OTULIN inhibits RIPK1-mediated keratinocyte necroptosis to prevent skin inflammation in mice

Hannah Schünke1,2, Ulrike Göbel2, Ivan Dikic3 & Manolis Pasparakis1,2,4

Linear ubiquitination regulates inflammatory and cell death signalling. Deficiency of the linear ubiquitin chain-specific deubiquitinase, OTULIN, causes OTULIN-related autoinflammatory syndrome (ORAS), a systemic inflammatory pathology affecting multiple organs including the skin. Here we show that mice with epidermis-specific OTULIN deficiency (OTULINC-KO) develop inflammatory skin lesions that are driven by TNFR1 signalling in keratinocytes and require RIPK1 kinase activity. OTULINC-KO mice lacking RIPK3 or MLKL have only very mild skin inflammation, implicating necroptosis as an important etiological mediator. Moreover, combined loss of RIPK3 and FADD fully prevents skin lesion development, showing that apoptosis also contributes to skin inflammation in a redundant function with necroptosis. Finally, MyD88 deficiency suppresses skin lesion development in OTULINC-KO mice, suggesting that toll-like receptor and/or IL-1 signalling are involved in mediating skin inflammation. Thus, OTULIN maintains homeostasis and prevents inflammation in the skin by inhibiting TNFR1-mediated, RIPK1 kinase activity-dependent keratinocyte death and primarily necroptosis.

The skin forms an essential structural and immunological barrier protecting the organism from dehydration and from mechanical, chemical and microbial challenges. The maintenance of a healthy skin depends on balanced proliferation and differentiation of epidermal keratinocytes and a tightly regulated cross-talk between epithelial, stromal and immune cells. Disturbance of skin immune homeostasis results in the pathogenesis of inflammatory skin diseases, such as psoriasis. The regulation of inflammatory and cell death signalling in keratinocytes has emerged as a key mechanism controlling skin immune homeostasis and contributing to the pathogenesis of skin diseases. Tumour necrosis factor (TNF) is a potent cytokine that has emerged as a critical therapeutic target in inflammatory diseases, including psoriasis. However, despite the proven clinical efficacy of anti-TNF therapy, the mechanisms by which TNF triggers inflammation in these patients remain poorly understood.

TNF signalling via TNF receptor 1 (TNFR1) not only induces the activation of inflammatory and pro-survival pathways, including the nuclear factor κB (NF-κB) and mitogen activated protein kinase (MAPK) cascades, but can also trigger cell death by activating caspase-8-induced apoptosis or receptor interacting protein kinase 3 (RIPK3)-mixed lineage kinase domain-like (MLKL)-induced necroptosis. Linear ubiquitination, the addition of methionine (M1)-linked ubiquitin chains, of RIPK1 and other components of the receptor-proximal signalling complex (often referred to as complex I) by the linear ubiquitin chain assembly complex (LUBAC) determines the outcome of TNFR1 signalling by stabilising complex I, thus promoting inflammatory and pro-survival signalling and preventing the induction of cell death. LUBAC is composed of SHANK-associated RH domain-interacting protein (Sharpin), Haem-oxydised iron-regulatory protein 2 ubiquitin ligase-1 (HOIL-1) and HOIL-1-interacting protein (HOIP). Linear ubiquitination is negatively regulated by OTULIN (OTU deubiquitinase with linear linkage specificity, also known as Fam105b or Gumby), a deubiquitinase specifically catalysing the degradation of linear ubiquitin chains. Studies in mouse models revealed important functions of linear ubiquitination in the regulation of skin immune homeostasis. Mutations in the gene encoding Sharpin were found to cause inflammatory skin lesions in a mouse model of chronic proliferative dermatitis (cpdm). Conditional ablation of Sharpin in epidermal keratinocytes was sufficient to trigger the cpdm phenotype showing that keratinocyte-intrinsic Sharpin deficiency causes the cutaneous inflammatory response. We and others showed that inflammatory skin lesion development in Sharpinpdm/cpdm mice is driven by TNFR1-induced, RIPK1 and Fas-associated death domain (FADD)–caspase-8-dependent keratinocyte apoptosis, revealing a key role of Sharpin in preventing keratinocyte cell death and skin inflammation. Epidermal keratinocyte-specific knockout of HOIP or HOIL-1 also causes severe skin inflammation in mice. Interestingly, skin inflammation caused by epidermis-specific HOIP or HOIL-1 deficiency depends on TNFR1- and RIPK1-independent caspase-8-mediated death of keratinocytes during the early postnatal period and young age; however, TNFR1-independent mechanisms as well as RIPK3-MLKL-dependent necroptosis also contribute to skin lesion development in older mice.

Human patients with mutations resulting in loss of OTULIN function develop a systemic autoinflammatory pathology termed ORAS (OTULIN-related autoinflammatory syndrome) involving multiple organs, including the skin. Treatment with anti-TNF antibodies is effective in the therapy of ORAS patients, showing that de-regulated TNF-mediated responses play an important role in the pathogenesis of this disease. Mice lacking OTULIN or expressing catalytically inactive OTULIN die during embryonic life, showing that OTULIN is essential for embryonic development in mice. TNFR1 deficiency or lack of RIPK1 kinase activity could only delay embryonic death in mice lacking OTULIN catalytic activity, whereas combined RIPK3–caspase-8 deficiency allowed these mice to develop to term, although these mice died perinatally. Triple deficiency in caspase-8, RIPK3 and RIPK1 prevented both embryonic and perinatal lethality of mice lacking OTULIN catalytic activity, suggesting that de-regulated linear ubiquitination causes embryonic and perinatal death by causing aberrant RIPK and caspase-8 activation. Furthermore, liver-specific OTULIN deficiency caused chronic hepatitis and liver tumour development in mice by sensitising hepatocytes to TNFR1-independent, RIPK1–FADD–caspase-8-dependent hepatoocyte apoptosis. Therefore, OTULIN exhibits important functions that are important for the regulation of tissue homeostasis and inflammation in both humans and mice; however, the tissue-specific role of OTULIN and the underlying mechanisms remain poorly characterised.

We here studied the role of OTULIN in the skin by generating and analysing mice with epidermal keratinocyte-specific OTULIN deficiency. We show that keratinocyte-specific OTULIN knock-out caused an inflammatory skin pathology morphologically different from the skin lesions developing in mice lacking LUBAC components. Skin inflammation in mice lacking OTULIN in keratinocytes was dependent on TNFR1 and RIPK1 kinase activity. However, in contrast to mice with LUBAC mutations where skin inflammation was caused primarily by caspase-8-dependent apoptosis, the skin pathology in epidermis-specific OTULIN knockout mice was largely driven by RIPK3-MLKL-dependent necroptosis of keratinocytes, suggesting that OTULIN exhibits unique functions in regulating necroptosis in the skin.

Results

Keratinocyte-specific ablation of OTULIN causes skin inflammation. To study the role of OTULIN in the epidermis, we crossed OTULIN KO mice with K14-Cre transgenic mice that express Cre recombinase under the control of the keratinocyte-specific keratin 14 (K14) promoter (Supplementary Fig. 1a). OTULIN KO/KO K14-Cre mice (hereafter referred to as OTULIN KO/KO) lacking OTULIN specifically in keratinocytes were born at the expected Mendelian ratio and during the first postnatal days were macroscopically indistinguishable from their OTULIN KO/KO littermates that did not express Cre recombinase. OTULIN KO/KO mice started to develop spontaneous cutaneous lesions involving the back and tail skin about 6 days after birth. The back skin presented with a small number of confined inflammatory foci that often localised close to the neck, whereas the lesions affected the entire tail (Supplementary Fig. 1a). The phenotype progressed with age and about 50% of the mice were culled by the age of 3 weeks because of reaching pre-determined severity criteria particularly concerning the tail lesions (Supplementary Fig. 1a). OTULIN KO/KO mice that did not develop severe skin lesions in the tail during the first weeks of life could be maintained for up to 14 weeks of age (Supplementary Fig. 1b). The skin lesions in the back of these mice progressed in severity but remained localised in small inflammatory foci resembling papillomas (Fig. 1a).

Histological analysis of sections from back skin and tail tissue of 3- or 14-week-old OTULIN KO/KO mice revealed marked thickening of the epidermis in lesional areas, which contained strongly increased numbers of proliferating keratinocytes revealed by immunostaining for Ki-67 (Fig. 1b and Supplementary Fig. 1c). Moreover, immunostaining for epithelial differentiation markers revealed increased expression of the basal keratinocyte marker K14 and reduced expression of the
Fig. 1 Mice lacking OTULIN in keratinocytes develop skin inflammation. 

a Photographs of lesional skin from OTULINE-KO mice at the age of 3 and 14 weeks and representative images from skin sections from 3- or 14-week-old mice from OTULINE-KO, stained with haematoxylin and eosin (H&E). Images shown are representative of OTULINE-KO mice (n = 25). Scale bars: H&E = 200 μm. 

b Representative images of skin sections from 3-week-old mice of the indicated genotypes, stained with H&E (n = 10) or immunostained with antibodies against cleaved caspase 3 (CC3) (n = 6), cleaved caspase 8 (CC8) (n = 6) or Ki67 (n = 6). The epidermis in the sections stained for Ki-67 is indicated by a dotted line, arrows point to hair follicles. Scale bar H&E = 100 μm; CC3, CC8, Ki-67 = 50 μm. 

c Representative images of skin sections from 3-week-old mice of the indicated genotypes, immunostained with antibodies against keratin 10 (K10), keratin 14 (K14) (n = 6), keratin 6 (K6) (n = 6), F4/80 (n = 6) and Gr-1 (n = 6) and counterstained with DAPI (DNA stain). Scale bars: K10, K14, K6 = 20 μm; F4/80, Gr-1 = 30 μm. 

d Heatmap of gene expression data of OTULINE-KO lesional or non-lesional skin tissue compared to skin from littermate OtulinFL/FL control mice. Columns represent gene expression profiles from 3-week-old mice (n = 5), showing genes with an absolute log2(FoldChange) of ≥1, and an uncorrected p value of ≤0.05. Uncorrected p values are used on purpose to include a maximal number of genes in the plot while excluding clearly irrelevant genes. The statistical test producing the p values is Wald test for the absence of differential expression, i.e. for a log2(FoldChange) of zero. It is computed by function nbinomWaldTest of the Bioconductor R package DESeq2, based on a negative binomial general linear model of the gene counts. Control mice include littermates that do not express K14-Cre. Source data for d are provided as a Source data file.
TNFRI signalling in keratinocytes causes skin inflammation in OTULINE-KO mice. Anti-TNF treatment in human ORAS patients and in mice with inducible systemic OTULIN deficiency was previously shown to prevent systemic inflammation. To address whether TNFRI signalling specifically in epidermal keratinocytes contributes to the development of inflammatory skin lesions in OTULINE-KO mice, we generated Otulin\(^{fl/fl}\) Tnfr1\(^{fl/fl}\) K14-Cre (hereafter referred to as OTULINE-KO; TNFR1E-KO) mice. In contrast to OTULINE-KO mice, OTULINE-KO; TNFR1E-KO mice did not develop skin pathology during the first weeks of life and remained lesion-free at least up to the age of 1 year (Fig. 2a, b and Supplementary Fig. 2a, b). Notably, also heterozygous keratinocyte-specific TNFR1 deficiency strongly ameliorated the development of skin pathology in OTULINE-KO mice (Fig. 2a, b). Consistent with the absence of macroscopically visible skin lesions, histological analysis of back and tail skin tissue revealed that keratinocyte-specific ablation of TNFRI fully prevented epidermal hyperplasia, keratinocyte death and the infiltration of myeloid cells in OTULINE-KO mice (Fig. 2c, d and Supplementary Fig. 2c, d). Quantitative reverse transcription polymerase chain reaction (qRT-PCR) analysis of selected inflammatory cytokines and chemokines showed that Ccl3, Cxcl3, Il6, Il1b, Tnf, Ccxl9 and Ccxl10 were upregulated in the skin of some of the OTULINE-KO mice (Fig. 2e). There was a high variability in the levels of expression of these genes between different OTULINE-KO mice, likely due to the highly focal nature of the skin lesions that made it difficult to ensure that the same amount of lesional skin was present within the samples used for RNA preparation. Epithelial-specific TNFR1 ablation generally suppressed the upregulation of cytokines and chemokines in the skin of OTULINE-KO mice, although the differences between the groups did not reach statistical significance due to the large variability of the values between individual mice (Fig. 2e). Taken together, these findings showed that keratinocyte-intrinsic TNFRI signalling is essential for the development of inflammatory skin lesions in OTULINE-KO mice.

TNF binding on TNFRI not only drives inflammatory gene expression by activating NF-\(\kappa\)B and MAPK signalling but also causes cell death when pro-survival signalling is compromised. To obtain insights into the mechanisms by which TNFRI signalling in OTULINE-deficient keratinocytes causes skin inflammation, we performed immunoblot analysis of total skin protein lysates from 3- and 14-week-old OTULINE-KO and littermate control mice. Immunoblotting with antibodies recognising M1-linked ubiquitin chains revealed the presence of increased amounts of linear ubiquitin chains in lesional skin from OTULINE-KO mice compared to WT mice, consistent with the loss of OTULINE deubiquitinase activity (Fig. 3a). Interestingly, we did not detect increased amounts of linear ubiquitin chains in non-lesional skin of OTULINE-KO mice (Fig. 3a). One explanation for this might be that other deubiquitinases may be able to partly compensate for OTULINE loss specifically in keratinocytes under normal homeostatic conditions. However, focal lesions develop in 100% of the mice and these involved skin areas show M1 chain accumulation, suggesting that local triggers are needed to precipitate the inflammatory response and this correlates with elevated M1 ubiquitination. It is also possible that the inflammatory environment may further enhance M1 ubiquitination, although the hierarchy of events is very difficult to resolve as the hyperplastic skin response occurs simultaneously with the immune cell infiltration. Furthermore, the activation of NF-\(\kappa\)B and MAPK signalling pathways was not considerably altered in skin and tail tissues of OTULINE-KO mice compared to littermate control mice (Fig. 3b). It should be noted that these samples were prepared from total tissue that contains also non-epidermal cells that are not targeted by K14-Cre and therefore express OTULIN.

In conclusion, OTULIN and TNFR1 are essential for skin homeostasis and their ablation results in hyperplastic inflammatory skin diseases in mice that may be amenable to clinical translation.
necroptosis when linear ubiquitination of TNFR1 signalling components is de-regulated. We therefore hypothesised that TNFR1 may drive skin inflammation in OTULINE-KO mice by triggering RIPK1 kinase-dependent cell death in keratinocytes and addressed the role of RIPK1 kinase activity by crossing OTULINE^{E-KO} with Ripk1^{D138N/D138N} mice expressing kinase inactive RIPK1^{D138N}. Otulin^{fl/fl} K14-Cre Ripk1^{D138N/D138N} mice (hereafter referred to as OTULINE^{E-KO}; Ripk1^{D138N/D138N}) did not develop macroscopically
visible skin lesions up to at least the age of 1 year (Fig. 4a, b and Supplementary Fig. 4a, b). Histological analysis of back and tail skin tissue revealed that loss of RIPK1 kinase activity prevented epidermal hyperplasia, keratinocyte death and the infiltration of myeloid cells in 3-week-old OTULINE-KO mice (Fig. 4c, d). In addition, qRT-PCR analysis of selected inflammatory cytokines and chemokines showed that inhibition of RIPK1 kinase activity also reduced the expression of inflammatory genes in the skin of OTULINE-KO mice (Fig. 4e). Interestingly, histological analysis of back and tail skin sections from OTULINE-F-KO Ripk1ΔI38N/D138N mice at the age of about 1 year revealed the presence of some skin areas displaying mild epidermal hyperproliferation, revealed by slightly increased numbers of Ki-67+...

The dots in the graphs represent individual mice. Mean ± s.e.m. is shown for each group of mice in all graphs. Statistical significance was determined using Kruskal–Wallis test (one-sided). c Representative images of skin sections from 3-week-old mice of the indicated genotypes stained with H&E ($n=5$) or immunostained with anti-CC3 ($n=3$), anti-CC8 ($n=3$) or anti-Ki-67 ($n=3$) antibodies. Scale bars: H&E = 100 μm; CC3, CC8, Ki-67 = 50 μm. d Representative images of skin sections from 3-week-old mice of the indicated genotypes, immunostained with anti-K10, anti-K14 ($n=4$), anti-K6 ($n=3$), anti-F4/80 ($n=3$) and anti-Gr-1 ($n=3$) antibodies and counterstained with DAPI (DNA stain). Scale bars: K10, K14, K6 = 20 μm; F4/80, Gr-1 = 30 μm. e Graphs depicting relative mRNA expression of the indicated genes in RNA from whole-skin tissue of 3-week-old mice of the indicated genotypes, measured by qRT-PCR. The dots in the graphs represent individual mice. Mean ± s.e.m. is shown for each group of mice in all graphs. Statistical significance was determined using Kruskal–Wallis test (one-sided). Control mice include littermates that do not express K14-Cre. Source data for a, b, e are provided as a Source data file.
keratinocytes and mild upregulation of K6 expression in the epidermis (Supplementary Fig. 4c, d). The development of mild skin alterations in older OTULINEE-KO; Ripk1D138N/D138N mice was in contrast to the full protection offered by TNFR1 deficiency, suggesting that RIPK1 kinase activity-independent TNFR1 signalling causes the mild skin alterations observed in older animals. Therefore, RIPK1 kinase activity-dependent signalling drives keratinocyte death, epidermal hyperplasia and skin inflammation in OTULINEE-KO mice.

RIPK3–MLKL-mediated necroptosis causes skin inflammation in OTULINEE-KO mice. RIPK1 kinase activity can induce both FADD–caspase-8-dependent apoptosis and RIPK3–MLKL-dependent necroptosis. Because necroptosis is a highly inflammatory type of cell death3, we reasoned that RIPK1-dependent keratinocyte necroptosis might be involved in skin lesion development in OTULINEE-KO mice. Therefore, to evaluate the role of necroptosis we crossed OTULINEE-KO mice with Ripk3−/− and Mlkl−/− mice. Both OTULINEE-KO; Ripk3−/− and OTULINEE-KO; Mlkl−/− mice were strongly protected from the development of severe skin lesions only showing very mild signs of macroscopically detected skin alterations presenting with small spots with scaly skin in the back but no lesions on the tail (Figs. 5a, b and 6a, b and Supplementary Figs. 5a, b and 6a, b). Heterozygous deficiency of RIPK3 or MLKL also considerably ameliorated the skin pathology in OTULINEE-KO mice suggesting a gene dosage effect (Figs. 5a, b and 6a, b). Histological analysis of back and tail skin from 3-week-old OTULINEE-KO; Ripk3−/− and OTULINEE-KO; Mlkl−/− mice confirmed the absence of severe skin lesions, revealing only small areas displaying mild increase in keratinocyte proliferation and slightly elevated immune cell infiltration (Figs. 5c, d and 6c, d). qRT-PCR analysis of skin RNA revealed reduced expression of some but not all inflammatory genes in both OTULINEE-KO; Ripk3−/− and OTULINEE-KO; Mlkl−/− mice compared to OTULINEE-KO animals (Figs. 5e and 6e), consistent with the histological findings that the development of skin lesions was not completely prevented by RIPK3 or MLKL deficiency. When followed for up to 1 year, the skin lesions in OTULINEE-KO; Ripk3−/− and OTULINEE-KO; Mlkl−/− mice did not progress and remained mild as judged by macroscopic and histological evaluation (Supplementary Figs. 5b–d and 6b–d). Collectively, these results showed that RIPK3 or MLKL deficiency strongly ameliorated the inflammatory skin pathology developing in OTULINEE-KO mice, demonstrating that RIPK3–MLKL-dependent necroptosis plays a critical role for the pathogenesis of skin lesions.

Combined ablation of FADD and RIPK3 fully prevents skin lesion development in OTULINEE-KO mice. RIPK3 and MLKL deficiencies could strongly ameliorate but did not fully prevent the development of skin lesions in OTULINEE-KO mice, suggesting that necroptosis-independent TNFR1–RIPK1 signalling also contributes to the pathology. The presence of keratinocytes immunostained for CC8 and CC3 in skin sections from OTULINEE-KO mice suggested that caspase-8-mediated apoptosis could also contribute to the development of skin lesions in addition to necroptosis. Therefore, to assess the potential contribution of caspase-8-mediated cell death we generated OTULINEE-KO mice that in addition lacked FADD specifically in keratinocytes and RIPK3 in all cells (OtulineE-KO; FaddD1438N/D1438N; K14-Cre Ripk3−/−, hereafter referred to as OTULINEE-KO; FADD−/−; Ripk3−/− mice). Combined inhibition of both FADD–caspase-8-mediated apoptosis and RIPK3–MLKL-dependent necroptosis fully prevented skin lesion development in OTULINEE-KO; FADD−/−; Ripk3−/− mice at least up to the age of 1 year, as revealed by macroscopic and histological analysis of back and tail skin (Fig. 7a–d and Supplementary Fig. 7a–d). qRT-PCR analysis of skin mRNA from 3-week-old OTULINEE-KO; FADD−/−; Ripk3−/− mice showed that the expression of Ccl3, Cxcl3, Tnf and Il6 was normalised to the levels of control mice; however, the expression of the type I IFN response genes Cxcl9 and Cxcl10 as well as Il1β were not suppressed compared to OTULINEE-KO mice (Fig. 7e). Taken together, these results demonstrate that the development of inflammatory skin pathology in OTULINEE-KO mice is driven primarily by RIPK3–MLKL-dependent necroptosis; however, when necroptosis is blocked then FADD–caspase-8-dependent apoptosis also contributes by inducing mild skin lesions.

MyD88 signalling contributes to the skin pathology of OTULINEE-KO mice. OTULINEE-KO mice develop skin lesions during the first weeks after birth, suggesting that environmental factors contribute to the initiation of the skin pathology. Colonisation of the skin with commensal bacteria happens after birth and could be implicated in driving the expression of TNF and other inflammatory mediators via activating Toll-like receptor (TLR) signalling, thus contributing to lesion development27. To assess the possible role of TLR signalling, we generated OTULINEE-KO mice that were deficient in MyD88, the key adaptor mediating TLR-induced inflammatory gene expression28,29. Indeed, OtulineEfl/fl K14-Cre Myd88−/− mice (hereafter referred to as OTULINEE-KO; Myd88−/−) were strongly protected from skin lesion development and most of these animals remained lesion-free until the age of about 14 weeks (Fig. 8a, b and Supplementary Fig. 8a). Consistently, histopathological analysis of skin sections from 3-week-old OTULINEE-KO; Myd88−/− mice revealed only mildly increased keratinocyte proliferation without signs of pronounced skin inflammation (Fig. 8c, d). When observed up to the age of 50 weeks, 50% of the OTULINEE-KO; Myd88−/− mice showed mild skin pathology (Supplementary Fig. 8b–d). Moreover, gene expression analysis showed that MyD88 deficiency inhibited the upregulation of most of the inflammatory genes tested in OTULINEE-KO mice (Fig. 8e). Collectively, these results revealed that MyD88 signalling critically contributes to the development of inflammatory skin lesions in OTULINEE-KO mice, indicating that TLR activation perhaps induced by commensal bacteria colonising the skin could be involved in triggering the response.

Discussion
Mutations resulting in loss of OTULIN function were shown to cause systemic inflammatory conditions in humans and mice, suggesting a critical role of OTULIN in preventing activation of aberrant immune responses and maintaining tissue homeostasis10,11,19–22. Anti-TNF antibodies are effective in the treatment of the inflammatory pathology developing in patients with OTULIN mutations as well as in mice with inducible OTULIN knockout, showing that TNF plays an important role in causing inflammation when OTULIN function is compromised19–21. Our findings showed that epidermis-specific OTULIN deficiency caused skin inflammation by sensitising keratinocytes to TNF1–RIPK1-mediated cell death. Although we did detect considerable amount of keratinocytes immunostained with antibodies against CC3 and CC8 in the epidermis of OTULINE-KO mice, our genetic studies revealed that RIPK3–MLKL-dependent necroptosis of OTULIN-deficient keratinocytes was primarily responsible for causing skin inflammation in these animals, with apoptosis playing a lesser role. This finding is consistent with necroptosis being a more inflammatory type of cell death compared to apoptosis30. Interestingly, while our genetic studies provided unequivocal evidence that keratinocyte necroptosis drives skin inflammation in OTULINEE-KO mice, we could not detect enhanced TNF-induced cell death in primary
keratinocytes from OTULINE-KO mice compared to control cells. The reasons behind this difference remain unclear at present, but it is possible that the generally high spontaneous cell death observed in primary keratinocyte cultures masks a small increase in necroptosis in OTULIN-deficient cells. Our previous studies showing that a very small number of necroptotic keratinocytes is capable to drive strong skin inflammation in FADDE-KO and RIPK1E-KO mice30,31 further supports that OTULIN deficiency may cause a weak sensitisation to TNF-induced cell death that is important but difficult to quantify in cultured keratinocytes. Alternatively, it is possible that OTULIN deficiency differentially affects keratinocytes according to their differentiation stage. OTULIN deficiency might cause necroptosis primarily in differentiated keratinocytes in the upper layers of the epidermis as opposed to the proliferating basal layer cells. In this case, TNF stimulation would not be expected to induce increased amounts of cell death in OTULIN-deficient keratinocytes, as cultured primary keratinocytes resemble the highly proliferating...
The important role of necroptosis in driving skin inflammation in OTULINE\(^{-}\text{KO}}\) mice is in contrast with the critical role of caspase-8-dependent keratinocyte apoptosis in driving skin inflammation in mice with impaired LUBAC function. Specifically, skin inflammation in \textbf{Sharpin}\(^{\text{cpdm/cpdm}}\) mice as well as in mice with keratinocyte-specific knockouts of HOIP or HOIL-1L was shown to be driven primarily by FADD–caspase-8-dependent apoptosis with RIPK3–MLKL-dependent necroptosis playing no or minor role\(^{4,14,16,17}\). Therefore, interference with linear ubiquitination by ablation of LUBAC components or OTULIN differentially affects TNFR1-mediated cell death. LUBAC deficiency directly RIPK1-dependent cell death signalling primarily towards the activation of FADD–caspase-8-mediated apoptosis, while OTULIN deficiency drives RIPK1 signalling towards the activation of RIPK3–MLKL-dependent necroptosis. The skin lesions of OTULINE\(^{-}\text{KO}}\) mice are also different from the skin pathologies developing in \textbf{Sharpin}\(^{\text{cpdm/cpdm}}\) and also in mice with epidermis-specific HOIP and HOIL-1 knockout. Keratinocyte-intrinsic OTULIN knockout causes highly localised inflammatory lesions in the back skin, which morphologically and histologically resemble papillomas, while in mice with LUBAC deficiency the entire skin is affected and there are no signs of papilloma-like structure appearance. OTULINE\(^{-}\text{KO}}\) mice also develop severe inflammatory skin lesions on the tail, which is not affected in \textbf{Sharpin}\(^{\text{cpdm/cpdm}}\) mice. Although the underlying mechanisms remain unclear at present, these results suggest that the effects of OTULIN deficiency cannot be explained solely by the inhibition of LUBAC activity as a consequence of increased linear ubiquitination of its components as previously suggested\(^{22}\).

Our findings also reveal that OTULIN deficiency in the epidermis or the liver caused inflammation by different mechanisms. Liver parenchymal cell-specific OTULIN deficiency caused chronic liver inflammation and hepatocarcinogenesis by sensitising hepatocytes to RIPK1–FADD–caspase-8-dependent apoptosis\(^{23,24}\). Interestingly, TNFR1 deficiency did not prevent hepatocyte apoptosis, hepatitis and liver tumour development in these mice, suggesting that TNFR1-independent pathways driving caspase-8-mediated apoptosis cause the pathology\(^{23,24}\). This is in contrast to the epidermis where OTULIN deficiency caused inflammation by inducing TNFR1–RIPK1-mediated necroptosis. Moreover, embryonic lethality of knock-in mice expressing catalytically inactive OTULIN was not rescued by RIPK3 deficiency showing that necroptosis does not play a major role\(^{22}\). Combined lack of RIPK3 and caspase-8 could prevent embryonic death in mice lacking OTULIN function showing that apoptosis is a major driver of lethality in these animals\(^{22}\). Therefore, our findings uncovered a unique function of OTULIN in preventing necroptosis in keratinocytes, in contrast to its role in other tissues including the liver as well as embryonic tissues and particularly the endothelium, where its main function is to prevent caspase-8-dependent apoptosis. Our results also provide further evidence that keratinocyte necroptosis constitutes a strong trigger of skin inflammation and could be influential in the development of inflammatory skin pathologies also in humans.

Besides TNFR1 signalling, recent studies suggested type 1 IFN signalling to play an important role in mice lacking OTULIN in the liver and in mice with defects in linear ubiquitination\(^{4,22,23}\). Both lesional and non-lesional skin from OTULINE\(^{-}\text{KO}}\) mice showed elevated expression of type 1 IFN signature genes, suggesting that also in the skin OTULIN deficiency causes activation of IFN responses that could contribute to the pathology. Furthermore, it remains unclear why the skin lesions in OTULINE\(^{-}\text{KO}}\) mice develop postnatally. One possible explanation for this could be related to the colonisation of the skin with commensal bacteria, which happens during the early postnatal period\(^{27}\). Our findings that MyD88 deficiency considerably delayed and ameliorated the development of skin lesions in OTULINE\(^{-}\text{KO}}\) mice would be consistent with a role of bacteria in driving inflammatory cytokine production in the skin by activating TLR signalling. Alternatively, MyD88 might act downstream of the IL-1 receptor to stimulate inflammation in response to the release of IL-1\(\beta\) or IL-1\(\alpha\), which are both important alarmins released by dying or damaged cells and could play an important role in driving necroptosis-mediated inflammation\(^{3}\). Taken together, our results revealed an important role of OTULIN for the maintenance of skin homoeostasis, where it functions in keratinocytes to prevent TNFR1–RIPK1-mediated necroptosis and inflammation. In line with our observations, an independent study by van Loo and colleagues published back to back with our manuscript\(^{32}\) describes similar findings, confirming the role of OTULIN in preventing skin inflammation by inhibiting the death of keratinocytes. These findings suggest that targeting necroptosis could be effective for the treatment of the inflammatory skin pathology of ORAS patients.

**Methods**

**Mice.** The following mouse lines were used: \textbf{Otulin}\(^{\text{fl/f}}\), \textbf{K14-Cre}\(^{-}\), \textbf{Tnfr1}\(^{\text{fl/fl}}\), \textbf{Ripk1}\(^{\text{fl/fl}}\), \textbf{Ripk3}\(^{\text{fl/fl}}\), \textbf{Mlkl}\(^{\text{fl/fl}}\), \textbf{Fadd}\(^{\text{fl/fl}}\), \textbf{Ripk3}\(^{−/−}\), \textbf{Tnfr1}\(^{−/−}\) and \textbf{Myd88}\(^{−/−}\). All experiments were performed on mice backcrossed into the C57BL/6 genetic background for at least five generations. In all experiments, littermates carrying the \textit{loxP}-flanked alleles but not expressing \textit{Cre} recombinase were used as WT controls. Mice used in this study were maintained in the animal facility of the CECAD Research Center, University of Cologne, in individually ventilated cages (Greenline GM500; Tecniplast) at 22 °C (±2 °C) and a relative humidity of 55% (±5%) under 12-h light cycle on sterilised bedding (Aspen wood, Abed, Germany) and with access to sterilised commercial pelleted diet (Sanifit Spezialdiäten GmbH) and acidified water ad libitum. The microbiological status was examined as recommended by Federation of European Laboratory Animal Science Associations, and the mice were free of all listed pathogens. All animal procedures were conducted in accordance with European, national, and institutional guidelines, and protocols were approved by local government authorities (Landesamt für Natur, Umwelt und Verbraucherschutz Nordrhein-Westfalen). Animals requiring medical attention were provided with appropriate care and were sacrificed when reaching pre-determined criteria of disease severity. No other exclusion criteria were used. Female and male mice of the indicated genotype were assigned at random to groups. Mouse studies as well as immunohistochimical assessment of pathology were performed in a blinded fashion.
Fig. 6 MLKL-mediated necroptosis triggers skin inflammation in OTULINE-KO mice. a Kaplan–Meier plot depicting survival of mice of the indicated genotypes. b Graph depicting macroscopic skin score of mice of the indicated genotypes. The dots in the graphs represent individual mice. Mean ± s.e.m. is shown for each group of mice in all graphs. Statistical significance was determined using Kruskal–Wallis test (one-sided). c Representative images of skin sections from 3-week-old mice of the indicated genotypes, stained with H&E (n = 4) or immunostained with anti-CC3 (n = 3), anti-CC8 (n = 3) or anti-Ki-67 (n = 3) antibodies. Scale bars: H&E = 100 μm; CC3, CC8, Ki-67 = 50 μm. d Representative images from skin sections from 3-week-old mice of the indicated genotypes, immunostained with anti-K10, anti-K14 (n = 4), anti-K6 (n = 3), anti-F4/80 (n = 3) and anti-Gr-1 (n = 3) antibodies and counterstained with DAPI (DNA stain). Scale bars: K10, K14, K6 = 20 μm; F4/80, Gr-1 = 30 μm. e Graphs depicting relative mRNA expression of the indicated genes in RNA from whole-skin tissue of 3-week-old mice of the indicated genotypes, measured by qRT-PCR. The dots in the graphs represent individual mice. Mean ± s.e.m. is shown for each group of mice in all graphs. Statistical significance was determined using Kruskal–Wallis test (one-sided). Control mice include littermates that do not express K14-Cre. Source data for a, b, e are provided as a Source data file.
Fig. 7 Combined ablation of FADD and RIPK3 fully prevents skin lesion development in OTULINE-KO mice. a Kaplan–Meier plot depicting survival of mice of the indicated genotypes. The dots in the graphs represent individual mice. Mean ± s.e.m. is shown for each group of mice in all graphs. Statistical significance was determined using Kruskal–Wallis test (one-sided).

b Representative images of skin sections from 3-week-old mice of the indicated genotypes, stained with H&E (n = 6) or immunostained with anti-CC3 (n = 4), anti-CC8 (n = 4) or anti-Ki-67 (n = 3) antibodies. Scale bar H&E = 100 μm; CC3, CC8, Ki-67 = 50 μm. d Representative images from skin sections of the indicated genotypes (n = 5), immunostained with anti-K6, anti-F4/80 (n = 3) and anti-Gr-1 (n = 3) antibodies and counterstained with DAPI (DNA stain). Scale bar K10, K14, K6 = 20 μm; F4/80, Gr-1 = 30 μm. e Graphs depicting relative mRNA expression of the indicated genes in RNA from whole-skin tissue of 3-week-old mice of the indicated genotypes, measured by qRT-PCR. Control mice include littermates that do not express K14-Cre. Source data for a, b, e are provided as a Source data file.
Skin samples from mice were fixed in 4% paraformaldehyde embedded in paraffin and cut in 3–5 µm sections and subjected to histological analysis by haematoxylin and eosin staining or immunohistochemical analysis. Paraffin sections were dehydrated and heat-induced antigen retrieval was performed in citrate, TRIS buffer (pH6). Sections were incubated with primary antibodies for anti-CC3 (9661, Cell Signalling, 1:1000), anti-CC8 (8592, Cell Signalling, 1:600) and anti-K6 (M7724901, DAKO, 1:1000). Biotinylated secondary antibodies were purchased from Perkin Elmer, DAKO and Invitrogen. Stainings were visualised with the ABC Kit Vectastain Elite (Vector Laboratories) and DAB substrate (Dako and Vector Laboratories). Sections were counterstained with DAPI. F4/80 and Gr-1 staining were performed on cryostat sections.

Skin score. The mice were scored at the age of 3 weeks or 14 weeks. A score of 0–3 was assigned to each mouse as follows: 0 = skin lesions; 1 = skin lesions, tail skin lesions; 2 = papilloma-like structures, tail skin lesions.

Gene expression analysis with qRT-PCR. Total RNA was extracted with Trizol Reagent (Life Technologies) and RNeasy Columns (Qiagen) followed by cDNA preparation with the Superscript III cDNA-synthesis Kit (Life Technologies). qRT-PCR was performed with TaqMan probes (ThermoScientific) in duplicates for each sample. Gene expression levels were calculated with the 2-ΔΔCt method and are presented in dot plot graphs.

Immunoblotting. For immunoblot analyses, 4 × 105 cells were seeded in collagen-coated 6-well plates (Corning, Bio-Coat, 354563), and 3 h before stimulation, the medium was replaced by fresh medium without epithelial growth factor. Keratinocytes were stimulated with TNF (VIB Protein Service Facility, Ghent, 20 ng ml−1) for different timepoints. Cell lysis buffer was supplemented with protease and phosphatase inhibitor tablets (Roche). Cell lysates were separated on Sodium dodecyl-sulfate polyacrylamide gel electrophoresis and transferred to polyvinylidene difluoride membranes (PVDF). Membranes were blocked with 5% milk/0.1% PBS and were probed with primary antibodies against α-tubulin (T6074, Sigma, 1:1000), OTULIN (14127, Cell Signaling, 1:1000), phospho-IkBα (4686, Cell Signaling, 1:1000), IκBα (sc-371, Cell Signaling, 1:1000), phospho-p38 MAPK (9211, Cell Signaling, 1:1000), phospho-JNK (Cell Signaling, 1:1000), JNK (9252, Santa Cruz, 1:1000), phosphop38 (9211, BD, 1:1000), p38 (9246, Cell Signaling, 1:1000), phospho-ERK (9211, Santa Cruz, 1:1000), ERK (9102, Cell Signaling, 1:1000) and M1-Ubiquitin (clone 1F1135Y102, Genentech, 1:1000) for 16 h at 4 °C. Membranes were washed with 0.1% PBS and were incubated with secondary horseradish peroxidase-coupled antibodies anti-rabbit, anti-mouse (GE Healthcare, Jackson Immunoresearch, 1:10,000) or anti-human IgG (709-036-149, Jackson Immunoresearch, 1:10,000) and Western Blotting Detection Reagent (RPN1206, GE Healthcare) and Supersignal West Pico PLUS Chemiluminescent substrate (34580, ThermoScientific) were used for detection. The membranes were reprobed after incubation in Restore Western Blot stripping buffer (21095, Thermo).

Cell death assay. For cell death analyses, 1 × 105 cells were seeded in collagen-coated 96-well plates (Corning, Bio-Coat, 354407). Keratinocytes were preincubated for 30 min with Z-VAD-fmk (Enzo, ALX-260-020-M005, 20 µM) and Birinapant (BioVision, 2597) and stimulated by 20 ng ml−1 TNF for 24 h in the presence of the dead stain Draq7 (Invitrogen, D15106, 0.3 µM). Cell death assays were performed using the IncuCyte bioimaging platform (Essen); two to four images per well were captured, analysed and averaged. Cell death was measured by the incorporation of Draq7.

Data availability. The RNA sequencing data generated in this study have been deposited in NCBI’s Gene Expression Omnibus and are accessible through GEO Series accession number GSE180024. Source data are provided with this paper.

Acknowledgements
We are grateful to C. Uhthoff-Hachenberg, E. Gareus, L. Elles, J. Kuth, P. Roggan, E. Stade and J. von Rhein for excellent technical assistance and to P. Wagle and A. Dilhey for assistance on RNA sequencing data analysis. We thank Yu-shin Sou and Masaaki Komatsu for providing ObitunSOB mice, George Kollias for providing Tnfr1fl/fl mice and Vishva Dixit and Genentech for providing Ripk3−/− mice. This work was supported by funding from the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) projects SFB829 (project no. 7311208), SFB1101 (project no. 414786233) and CECAD (project no. 390661388).

Author contributions
H.S. designed and performed all experiments, analysed the data and drafted and revised the manuscript. U.G. analysed RNA sequencing data. I.D. contributed to the study design and manuscript drafting. M.P. designed and supervised the study, interpreted data and wrote the manuscript.

Funding
Open Access funding enabled and organized by Projekt DEAL.

Competing interests
The authors declare the following competing interests: M.P. received consulting and speaker fees from Genentech, GSK, Boehringer Ingelheim and Sanofi. The other authors declare no competing interests.
