Evaluation of Pumpkin Cultivars for Powdery and Downy Mildew Resistance, Virus Tolerance, and Yield

Anthony P. Keinath and Virginia B. DuBose
Department of Plant Pathology and Physiology, Clemson University, Coastal Research and Education Center, Charleston, SC 29414-5332

Abstract. Twenty-six cultivars and two numbered selections of Cucurbita pepo L. pumpkin and four cultivars of C. maxima Duchesne pumpkin were evaluated in field experiments in 1996 and 1997 in Charleston, S.C. The four C. maxima cultivars ('Mammoth Gold', 'Big Max', 'Rouge Viif d'Etamps', and 'Lumina') and three C. pepo cultivars (HMX 6686, HMX 6688, and Magic Lantern) had lower powdery mildew [Sphaerotheca fuliginea (Schlechtendal. Fr.) Pollacci] severities than did the other C. pepo cultivars. Overall, C. maxima cultivars also had less foliage showing virus symptoms and less downy mildew [Pseudoperonospora cubensis (Berk. & M.A. Curtis) Rostovzev] than did C. pepo cultivars. Mid- and long-season cultivars of both species (>100 days to maturity) produced a greater number of marketable-quality fruit than did short-season cultivars. Cucurbita maxima and C. pepo produced similar numbers of marketable fruit; however, more potential marketable yield was possible in C. maxima since most fruit were affected by virus. The C. pepo cultivars Spookie, HMX 6686, and Spooktacular produced the greatest numbers of marketable fruit. In general, no cultivars were well-adapted to the growing conditions of the humid coastal plain of the southeastern United States.

Pumpkin can be a profitable crop when grown for the Halloween market. Because of the high potential return per hectare, pumpkin is particularly suited for growers with limited acreage or those located near urban areas. To yield well under current management practices, pumpkin requires expensive inputs, such as white or black polyethylene mulch and regular insecticide and fungicide applications (Kemble et al., 1997). Because pumpkin has a long growing season (90 to 120 d) and is planted later than most warm-season vegetable crops, vines must be protected from several foliar pathogens. In the southeastern United States, both powdery mildew and powdery mildew reduce yields (Bost et al., 1991; Shoemaker, 1994). In addition, viruses such as papaya ringspot virus (PRSV), watermelon mosaic virus (WMV), and zucchini yellow mosaic virus (ZYMV) infect C. pepo and reduce marketable yields in this region (Schultheis and Walters, 1998). Little information is available on management of pumpkin diseases in the southeastern coastal plain. Minimizing pesticide inputs may improve the profit margin of the crop (Olson et al., 1995), although some fungicide must be applied to prevent premature defoliation and senescence.

Careful selection of pumpkin cultivar can reduce disease severity. For example, without fungicide applications, 'Big Max' had less downy and powdery mildew than seven other cultivars (Bost et al., 1991). The heirloom cultivar Rouge Viif d'Etamps had significantly less powdery mildew than nine other cultivars (Precheur et al., 1994). However, both of these cultivars are C. maxima, and do not produce typical jack-o’-lantern-type fruit. Consequently, this resistance is not as useful for commercial producers as resistance or tolerance would be in C. pepo cultivars. Recently, C. pepo lines with resistance to powdery mildew have been evaluated in the northeastern United States (McGrath and Sieczka, 1997), but their yield, fruit quality, and resistance to other diseases under southeastern conditions are not known. No commercially available cultivars have resistance to viral diseases, although the cultivars Autumn Gold and Big Autumn have the precocious yellow gene (Py), which masks color-breaking caused by virus infection (Snyder et al., 1993).

The objective of this study was to evaluate commercially available pumpkin cultivars and advanced numbered selections for resistance to powdery mildew and potential for yield under the humid growing conditions of the coastal plain of the southeastern United States. Tolerance to virus infection and downy mildew also was assessed.

Materials and Methods

Pumpkin cultivar evaluations were conducted at the Coastal Research and Education Center, Charleston, S.C., on Yongs loamy fine sand (fine-loamy, mixed, thermic, Typic Albaquults). The experiments were randomized complete blocks with three replications in 1996 and four replications in 1997. Each plot was a single row of eight plants.

In previous cultivar evaluations, pumpkins with different maturity dates were all seeded or transplanted and harvested at the same time, which may not provide an equitable yield comparison among cultivars (Bost et al., 1991; Precheur et al., 1994, 1998). In our experiments, three seeding and transplanting dates were used so that all cultivars reached maturity at the same time, because harvest date is important for marketing pumpkins. Thirty-two pumpkin cultivars were separated into three groups based upon days to maturity (DTM) as indicated by seed company descriptions. Long- (110-120 d), mid- (100-105 d), and short-season (85-95 d) pumpkins were seeded on 11 June, 21 June, and 1 July 1996, respectively, and 27 June, 8 and 18 July 1997, respectively. Seedlings within each maturity date were transplanted to the field 10 or 11 d after seeding, so that the harvest dates would coincide. Plants were spaced 0.9 m apart within rows in 1996 and 1.2 m apart in 1997. Plots were separated by 3.0 m of space within rows. Row spacing was 1.8 m on bed center and every other row was planted. Transplants that died within 1 week of transplanting were replaced so that all plots contained eight plants. In 1996, but not in 1997, vines were moved into the 1.8-m-wide area until late in the season because of sprayer limitations.

Before planting, 900 kg ha⁻¹ of 10N-4.4P-8.3K (1996) or 670 kg ha⁻¹ of 15N-0P-12.5K fertilizer (1997) were broadcast before raised beds were shaped and covered with white-on-black polyethylene mulch. Plots were side-dressed in the alleys in 25 July in both years with 220 kg ha⁻¹ 10N-4.4P-8.3K. For weed control, bensulide (5,2-benzensulfonamidoethyl O.O-di-isopropyl phosphorodithioate) (3.4 kg ha⁻¹ a.i.) was applied preplant to alleys in 1996 and clomazone [2-[(2-chlorophenyl) methyl]-4,4-dimethyl-3-isoxazolidinone] (1.1 kg ha⁻¹ a.i.) was broadcast preplant in 1997. Sethoxydim [2-[1-(ethoxyimino)butyl]-5-[2-(ethylthio) propyl]-3-hydroxy-2-cyclohexene-1-one] (0.31 kg ha⁻¹ a.i.) also was applied to control grasses in 1997. To manage insects, maximum labeled rates of esfenvalerate [(S)-α-cyano-3-phenoxybenzoyl(S)-2-(4-chlorophenyl)-3-methylbutyrate] or endosulfan (6.7,8,9,10,10-hexachloro-1,5,5a,6,9,9a-hexahydro-6,9-methano-2,4-benzoxidithiophene-3-oxide) were applied in alternate weeks from planting until harvest both years; in 1997, Bacillus thuringiensis and permethrin [3-phenoxybenzyl (1RS)-cis,trans-3,2,2-dichlorovinyl]-2,2-dimethylcyclopropanecarboxylate] also were used. In 1996, the fungicides chlorothalonil (tetracloroisophthalonitrile) - triadimefon [1-(4-chlorophenox)-3,3-dimethyl-1-(1H-1,2,4-triazol-1-yl)-2-butanoate] (1.7 or 2.5 kg ha⁻¹ a.i.) was applied preplant to alleys in 1997.
kg·ha⁻¹ a.i. chlorothalonil plus 0.09 or 0.13 kg·ha⁻¹ a.i. maneb or 1.6 kg·ha⁻¹ a.i. chlorothalonil (Table 1). In both years, C. maxima cultivars had less powdery mildew overall than did C. pepo cultigens (P = 0.0001).

When ratings for both years were combined and analyzed together, there was a significant genotype × year interaction (P ≤ 0.001), probably because a few cultivars, such as ‘Big Autumn’, ‘Oz’, and ‘Tom Fox’, were severely diseased one year but had less mildew the other year (Table 1). However, despite this interaction, ‘Wizard’, ‘Happy Jack’, and ‘Sprookie’ were ranked among the most susceptible cultivars in both years, and ‘Magic Lantern’ and ‘Lumina’ had low levels of mildew both years. Overall, the cultigens with the lowest ratings (most resistant) were HMX 6688, Magic Lantern, and HMX 6686, and the C. maxima cultivars Rouge Vif d’Étamps and Lumina.

Downy mildew. Downy mildew was present both years and, similar to powdery mildew, progressed faster in 1996 than in 1997. However, downy mildew increased late in the season in 1997 and contributed to foliage senescence. The highest mean mildew rating on 19 Aug. 1996 was 54% for ‘Rocket’, but on 5 Sept. 1997, the highest rating was only 3.6% for both ‘Connecticut Field’ and ‘Howden’ (Table 1). In both years, C. maxima was less susceptible to mildew than was C. pepo (P ≤ 0.001). ‘Big Max’ and ‘Mammoth Gold’, both C. maxima cultivars, were among the cultigens with the lowest ratings both years.

Virus symptoms. Leaves of all cultivars were distorted and mottled with virus symptoms by the end of August in both years. In 1996, ZYMV and PRSV were detected in all samples and WMV was detected in half of the samples. In 1997, samples of distorted leaves were positive for both ZYMV and PRSV.

### Table 1. Powdery mildew severity on 26 Cucurbita pepo and four C. maxima pumpkin cultivars in 1996 and 1997.

| Cultigen                  | Powdery mildew severity (%) | Downy mildew severity (%) | Foliar virus severity (%) |
|---------------------------|-----------------------------|---------------------------|---------------------------|
|                            | 1996*                      | 1997                      | 1996*                     | 1997                      |

*Percentage of upper and lower leaf surface area covered with powdery mildew on 19 Aug. 1996 and 5 Sept. 1997, respectively.

*Percentage of upper and lower leaf surface area covered with downy mildew on 19 Aug. 1996 and 5 Sept. 1997, respectively.

*Percentage of leaf surface area with virus symptoms on 29 Aug. 1996 and 16 Sept. 1997, respectively.

*Cultigen × year interaction significant at P ≤ 0.0001.

*Mean separation within years by Waller–Duncan k ratio t test; k = 500 (approximates P = 0.01) for powdery mildew and virus and k = 100 (approximates P = 0.05) for downy mildew.

*Cultigen with resistance to powdery mildew.
whereas samples of leaves with mosaic were positive for only ZYMV; WMV was not detected. Rankings of the cultivars based on foliar virus symptoms differed in the 2 years (Table 1). In 1996, percentage leaf area with symptoms was significantly less in ‘Rouge Vif d’Etamps,’ ‘Big Max,’ ‘Lumina,’ and ‘Spooktacular’ than in ‘Little Lantern,’ ‘Trickster,’ and ‘Oz.’ In 1997, ‘Lumina’ and ‘Tallman’ had significantly less foliage with symptoms than did ‘Happy Jack,’ ‘Small Sugar,’ and ‘Wizard.’ In both years, C. maxima cultivars had fewer symptoms overall than did C. pepo cultivars (P ≤ 0.0001).

**Yield of fruit.** Fruit numbers were low for most cultivars in both years. In 1996, harvest was 3 weeks earlier than anticipated because of accelerated foliage senescence. Choanephora wet rot, caused by *Choanephora cucurbitarum* (Berk. & Ravenel) Thaxt., was observed on decaying young fruit in both years. Cultivars Autumn Gold, Happy Jack, and Tom Fox set no fruit in 1996, but all cultivars except Big Autumn produced at least one fruit per plot in 1997. Most cultivars produced more total and marketable fruit in 1997 than in 1996; however, ‘Spooktacular,’ ‘Funny Face,’ ‘Oz,’ and ‘Trickster’ produced more marketable-quality fruit in 1996 than in 1997 (Table 2). HMX 6686 had the highest number of total fruit both years and ‘Spooktacular’ and ‘Spookie’ had the highest number of marketable-quality fruit in 1996 and 1997, respectively. Among C. maxima cultivars, Rouge Vif d’Etamps yielded the most total fruit both years, but marketable yields were low for all four C. maxima cultivars. Most of the nonmarketable fruits were disfigured with warts or knobs or had uneven green-orange coloration due to virus infection.

**Mean fruit weight.** In 1996, mean fruit weights were uniformly low (Table 2). In 1997, weights for 13 cultivars fell within the ranges of expected values (∼4.5 kg, 5.3 kg, and 7.1 kg for cultivars with small, medium, and large fruit, respectively) (Table 2). Five cultivars expected to produce large fruit had fruit weights less than 9.1 kg and nine cultivars expected to produce medium-sized fruit had fruit weights <4.5 kg. Two cultivars, ‘Rouge Vif d’Etamps’ and ‘Tallman,’ produced fruit weighing more than the upper threshold for medium-sized fruit. By size class, mean fruit weights for cultivars with small (0.36 kg), medium (0.82 kg), and large fruits (1.25 kg) also were very low in 1996. In 1997, weights for the three size classes were similar to expected values: 10.1 kg (range 22.1 to 5.3) for large-, 5.1 kg (range 12.6 to 2.0) for medium-, and 1.8 kg (range 2.6 to 1.1) for small-fruited cultivars. In both years, class means for the three sizes differed significantly from each other (P ≤ 0.01 in 1996 and P ≤ 0.0001 in 1997).

**Comparison of classes of cultivars.** Because of the large number of cultivars examined in this study, means also were compared by classes of cultivars (Table 3). Cultivars were assigned to classes according to species, expected days to maturity, expected fruit size, growth habit (vine or semi-bush) and type of pollination (open-pollinated or hybrid) (Tables 1 and 2). *Cucurbita maxima* cultivars, as a group, produced significantly higher numbers of total fruit than did *C. pepo* cultivars in both

* Cultigen × year interaction significant at P ≤ 0.01.
* Means for three replications in 1996 and four replications in 1997.
* Expected days to maturity based on seed company descriptions.
* Fruit size, S = expected mean fruit weight <4.5 kg, M = expected mean fruit weight ≥4.5 kg but <9.1 kg, and L = mean fruit weight >9.1 kg, based on seed company descriptions.
* Vine = vining plant type, semi = semi-bush type of plant, based on field observations.
* Fruit with no decay, intact stems, and no disfiguration or color-breaking due to virus.
* Fruit with no decay, intact stems, and <20% surface area with virus symptoms.
* Mean separation by Waller–Duncan k ratio t test; k = 500 (approximates P = 0.01).
* No fruit produced in this year.
* Open-pollinated.
* Only value significantly different from 0.0 in 1996, Dunnett’s t test, P ≤ 0.01.
years (Table 3). However, the number of marketable fruit did not differ significantly between the two species. On average, long- and mid-season cultivars produced greater numbers of total and marketable fruit than did short-season cultivars, except for long-season cultivars in 1996 (Table 3). Small-fruited cultivars produced more total and marketable fruit than did cultivars with medium-sized fruit both years. Likewise, cultivars with large fruit produced more fruit than did cultivars with medium-sized fruit, except for marketable fruit of both species in 1996. However, number of marketable fruit generally did not differ between small- and large-fruited cultivars (data not shown). Vining cultivars produced more fruit than did bush cultivars in 1997, but not in 1996. Open-pollinated cultivars produced more fruit than did hybrid cultivars in 1997 but not in 1996.

### Discussion

In general, all four *C. maxima* cultivars and the three *C. pepo* cultivars with powdery mildew resistance exhibited significantly lower powdery mildew severities than did susceptible *C. pepo* cultivars. These results were consistent in both years, even though powdery mildew was more severe in 1996 than in 1997. When tested in other locations, ‘Magic Lantern’ (HMX 5683) and HMX 6686 also had less powdery mildew than standard susceptible cultivars (McGrath, 1998; McGrath and SIECKZA, 1997). We found the resistance of HMX 6688 to be as effective as the other two powdery mildew-resistant lines we tested, as reported by McGrath and SIECKZA (1997). However, in Ohio ratings for HMX 6688 were not significantly different from ratings for ‘Jackpot,’ which is susceptible to powdery mildew (PRECHER et al., 1998). Because ‘Spookie’ had good marketable yields despite high levels of powdery mildew, it may have some tolerance to this pathogen.

Although we did not evaluate cultivars without applying fungicides, reducing the amount or frequency of fungicides applied to pumpkin cultivars with resistance to powdery mildew may be possible, as has been done successfully with resistant summer squash cultivars (McGRATH et al., 1996). A cultural control to supplement fungicial control of powdery mildew is needed, since in many areas of the United States the fungus is resistant to benomyl and triadimefon, the two most widely-used systemic fungicides effective against powdery mildew on cucurbits (McGRATH et al., 1996). However, powdery mildew-resistant plant cultivars cannot be grown without fungicides, based on trials conducted in Ohio (PRECHER et al., 1998) and New York (McGRATH, 1998).

Without fungicide, ‘Magic Lantern’ had less powdery mildew than a related susceptible experimental line, but more than the same line that was sprayed with fungicide (McGRATH, 1998).

In North Carolina, PRSV and WMV were detected on summer squash one year, whereas PRSV, WMV, and ZYMV were detected the following year (SCHULTHEIS and WALTERS, 1998).

### Table 3: Comparison of numbers of total and marketable fruit in 1996 and 1997 by different classes of 26 *Cucurbita pepo* and four *C. maxima* pumpkin cultivars.

1 Number of fruit per 9.7-m row. Means for three replications in 1996 and four replications in 1997.

2 Probability that the mean for the class listed first was greater than the mean for the second class. Preplanned single-degree-of-freedom contrasts.

3 The mean for the class listed second was greater than the mean for the first class.

4 Large-fruited = expected average fruit weight >9.1 kg, medium = 4.5–9.1 kg, and small = ≤4.5 kg.

Similarly, we detected PRSV, WMV, and ZYMV in 1996 but only PRSV and ZYMV in 1997. Apparently, PRSV is one of the most common cucurbit viruses, whereas incidence of ZYMV and WMV can vary by year and location. As noted by SCHULTHEIS and WALTERS (1998), cultivars with resistance to PRSV are needed to improve marketable yields of fall-grown cultivars in the southeastern United States. In summer squash, fruit expression of virus symptoms did not appear to be related to the severity of foliar symptoms (SCHULTHEIS and WALTERS, 1998). Similarly, ‘Small Sugar’ and ‘Little Lantern’ pumpkin had good yields of marketable-quality fruit, even though leaf symptoms of virus were severe. In contrast, although the *C. maxima* cultivars had fewer foliar virus symptoms than *C. pepo* cultivars, most of the fruits graded as unmarketable had color-breaking and disfigurement typical of virus infection (ZITTER et al., 1996).

The two cultivars with the *Py* gene, ‘Big Autumn’ and ‘Autumn Gold’, produced few fruit, some of which still showed color-breaking due to virus. Powdery mildew severity also was not statistically correlated with marketable yield of fruit, probably because downy mildew and virus also reduced yields.

Yields of total and marketable fruit were greater in 1997 than in 1996. Most cultivars seemed to require more than the 1.8-m spacing allowed in 1996, and turning the fragile vines damaged them, possibly reducing yields. Plant spacing of 0.9 m within rows in 1996 also may have been too close for optimum yields. In addition, downy and powdery mildew pressure was higher earlier in the season in 1996 than in 1997, which probably reduced yields as well. Using lower rates of fungicides for most of the 1996 season may have contributed to the higher disease pressure.

As a group, short-season cultivars (<95 d to maturity) had lower total and marketable yields than did mid- or long-season cultivars. Because of the later transplanting date used for short-season cultivars in these tests, they may have been exposed at transplanting to virus or powdery mildew inoculum from the earlier-planted cultivars. Cultivars with small (<4.5 kg) or large (>29.1 kg) fruit produced greater numbers of fruit than cultivars with medium-sized fruit (≥24.5 kg but <9.1 kg). The lower yields of cultivars with medium-sized fruit may be explained partially by vining type, since seven of the nine medium-sized cultivars were semi-bush types that, as a group, had lower yields than vining types in 1997. In addition, all five top-yielding cultivars, Spookie, HMX 6686, Spooktacular, Magic Lantern, and Small Sugar, are vining types. In 1997, of the 32 cultivars tested produced fruit that reached the expected sizes, whereas 14 produced fruit that were smaller than expected. Only two *C. pepo* cultivars, ‘Howden Biggie’ and ‘Tallman’, produced large fruit (>29.1 kg) and neither of these cultivars had high yields.

Based on these 2 years of testing in one location, none of the 32 cultivars we examined were particularly well-adapted for production in the southeastern coastal plain, very likely because no cultivar combines resistances to powdery mildew, downy mildew, PRSV, ZYMV, and WMV. The two best-yielding cultivars were ‘Spooktacular’ and ‘Magic Lantern’. Although ‘Spookie’ had a higher mean marketable yield (8.4 fruit per 9.7-m row of eight plants) over the 2 years than did ‘Spooktacular’ (4.5 fruit), ‘Spooktacular’ had a much lower variance (20.0 compared with 85.4), indicating that it was a more reliable producer. ‘Spooktacular’ produced small fruit, suitable for ‘pick-your-own’ and other direct markets. ‘Magic Lantern,’ which is resistant to powdery mildew, produced medium-sized fruit, suitable for both direct and wholesale markets. Because few cultivars yielded well under the hot, humid conditions, there is a need to develop pumpkin cultivars that are adapted to production in the lower coastal plains of the southeastern United States.
