc test), while the “long” latency group responds with a lower mean firing rate. The baseline firing (Bkg) increased slightly (p < 0.05, post hoc test) in “normal” latency group, compared to the other two groups. For visual cues, the short latency group “A” trials had higher pre-movement firing rate (by ∼5 spk/s) during flexion trials than the S-1 trials (p < 0.01; post hoc test) but not for vibratory cues. These results indicate that modulations in NS neurons reflected changes in movement vigor, as well as movement direction and cue type.

**Modulation of activity timing by reward uncertainty**

To quantify pre-movement timing at the population level for trials with certain and uncertain rewards, we partitioned the RT period (see **Figure 1B**) into latency (R1) and pre-movement epochs (R2; see **Table 2**).

**Pre-movement activity duration.** Pre-movement durations, R2s, increased significantly with the increase in the number of consecutively rewarded trials in vibratory cued trials (**Figures 6A,B**), for both flexion and extension movements (for all conditions p < 0.001; post hoc test, except for A vs. S-2 extensions the level of significance was p < 0.01, post hoc test). R2s increased less with the increase in the number of consecutively rewarded trials for visually cued trials (**Figures 6C,D**), but significantly (p < 0.05; post hoc test) for flexions and for “A” vs. S-3 extension movements (see **Table 2**). The general trend in PMA following withheld rewards was that the duration of pre-movement time became shorter when reward was certain (“A” trials), and longer when reward was uncertain (in the subsequent trials S-1 to S-3). Moreover, we found increased slopes of rate changes in “A” trials (p < 0.01, post hoc test). Thus, changes in reward probability caused both changes in characteristics of behavior (RT and movement speed) and in NS modulations.

**FIGURE 5 | Pre-movement firing activity as a function of onset time.** Mean firing rate for pre-movement activity and baseline are compared between certain reward “A” trials and uncertain reward S-1 trials under vibratory cues (A) VIB–Flex and (B) VIB–Ext and visual cues (C) VIS–Flex and (D) VIS–Ext. Pre-movement activity (Resp) and baseline (Bkg) are in red and blue color lines, respectively. The abscissa category “latency R1” is split into three unequal time intervals: short, normal, and long containing equal neuron numbers. The ordinate is showing the mean firing rate in spikes per second (spk/s) for each category group. Asterisks (*p < 0.05, ** p < 0.01) indicate significant differences in mean firing rates for A vs. S-1 trials.
Table 2 | Activity onset timing. The reaction time interval was divided into R1, which was the time from go-stimulus onset to significant activity change, and R2 (the pre-movement epoch) form activity change until MOS.

| Sensory modality | Movement direction | Certain reward | Uncertain reward |
|------------------|--------------------|----------------|------------------|
|                  |                    | A              | S-1              | S-2              | S-3              |

![Figure 6](image-url)  
**FIGURE 6** | Latency and pre-movement activity durations as a function of reward sequence. Left: Pre-movement durations (mean ± SEM) are plotted for vibratory cues ([A] flexions sequence trials and [B] extensions). Similarly, R2s for visual cues ([C] flexions and [D] extensions). Right: Neural latencies R1s (mean ± SEM) are plotted for vibratory cues ([E] flexions and [F] extensions) and for visual cues ([G] flexions and [H] extensions). The horizontal gray lines represent the temporal bias reference lines (Bias Line in [B]). Temporal selection bias (Bias) is represented on the Time axis in panel b together with the key events: activity onset (AOS) and movement onset (MOS). Numerical values of R1s and R2s are shown in Table 2. Asterisks (*) p < 0.05, **p < 0.001 indicate significant differences in mean pre-movement times for A vs. S-1, S-2, and S-3 trials.

Neural latency: The time epoch in the PETH from cue onset to the onset of firing modulation is called here "neural latency" and corresponds to R1 in Figure 1B. R1s increased slightly with the increase in the number of consecutively rewarded trials in vibratory cued trials (Figures 6E,F), for both flexion and extension movements (for all conditions, p < 0.05, post hoc test, except for “A” vs. S-1 flexions in which the level of significance was p < 0.001). Under visual cues (Figures 6G,H), R1s increased with the increase in the number of consecutively rewarded trials for several conditions (p < 0.05; post hoc test for “A” vs. S-2 and S-3, flexions and also for “A” vs. S-1 and...
S-3 extensions; see Table 2). This suggests that reward uncertainty mediated a “rubber-band” temporal effect (Renoult et al., 2006) for the RT period: when RTs increased, R1s and R2s increased, as well.

Comparison of pre-movement modulations across modality

The parameters of movements and neuronal modulations in the striatum depended on the sensory modality of the go-cue (VIB vs. VIS go-cues). Comparisons of pre-movement times R2s between visual and vibratory cues showed significantly longer R2s (~20–40 ms) for flexions cued by visual VIS stimuli (“A” trials: p < 0.001, unpaired two-tails t-test; S-1, S-2, and S-3 trials: p < 0.01, post hoc test) than those cued by VIB stimulation. Also, R2s for extension were slightly longer (~5–20 ms) when cued by VIS stimuli (“A” trials, p < 0.001, unpaired two-tails t-test) and p < 0.01, post hoc test; S-1, S-2, and S-3 trials: p < 0.01, post hoc test) compared to vibratory VIB cues.

On the other hand, comparisons of R1s across sensory modality showed significantly longer latencies for flexions (VIB vs. VIS cues; “A” to S-3 conditions: p < 0.001, unpaired two-tails t-test; “A” and S-1 trials: p < 0.01, post hoc test) and extensions under vibratory cues (“A” to S-3 conditions: p < 0.001, unpaired two-tails t-test) compared to visual cues. Thus, the temporal bias caused by the changes in reward probability varied differentially with the sensory modality, occurring faster for visual cues than for vibratory stimuli.

The modality effect was reflected also by the monkeys’ behavior in the error trials. The animals made more than four error trials per session (required to be considered for analysis) in 46/198 (23%) visual sessions and in 139/296 (47%) sessions. Of these, flexion trials errors occurred in 94/247 (38%) sessions and extension trial errors in 91/247 (37%) sessions. Thus, animals were more than twice likely to make errors in VIB-trials in which the vibratory cue did not provide a directional instruction than in VIS-trials in which the visual cue clearly indicated such instruction.

Wrist movement velocity varies with reward uncertainty

The changes in wrist velocity with reward probability are shown in Figures 7A–D that depicts the distribution of mean wrist movement velocities across reward conditions. Wrist movements were performed with higher velocities in trials with certain rewards (“A” trials) than in trials with uncertain rewards (S-1 to S-3 trials) for all modalities and directions (p < 0.05; unpaired two-tails t-test, post hoc test). Across modalities (VIS vs. VIB) wrist Flex velocities (Figures 7A,C) were slower with ~2–4°/s than for Ext velocities (Figures 7B,D; p < 0.001; unpaired two-tails t-test, post hoc test).

Correlation between pre-movement time and wrist velocity

Pre-movement changes in duration were correlated with RTs, MTs, and hand wrist velocity (Figures 8 and 9). The changes in reaction time and pre-movement activity duration. As shown in Figure 6, both components of the RT: latency R1 and pre-movement duration R2 show a clear dependency on reward probability which followed the previously
Correlation between movement time and pre-movement activity duration. To examine whether PMA duration was correlated with movement parameters, we calculated Pearson correlation coefficients between these two variables. Figure 8A shows a linear dependence of Flex MTs on R2s under VIB cues reflected in the correlation coefficients \( r = 0.259 \) for S-1, \( r = 0.336 \) for S-2, \( r = 0.385 \) for S-3. Similarly under VIS cues (Figure 8B), the coefficients values were \( r = 0.265 \) for S-1, \( r = 0.335 \) for S-2, \( r = 0.250 \) for S-3. Pearson’s coefficients were statistically significant for S-1 to S-3 trials (\( p < 0.05 \)) in both modalities (VIB and VIS), but not significant for “A” trials in which R2s were more stable.

Correlation between mean wrist velocity and pre-movement time across sensory modality and movement direction. We found a consistent correlation between wrist velocity and pre-movement time in NS neurons across sensory modalities and movement directions (shown in Figure 9) and clustered within the same modality/direction category. This relationship was noticeable when Pearson correlation between pre-movement duration and average wrist movement velocity (Figure 9) were examined across reward groups (\( n = 4 \)) under both VIB and VIS cued flexions (\( r = -0.999, p = 0.001 \); two-tailed). Extension movements performed under VIB cues (\( r = -0.989, p = 0.011 \)), and VIS cues (\( r = -0.991, p = 0.009 \)) revealed this effect. Thus,
in a consistent manner, average wrist velocity decreased in cohort with the increase in the pre-movement duration across modalities.

**Variability in movement planning induced by reward unpredictability**

The coefficient of variation (CV) represents the ratio between SD and the mean. We compared the degree of variability in neural/behavioral measures (latency, PMA time, RT, and MT) between certain and uncertain rewards. Figure 10A shows a sequence of spike rasters indicating the increase in variability of event timing as a function of reward uncertainty. The CVs in Figure 10B indicate that variability in pre-movement time (R2) tended to be higher than that in latency (R1) and MT. Such increase in CVs may be explained by variations in reward unpredictability.

**DISCUSSION**

In the present study we recorded the activity of neostriatal neurons in two rhesus monkeys performing wrist movements in a pseudo-random reward task. We analyzed the PMA and behavioral data under three conditions: (a) certain vs. uncertain rewards, (b) vibratory vs. visual go-cues, and (c) flexion vs. extension movements. Our results show that both PMA of most dorsal striatal neurons and wrist movement parameters changed as a function of reward contingency (results published in abstract form, Nelson et al. 1996, 1997).

Pre-movement modulations in dorsal striatal neurons have been hypothesized to be related to movement planning (Alexander and Crutcher 1990; Hoshi and Tanji, 2000; Hori et al., 2009). In our experiments, the magnitude of pre-movement firing did not change substantially across reward conditions, likely because monkeys produced movement of similar amplitude. What changed instead were the RTs, the onsets of the modulation in the firing rates of dorsal striatal neurons and the slopes of their rate changes. These changes in neural timing also manifested themselves as alterations of neural latency and pre-movement time, in agreement with Mirenowicz and Schultz (1994) and Blazquez et al. (2002). Thus, reward probability affected both bottom up sensory processing reflected by neural latency and the top down flow of information through the basal ganglia-thalamocortical loops expressed as pre-movement time, rate, and rate slope.

**UNPREDICTABLE REWARD AND THE ACTION/MOVEMENT PLAN**

*Does reward expectation modulate the temporal and kinematic parameters represented by a movement plan?* It is well documented that reward schedule is a key factor in the shaping of animal’s behavior (Herrnstein, 1961; Staddon 2001; Sugrue et al., 2004). According to Herrnstein’s matching rule, an animal’s choice optimizes reinforcement probability, so that the choice matches the probability of reinforcement (Herrnstein, 1961; Sugrue et al., 2004; Lau and Glimcher, 2008; Platt and Huettel, 2008). To modulate the timing of a movement plan the brain evaluates the utility of each option and selects the most valuable action (Seideman et al., 1998; Schall, 2003; Samejima et al., 2005; Maimon and Assad, 2006; O’Shea et al., 2007; Pasquereau et al., 2007; Horikoshi et al., 2009), by activating neuronal circuits in fronto-parietal cortex, striatum, and the subcortical regions in the brain (Simmons and Richmond, 2008; Opris et al., 2009; Hikosaka and Isoda, 2010; Tsujimoto et al., 2010; Turner and Desmurget, 2010).
Our results show changes in pre-movement firing (Figure 5) and timing (Figure 6) in dorsal striatum with reward expectation, suggesting that NS is involved in the modulation of movement vigor (Mirenowicz and Schultz, 1994; Blazquez et al., 2002; Turner and Desmurget, 2010). Manipulations of reward probability produced both types of changes (in motor parameters and in neurological modulations) in our experiments. When reward was uncertain MOS shifted in time (away from COS) and movement was initiated after a delay of ~30–60 ms (depending on sensory modality and movement direction; Figure 6). Conversely, when reward becomes certain wrist movements were initiated sooner. The velocity of wrist movements increased when reward was certain and decreased when reward became uncertain, showing evidence for a role of reward contingency in movement "vigor" modulation (Figures 4 and 7). These changes in movement parameters were linked to changes in dorsal striatal activity as a function of reward probability. Our results show that changes in PMA and movement velocity were correlated (Figure 9). Thus, such correlation provides evidence for a linkage between movement vigor and the optimization (discounting) of action-based reward value in time (Shadmehr et al., 2010).

ROLE OF BASAL GANGLIA ACTIVITY IN MOVEMENT VIGOR AND TEMPORAL BIAS

Horak and Anderson (1984) and more recently Turner and Desmurget (2010) have suggested that basal ganglia influence the "vigor" of movements.

Relationship to movement vigor

It is reasonable to suggest that when a monkey is expecting a reward it becomes more "excited" and moves more quickly toward the goal than when the reward becomes uncertain. An uncertain reward, on the other hand, will only reduce animal's vigor. Dorsal striatum likely has a role in the modulation of movement vigor, as suggested by the study showing that it mediates cortical signals necessary for behavioral switching (Hikosaka and Isoda, 2010). Thus, dorsal striatal circuits may modulate movement vigor through a switch that is related to the reward mechanism and differentially biases movements (Ding and Hikosaka, 2007). Therefore, based on the pre-movement timing, dorsal striatum cells may modulate movement vigor before the pallidal cells do (Horak and Anderson, 1984; Turner and Desmurget, 2010).

Temporal bias

We define temporal bias as a temporal shift in movement initiation with respect to the cue onset. Such bias may have a role in the "proactive timing of action" (Maimon and Assad, 2006). Our data (Figures 5A–D) show a temporal bias in the pre-movement timing as a function of reward expectation. When the reward was certain, a temporal shift in MOS caused the movement to occur sooner, and when it was uncertain the MOS came later. Consequently, the velocity of movement became faster in trials with certain rewards or slower when the reward was uncertain. Changes in temporal bias and accompanying changes in striatal activity that we observed here are somewhat analogous to the well-known modulations of behavioral choices and selections by caudate-putamen and other components of the basal ganglia-thalamo-cortical loops that act as switches between the representations of many behavioral degrees of freedom (Redgrave et al., 1999; Salinas et al., 2000; Kimura et al., 2003; Schall, 2003; O'Shea et al., 2007). The difference between the selection and temporal bias is that selection involves choosing between discrete options whereas the temporal bias represents a continuous modulation of motor preparation.

ANALOGIES BETWEEN TEMPORAL BIAS AND COVERT CHOICE

Consistent with the free choice hypothesis, a decision mechanism may select an option based on (i) reward value, (ii) knowledge from previous experience, and (iii) the accumulation of sensory evidence (for review see Schall, 2003; Opris and Bruce, 2005; Padoa-Schioppa and Assad, 2006; Beck et al., 2008; Platt and Huettel, 2008). In our experiment there are faster or slower movements and certain vs. uncertain rewards, with the certain reward having a higher value than the uncertain one. Also, the previous "no-reward" trial acts as a cue indicating a certain reward in the current trial, thus providing the prior information. Since reward availability/probability is not indicated by an instruction cue, no sensory accumulation occurs and the choice is covert.

COMPARISON WITH OTHER STUDIES

Previously, Lauwereyns et al. (2002) identified neurons in the primate Caudate Nucleus that create a spatially selective "response bias." Their response bias was associated to the spatial location of the visual target. In our case the bias signal (triggered by the uncertainty of reward) is associated to the temporal dimension because it affects the onset of movement initiation and the velocity of wrist movements (Seideman et al., 1998; Frederick et al., 2002; Ditterich, 2006; Machens et al., 2010). Looking from the value of the action perspective (Samejima et al., 2005; Lau and Glimcher, 2008; Hori et al., 2009) a certain reward has a higher value and it is likely to activate the selection circuitry of faster movements, while an uncertain reward carries a lower value and will activate the circuitry for slower movements (Samejima et al., 2005; O'Shea et al., 2007; Shadmehr et al., 2010). The difference in timing between fast and slow pre-movement times is 30–60 ms, but long enough for a decision to take place (Schall, 2003; Stanford et al., 2010).

Another aspect of movement planning under uncertain reward deals with pre-movement variability (Figure 10). Movements are planned such that their variability gets minimized (Harris and Wolpert, 1998; Mohr and Nagel, 2010). Churchland et al. (2006b) argues that variability in arm movements originates mostly in central movement planning. In our experiments, the sources of variability for RTs, especially of pre-movement times (as shown in Figure 10B) are coming from changes in reward probability. These results support the idea that reward contingency contributes to the variability in movement planning and in wrist movement trajectories.

RELEVANCE TO NEUROECONOMICS

Our study is relevant to the neuroeconomics field for the dissociation of movement planning (“vigor” and temporal bias) in dorsal striatum under certain vs. uncertain rewards. A vigorous (forceful) movement can be viewed as a “valuable investment,” being engaged only when the monkey is sure about a trial’s outcome. Indeed, fast movements are somewhat more expensive since they involve more muscle contraction, probably more brain and energy resources. In other cases the monkey moves slowly, because the animal has “invested” less in that action (Kim et al., 2008; Shadmehr et al., 2010).
Action planning and choice under uncertain conditions are risky and difficult since no plan of action is available to the decision maker for a specific outcome (Kim et al., 2008; Platt and Huettel, 2008). From our results emerges a clear clue that an increase in reward uncertainty delays a plan for action, while a switch from uncertain to certain rewards speeds up the plan to act. In fact, this is another pointer to neuroeconomics, based on the fact that velocity of wrist movements increased when reward was certain and decreased when reward became uncertain. This provides evidence for optimization vs. discounting of action in time based on reward value (Shadmehr et al., 2010).

In conclusion, our results show several important features of a motor planning mechanism depending on reward contingency, providing evidence for a neural substrate of movement “vigor” planning in dorsal striatum. First, in the trials with certain rewards, striatal neurons modulated their firing rates earlier. Second, pre-movement changes in firing rate timing are correlated with the MTs and wrist movement velocity. Third, these modulations depended on the sensory modality of the cue (visual vs. vibratory) and/or movement direction (flexions vs. extensions). Finally, the motor planning mechanism in dorsal striatum may be responsible for the modulation of movement “vigor” according to reward contingency.

ACKNOWLEDGMENTS

The authors wish to thank John M. Denton who assisted during the gathering of data that was presented in this manuscript, to John E. R. Staddon, D. James Surmeier, and Charles J. Wilson for detailed comments on versions of this manuscript and to Michael Platt and Scott Huettel for insightful discussions. We would also like to thank the two reviewers for their insightful suggestions. This work was supported by NIH Program Project Grant NS26473, and conducted under the auspices of a project thereof under the direction of Randall J. Nelson.
