(Dated: July 2, 2015)

The quantum interference and orbital filling effects on the thermoelectric (TE) properties of quantum dot molecules with high figure of merit are illustrated via the full solution to the Hubbard-Anderson model in the Coulomb blockade regime. It is found that under certain condition in the triangular QD molecule (TQDM), destructive quantum interference (QI) can occur, which leads to vanishing small electrical conductance, while the Seebeck coefficient is modified dramatically. When TQDM is in the charge localization state due to QI, the Seebeck coefficient is seriously suppressed at low temperature, but highly enhanced at high temperature. Meanwhile, the behavior of Lorenz number reveals that it is easier to block charge transport via destructive QI than the electron heat transport at high temperatures. The maximum power factor (PF) in TQDM occurs at full-filling condition. Nevertheless, low-filling condition is preferred for getting maximum PF in serially coupled triple QDs in general. In double QDs, the maximum PF can be achieved either with orbital-depletion or orbital-filling as a result of electron-hole symmetry. Our theoretical work provides a useful guideline for advancing the nanoscale TE technology.

I. INTRODUCTION

To design solid-state coolers and power generators,[1-7] many efforts seek efficient thermoelectric (TE) materials with the figure of merit (ZT) larger than 3, which will lead to efficient TE conversion, making the TE device competitive with conventional air conditioners and power generators.[1,2] Furthermore, the energy harvesting by using TE materials is one of several advanced techniques considered for clean energies. The optimization of $ZT = S^2 G_e T / \kappa$ depends on the electrical conductance ($G_e$), Seebeck coefficient (S), and thermal conductance ($\kappa$). $T$ is the equilibrium temperature. These physical quantities are usually related to one another. Mechanisms leading to the enhancement of power factor ($PF = S^2 G_e$) would also enhance the thermal conductance. Consequently, it is difficult to obtain $ZT$ above one in conventional bulk materials.[1]

Recently, quantum dot superlattice (QDSL) nanowires with impressive $ZT$ values (larger than one) have been demonstrated experimentally.[8] The power factor and thermal conductance become independent thermoelectric variables under the condition $\kappa_e / \kappa_{ph} \ll 1$, where $\kappa_e$ and $\kappa_{ph}$ denote, respectively, the electron thermal conductance and phonon thermal conductance.[8] In the Coulomb blockade regime, electron transport process is seriously suppressed by the electron Coulomb interactions, causing $\kappa_e$ and $G_e$ to be reduced simultaneously.[9] On the other hand, under the condition $\kappa_e / \kappa_{ph} \ll 1$, one can increase the power factor (PF) [10-15] and decrease the phonon thermal conductance [16-21] simultaneously to optimize $ZT$. The $ZT$ enhancement of QDSL mostly arises from changes induced by dimensional confinement in the electronic band structures as well as enhanced phonon scattering resulting from the scattering at nanowire surface and interfaces surrounding QDs.[1,2]

Although many theoretical efforts have investigated the PF enhancement of QDs[10-15] and molecular junctions[22-24], quantum interference (QI) and orbital filling effects on the PF optimization are still puzzling due to the difficulty to treat many-body effect reliably in either QDSLs or molecules.[25] For example, in the triangular QD molecule (TQDM), there are 923 electron correlation functions appeared in the 4752 Green’s functions need to be solved, when electron Coulomb interactions are turned on, even though one just considers one energy level for each QD. As a consequence, a theoretical framework to treat adequately the many-body problem of a molecular junction remains elusive. QI is a remarkable effect, which influences the charge transport of QD array [6-8] and molecules [22-24] with multiple quantum paths. When the energy levels of QDSLs or molecules are below the Fermi energy of electrodes, the orbital filling effects can not be avoided for charge/heat transport. To reveal the many-body effects on the TE properties of QD junction system, we theoretically investigate QD molecules (QDMs), including double QD molecule (DQD), serially coupled triple QDs (SCTQD), and TQDM with a full many-body solution which takes into account all correlation functions resulting from electron Coulomb interactions in QDMs. Our results indicate that the effects of QI and structure-dependent orbital filling are quite significant in determining the behaviors of TE coefficients for junctions of QDSL or molecules (such as benzene).
II. FORMALISM

Here we consider nanoscale semiconductor QDs, in which the energy level separations are much larger than their on-site Coulomb interactions and thermal energies. Thus, only one energy level for each quantum dot needs to be considered. An extended Hubbard-Anderson model is employed to simulate a QDMs connected to electrodes (see the inset of Fig. 1(b). The Hamiltonian of the QDM junction is given by $H = H_0 + H_{QD}$:

$$H_0 = \sum_{k,\sigma} \epsilon_k a_{k,\sigma}^\dagger a_{k,\sigma} + \sum_{k,\sigma} \epsilon_k b_{k,\sigma}^\dagger b_{k,\sigma}$$

$$+ \sum_{k} V_{kL} d_{L,\sigma}^\dagger a_{k,\sigma} + \sum_{k} V_{kR} d_{R,\sigma}^\dagger b_{k,\sigma} + c.c.$$

where the first two terms describe the free electron gas of left and right electrodes. $a_{k,\sigma}^\dagger$ creates an electron of momentum $k$ and spin $\sigma$ with energy $\epsilon_k$ in the left (right) electrode. $V_{kL}$ ($L = L, R$) describes the coupling between the electrodes and the left (right) QD. $d_{L,\sigma}^\dagger$ (for $L$-dot) creates (destroys) an electron in the $L$-th dot.

$$H_{QD} = \sum_{t,s} E_t n_{t,s} + \sum_{t} U_{t} n_{t,s} n_{t,s}$$

$$+ \frac{1}{2} \sum_{t'j,\sigma,\sigma'} U_{t,j} n_{t',\sigma} n_{j,\sigma'} + \sum_{t'j} t_{t'j} d_{L,\sigma}^\dagger d_{j,\sigma'},$$

where $E_t$ is the spin-independent QD energy level, and $n_{t,s} = d_{t,s}^\dagger d_{t,s}$. Notations $U_{t}$ and $U_{t,j}$ describe the intradot and interdot Coulomb interactions, respectively. $t_{t,j}$ describes the electron interdot hopping. Noting that the interdot Coulomb interactions as well as intradot Coulomb interactions play a significant role on the charge transport for semiconductor QDs and molecular structures.

Using the Keldysh-Green’s function technique, the charge and heat currents from reservoir $\alpha$ to the QDM junction are calculated according to the Meir-Wingreen formula:

$$J_\alpha = \frac{i e}{\hbar} \sum_{j,\sigma} \int d\epsilon \Gamma_\alpha^j(\epsilon) [G_{j\sigma}^R(\epsilon) + f_\alpha(\epsilon)(G_{j\sigma}^A(\epsilon) - G_{j\sigma}^R(\epsilon))]$$

$$Q_\alpha = \frac{i}{\hbar} \sum_{j,\sigma} \int d\epsilon (\epsilon - \mu_\alpha) \Gamma_\alpha^j(\epsilon) [G_{j\sigma}^R(\epsilon) f_\alpha(\epsilon)$$

$$- (G_{j\sigma}^A(\epsilon) - G_{j\sigma}^R(\epsilon))].$$

Notation $\Gamma_\alpha^j = \sum_k |V_{kL}\alpha|^2 \delta(\epsilon - \epsilon_k)$ is the tunneling rate between the $\alpha$-th reservoir and the $L$-th QD. $f_\alpha(\epsilon) = 1/\{\exp[(\epsilon - \mu_\alpha)/k_B T_\alpha] + 1\}$ denotes the Fermi distribution function for the $\alpha$-th electrode, where $\mu_\alpha$ and $T_\alpha$ are the chemical potential and the temperature of the $\alpha$ electrode. $\mu_L - \mu_R = \Delta V$ and $T_L - T_R = \Delta T$. $e$, $h$, and $k_B$ denote the electron charge, the Planck’s constant, and the Boltzmann constant, respectively. $G_{j\sigma}^R(\epsilon)$, $G_{j\sigma}^A(\epsilon)$, and $G_{j\sigma}^\alpha(\epsilon)$ are the frequency domain representations of the one-particle lesser, retarded, and advanced Green’s functions $G_{j\sigma}^R(t, t') = i \langle \delta J_{j\sigma}(t') \delta J_{j\sigma}(t) \rangle$, $G_{j\sigma}^A(t, t') = -i \langle \delta J_{j\sigma}(t) \delta J_{j\sigma}(t') \rangle$, and $G_{j\sigma}^\alpha(t, t') = i \langle \delta J_{j\sigma}(t) \delta J_{j\sigma}(t') \rangle$, respectively. These one-particle Green’s functions are related recursively to other Green’s functions and density-density correlators via the few-body equation of motion,[25] which we solve via an iterative numerical procedure to obtain all $n$-particle Green’s functions and correlators for the QDM. The coupling between electrons in the leads and electrons in QDM is included in the self-energy term, $\Gamma_\alpha^j$. Because of this approximation, our procedure is valid only in the Coulomb blockade regime, but not the Kondo regime.[28]

Thermoelectric coefficients in the linear response regime are

$$G_e = \frac{(\delta J_\alpha)}{(\delta \Delta V)} \Delta T = 0$$

$$S = -\frac{(\delta J_\alpha)}{(\delta \Delta T)} \Delta V = 0$$

$$\kappa_e = \frac{(\delta Q_\alpha)}{(\delta \Delta T)} \Delta V = 0$$

$$\frac{(\delta Q_\alpha)}{(\delta \Delta V)} \Delta T = 0$$

$$\frac{(\delta J_\alpha)}{(\delta \Delta V)} \Delta V = 0$$

$$\frac{(\delta J_\alpha)}{(\delta \Delta T)} \Delta V = 0$$

The quantity $\frac{(\delta J_\alpha)}{(\delta \Delta V)}$ is obtained by solving the variation of the equation of motion with respect to the change in Fermi-Dirac distribution, $f_\alpha(\epsilon)$. Here we have assumed the variation of the correlation functions with respect to $\delta f_\alpha(\epsilon)$ is of the second order. Note that we have to take $\Delta V \to 0$ for the calculations of $\frac{(\delta f_\alpha)}{(\delta \Delta V)} \Delta T = 0$ and $\frac{(\delta f_\alpha)}{(\delta \Delta T)} \Delta V = 0$. 

The Hamiltonian of the QDM junction is given by $H = H_0 + H_{QD}$:

$$H_0 = \sum_{k,\sigma} \epsilon_k a_{k,\sigma}^\dagger a_{k,\sigma} + \sum_{k,\sigma} \epsilon_k b_{k,\sigma}^\dagger b_{k,\sigma}$$

$$+ \sum_{k} V_{kL} d_{L,\sigma}^\dagger a_{k,\sigma} + \sum_{k} V_{kR} d_{R,\sigma}^\dagger b_{k,\sigma} + c.c.$$
\[
\frac{\partial G}{\partial T}\big|_{T=0}. \quad \text{Meanwhile we take } \Delta T \to 0 \text{ for Eqs. (9) and (10). } E_F \text{ is the Fermi energy of electrodes. There is a Joule heating term } \Delta V \times J_n \text{ arising from Eq. (4) which can be ignored in the linear response regime.}
\]

It is a challenge to prove that whether the Eqs. (3) and (4) can be expressed in terms of transmission coefficient (or Landauer’s expression) when one takes into account all Green’s functions and correlation functions fully. To gain deeper insight into the electron correlation effect, we adopt the approximation procedure of Ref. [9] and obtain

\[
G_e = e^2L_0, \quad S = -L_1/(eT_0), \quad \text{and } \kappa_e = \frac{\pi}{2}(L_2 - L_1^2/L_0),
\]

which can be calculated by a closed form expression for the transmission coefficient. \( L_n \) is given by

\[
L_n = \frac{2}{h} \int d\epsilon T_{LR}(\epsilon)(\epsilon - E_F)^n \frac{\partial f(\epsilon)}{\partial E_F},
\]

where \( T_{LR}(\epsilon) \) is the transmission coefficient. \( f(\epsilon) = 1/(e^{(\epsilon-E_F)/k_B T} + 1) \). The thermolectric coefficients determined by Eq. (12) are employed to compare with results of Eqs. (5)-(7). Because the condition \( \kappa_e/\kappa_{ph} \ll 1 \) is readily satisfied in the Coulomb blockade regime, [9] the optimization of ZT can be improved by finding the best power factor \( PF = S^2G_e \).

### III. RESULTS AND DISCUSSION

#### A. Effect of destructive QI

Firstly, we consider TQDM with electron hopping strengths \( t_{LC} = t_{CR} = t_c \neq t_{LR} \). Figure 1 shows the electrical conductance and Seebeck coefficient as functions of the energy level of central QD \( \Delta_C = E_C - E_F \) for various coupling strengths, \( t_{LR} \) at \( k_B T = 1\Gamma_0 \). In the small \( \Delta_C \) regime (\( \Delta_C \leq 10\Gamma_0 \)) \( G_e \) is found to be insensitive to \( t_{LR} \), because the charge transport is dominated by the near-resonant tunneling process through levels at \( E_F \) and \( \sqrt{2}t_c \), \( E_F \) and \( E_F - \sqrt{2}t_c \). On the other hand, \( G_e \) changes significantly with the variation of \( t_{LR} \) in the regime of \( \Delta_C / \Gamma_0 \geq 10 \). For \( t_{LR} = 0.1\Gamma_0 \), \( G_e \) is vanishingly small at \( \Delta_C = 90\Gamma_0 \). The minimum of \( G_e \) occurs at lower \( \Delta_C \) if \( t_{LR} \) is increased. For example, the minimum of \( G_e \) occurs at \( \Delta_C = 45\Gamma_0 \), \( \Delta_C = 30\Gamma_0 \), and \( \Delta_C = 22.5\Gamma_0 \) for \( t_{LR} = 0.2\Gamma_0 \), \( t_{LR} = 0.3\Gamma_0 \) and \( t_{LR} = 0.4\Gamma_0 \), respectively. This behavior is caused by the quantum interference (QI) between two paths. This direct coupling \( t_{LR} \) between the outer QDs provides one path. The long distance coherent tunneling (LDCT)[25] mediated by the central QD provides another path, which leads to an effective electron hopping strength \( t_{eff} = -t_{LC}t_{CR}/\Delta_C \) between the outer QDs. Such an effective coupling between outer dots can be used to manipulate the spin entanglement between dots separated by a long distance. [29-31] We note that the vanishingly small \( G_e \) occurs when the condition of \( |t_{eff}| = t_{LR} \) is met. To depict the behavior of Fig. 1(a), we also calculate \( G_e \) by using the approximate expression \( T_{LR}(\epsilon) \) for transmission coefficient as given below.

\[
T_{LR}(\epsilon) = \frac{\mu_1\mu_2\mu_3 - t_{LR}^2t_{RC}\mu_1 - t_{LR}^2t_{CR}\mu_3 - 2t_{LR}t_{LC}t_{CR}}{\mu_1\mu_2\mu_3},
\]

where \( \mu_1 = \epsilon - E_L + i\Gamma_L \), \( \mu_2 = \epsilon - E_C + i\Gamma_C \) and \( \mu_3 = \epsilon - E_R + i\Gamma_R \). \( P_1 \) denotes the probability weight of electron transport through TQDM in an empty state, which is determined by the one particle occupation number and on-site two particle correlation functions resulting from electron Coulomb interactions. \( P_1 \) equals to one in the absence of electron Coulomb interactions. The numerator \( F_{QI} = (t_{LC}t_{CR} + t_{LR}t_{C})^2 \) causes the QI effect. The first term and the second term of \( F_{QI} \) describe, respectively, the upper path through the central QD and lower path for direct hopping between the outer QDs. Due to \( t_{LC} = t_{CR} = t_c \neq t_{LR} \), there are three poles in the denominator of Eq. (13). If we take \( \Gamma = 0 \), the poles occur at

\[
\epsilon_\pm = \frac{E_C + E_0 + t_{LR}}{2} \pm \frac{1}{2} \sqrt{(E_C - E_0 - t_{LR})^2 + 8t_c^2},
\]

\[
e_0 = E_0 - t_{LR}.
\]

Here, \( E_0 = E_L = E_R = E_F \) in Eq. (14). For higher symmetry TQDM (\( t_{LR} = t_{ LC} = t_c = t_c \) and \( E_0 = E_0 \)), we have \( \epsilon_+ = E_0 + 2t_c, \epsilon_- = E_0 - t_c \) and \( e_0 = E_0 - t_c \). Once \( \Delta_C = E_C - E_R \gg 2t_c \), the lowest energy level is given by \( e_0 = E_0 - t_{LR} \). Keeping only the resonant channel at \( e_0 \), we obtain

\[
G_e = \frac{2e^2}{h} \frac{\Gamma}{(t_{LR} + t_{eff})^2 + (\Gamma/2)^2} \cosh(\frac{t_{LR}}{2k_BT}),
\]

where \( t_{eff} = -t_c^2/\Delta_C \). This expression can well explain the destructive QI behavior shown in Fig. 1(a). According to Eq. (13), the QI observed in Fig. 1(a) will disappear as \( t_{LR} = 0 \) (the case of SCTQD). In Sanchez et al.[32] it was proposed that destructive QI of two superexchange trajectories can also occur in SCTQD. Note that such a effect is easily masked by the background current at finite temperatures. Thus, it is not as robust as the QI effect described here. Using Eq. (12) and considering the \( e_0 \) pole of Eq. (14), we can show that \( S = t_{LR}/T \) is positive and independent on \( \Delta_C \). However, \( S = t_{LR}/T \) can not describe the behavior of \( S \) shown in Fig. 1(b) (obtained by the full calculation), which is a function of \( \Delta_C \). This implies that the resonant channels involving \( E_C \) can not be ignored for calculating \( S \) in the regime of \( t_{eff}/t_{LR} \gg 1 \). The positive sign of \( S \) indicates that the hole diffusion dominates over electron diffusion at low temperature \( (k_B T = 1\Gamma_0) \). Here poles are defined as missing electrons in states below \( E_F \). The results of Fig. 1(b) show that the Seebeck coefficient is seriously suppressed under the destructive QI effect. Such a behavior is quite different from the general behavior of thermal voltage observed in QD junction systems.[10-15] (See results of Figs. 5-8 and note that the minimum of \( S \) occurs at the maximum of \( G_e \).
To further clarify the above destructive QI behavior, we plot the electrical conductance and Seebeck coefficient at various temperatures for $t_{LR} = 0.3 \Gamma_0$ in Fig. 2. It shows that $G_e$ is suppressed with increasing temperature. Meanwhile, the destructive QI effect on $G_e$ is very robust with respect to temperature variation when $k_B T$ is tuned up to $5 \Gamma_0$. The results of Fig. 2(a) imply that a single-electron QI transistor is achievable even at room temperature.[33] The change of sign for $S$ from positive to negative indicates that the resonant channels above $E_F$ become important with increasing temperature with electron contribution dominating over hole contribution. In particular, we noticed a large enhancement of the negative $S$ peak at $\Delta_{QI}$ (the value of $\Delta_C$ where QI occurs) as temperature increases. Namely, the thermal voltage changes sign and enhances with increasing temperature. We also noticed that peak value of $|S|$ reaches a maximum near $k_B T = 4 \Gamma_0$ and decreases afterwards.

To reveal the importance of electron correlation effects and understand the interesting behavior of $S$ in Fig. 2(b), we recalculate the results of Fig. 2 with the procedure of Ref. [9]. There are 32 configurations in the transmission coefficient of Eq. (12) for electrons with spin $\sigma$ in the electrodes. The expression of Eq. (13) is for an empty QD. The curves in Fig. 3 have one-to-one correspondence to those of Fig. 2. We found significant differences between Fig. 2(a) and Fig. 3(a), when $\Delta_C$ is smaller than 20 $\Gamma_0$. This implies that the electron correlation effects become important when $E_C$ closes to $E_F$. In particular, two-particle interdot correlation functions. However, both approaches give similar QI effect with the same value for $\Delta_{QI}$. This is because QI is mainly caused by the single-particle transport process. Fig. 3(b) also shows enhancement of $|S|$ at $\Delta_{QI}$ with increasing temperature, but the degree of enhancement is overestimated compared with the full calculation. The temperature dependence of $S_{\text{max}}$ (at $\Delta_{QI}$) is plotted in the inset of Fig. 3(b). It is seen that $S_{\text{max}}$ obeys the simple relation $S \approx -\frac{\Delta_{QI}}{k_B T}$ when $k_B T > 2 \Gamma_0$. One can show that the next important contribution to $S$ is from the resonant channel near $\epsilon = E_0 + U_{LR} - t_{LR}$, but not from $\epsilon_+$, given by Eq. (14). Note that the contribution of this resonant channel to $G_e$ is small compared to the $\epsilon_0$ channel. To demonstrate the effect of electron Coulomb interactions, we plot the curve with red triangle marks for $U_t = U_{t,j} = 0$ at $k_B T = 2 \Gamma_0$. Now, $S_{\text{max}} = t_{LR}/T$ becomes very small in the absence of electron Coulomb interactions. This proves that the enhancement of $|S_{\text{max}}|$ results from the resonant channels involving electron Coulomb interactions. This also explains the enhancement of $|S_{\text{max}}|$ shown in Fig. 2(b).

According to the results of Figs. (1) and (2), the destructive QI effect can blockade the charge transport. Next, we clarify how QI influences electron heat transport. Fig. 4 shows the electron thermal conductance ($\kappa_e$) and Lorenz number ($L_z = \kappa_e/(G_e T)$) as functions of $\Delta_C$. The physical parameters adopted in the calculation are the same as those for Fig. 2. Like $G_e$, the electron heat transport can be modulated by tuning the central QD energy level. We see that the electron thermal conductance is also vanishingly small at $\Delta_{QI} = 30 \Gamma_0$ due to the destructive QI. There is the Wiedemann-Franz law in metals to link two physical quantities ($G_e$ and $\kappa_e$). Here, we recheck the Wiedemann-Franz law by calculating the Lorenz number in Fig. 4(b). A highly temperature-dependent behavior of $L_z$ occurs at $\Delta_{QI}$. The fact that $L_z$ larger than one indicates that it is easier to block charge transport via destructive QI than the electron heat transport. In metals the Lorenz number is a universal constant $L_z = \frac{2}{3}(k_B/e)^2$, which is independent of $T$. Our results obviously violate the Wiedemann-Franz law near $\Delta_C = \Delta_{QI}$ for all temperatures. The violation of Wiedemann-Franz law is a typical phenomenon for nanostructures with discrete energy levels.[3] The QI effects on the TE properties are illustrated by using QDMs with $N=3$ as an example. The asymmetrical features of $t_{L,C} = t_{LR} \neq t_{JR}$. $U_{L,C} = U_{CR} \neq U_{LR}$ and $E_L = E_R \neq E_C$ considered in TQDM can be used to reveal the effects of QD size fluctuation and nonuniform interdot separation on the charge transport of QDSL system.[6,8]

### B. Orbital filling effects

Many theoretical studies have used the first-principles method (within mean-field approximation) to predict the TE coefficient of realistic molecules with orbital below the $E_F$ of electrodes.[22-25] Such a mean-field approach does not take full account of the electron correlation effects. Therefore, the predicted $G_e$, $S$ and PF cannot reveal the realistic TE properties of molecule junction systems in the Coulomb blockade regime. To reveal the orbital charge-filling (orbital below $E_F$) effects on the thermoelectric properties of TQDM, we plot the total occupation number ($N = \sum (N_{L,\sigma} + N_{R,\sigma})$), $G_e$, and $S$ as functions of gate voltage $V_g$ ($E_e = E_F + 30 \Gamma_0 - eV_g$) at $\Gamma = 0.3 \Gamma_0$, $t_{t,j} = 3 \Gamma_0$ and $U_{t,j} = 30 \Gamma_0$ for various temperatures in Fig. 5. Here, the QD energy levels are placed at $30 \Gamma_0$ above $E_F$ when $eV_g = 0$. The average total occupation number ($N$) display an staircase behavior with six plateaus. The step edges are broadened as temperature increases. The height of each staircase is equal to one. The onsets of these plateaus are roughly determined by $U_{t,j}$ and $U_t$. Therefore, the electron number of TQDM is tuned from one to six with increasing gate voltage. The spectrum of $G_e$ exhibits a Coulomb oscillation behavior with respect to gate voltage. Six main peaks of $G_e$, labeled by $\epsilon_n$, correspond to the particle-addition energy of TQDM with different many-body states. For $k_B T = 1 \Gamma_0$, there are several insulating states (with vanishingly small $G_e$). Such insulating states are not due to the QI effect, but the Coulomb blockade effect. The regime of vanishingly small $G_e$ is related to a very small transmission coefficient resulting from the absence of resonant levels near $E_F$. The insulating state of a single benzene molecule calculated by the DFT method was
suggested from the destructive QI effect.\[22-24] The suggestions from Refs.\[22-24] are unclear due to the deficiency of the mean-field theory (DFT). Although the behavior of \( G_e \) with respect to \( k_B T \) is a typical behavior that the magnitude of \( G_e \) peak is suppressed with increasing temperature, meanwhile the width of each peak becomes broadened, we find a more dramatic reduction of \( \epsilon_6 \) peak when \( k_B T \) is tuned from \( 1\Gamma_0 \) to \( 2\Gamma_0 \). In addition, the peak position is shifted with increasing temperature. Several secondary peaks resulting from excite states around these main peaks are washed out by increasing temperature. The separation between \( \epsilon_3 \) and \( \epsilon_4 \) is the so called "Coulomb gap" (these two peaks are separated by the intradot Coulomb interaction \( U_{t,j} \).\[25] Using the middle Coulomb gap as a reference point, the \( G_e \) spectrum does not maintain the mirror symmetry. This is different from that of DQDs.

The Seebeck coefficient shown in Fig. 5(c) also shows an oscillatory behaviors with respect to gate voltage. When QD energy levels are above \( E_F \) the Seebeck coefficients are negative, which indicates that electrons dominate the diffusion process of thermoelectric properties. When QD energy levels near \( E_F \), \( S \) almost vanishes due to the electron-hole balance. The positive \( S \) indicates that holes through resonant level below \( E_F \) become majority carriers. Such bipolar effects are the interplay between holes and electrons. When the resonant levels corresponding to the two-electron and three-electron states of TQDM (\( \epsilon_2 \) and \( \epsilon_3 \)) are near \( E_F \), once again the Seebeck coefficients become very small. We note that when \( G_e \) reaches the maximum, the Seebeck coefficient \( S = \Delta V/\Delta T \) reaches zero. This is different from that of Fig. 2. The Seebeck coefficient near the onsets of plateaus for \( N = 1, 3, 4, \) and 6 are highly enhanced with increasing temperature. Like the \( G_e \) spectrum, the Seebeck coefficient does not exhibit a mirror symmetry. We find prominent secondary oscillatory structures of \( S \) (clearly noticeable at \( k_B T = 1\Gamma_0 \)), which arise from the secondary resonant levels around the main peaks of \( G_e \). Compared to the spectrum of \( G_e \) at low temperature, the spectrum of \( S \) can clearly resolve the structures arising from the excited states (secondary resonances) of TQDM. Consequently, the measurement of \( S \) is a powerful means to reveal various configurations of TQDM arising from the many-body effect. Unlike the case of metallic QDs,\[34] the spectrum of \( S \) does not show the periodically oscillating oscillatory structure with respect to the gate voltage due to \( U_t \neq U_{t,j} \) and electron correlation effects. The interdot Coulomb interactions as well as intradot Coulomb interactions play significant roles for electron transport.

To examine the interdot Coulomb interaction effects, Figure 6 shows (a) the electrical conductance, (b) Seebeck coefficient and (c) power factor as functions of \( V_g \) for three different values of \( U_{t,j} \) at \( k_B T = 1\Gamma_0 \). Other physical parameters are the same as those of Fig. 5. From the results of \( G_e \), we find that the interdot Coulomb interactions not only influence the peak positions, but also change the magnitude of each peak. For \( U_{t,j} = 0 \), the \( G_e \) spectrum shows only four peaks (see blue dashed line). The first two peaks (separated by \( 3t_c \)) correspond to the resonant levels \( \epsilon_{BB} = E_0 - t_c \) (bonding state) and \( \epsilon_{AB} = E_0 + 2t_c \) (antibonding state). It is noted that the first \( G_e \) peak at \( \epsilon_{BD} \) is significantly reduced and the second peak at \( \epsilon_{AB} \) is totally suppressed when \( U_{t,j} \) becomes finite.

The peak structures of the \( G_e \) spectrum for \( U_{t,j} = 15\Gamma_0 \) is quite similar to that for \( U_{t,j} = 30\Gamma_0 \), except the spacings between peaks are different, which leads to very different behavior in the Seebeck coefficient. Previous theoretical works predicted the thermal power (or Seebeck coefficient) spectra without considering interdot Coulomb interactions.\[15] This is inadequate for studying semiconductor QD molecules with nanoscale separation between QDs. Our calculations indicate that to achieve large maximum power factor \( \text{PF}_{\text{max}} \) in TQDM with homogenous QD energy levels and electron hopping strengths, the full-filling condition (with six-electron state) is preferred. This is due to the fact that three resonant channels associated states localized at dot L, C, and R (with energies at \( E_L = U_0 + 2\Gamma_0 + U_{LR} \), \( E_C = U_0 + 2\Gamma_0 + U_{LC} + 2U_{CR} \), and \( E_R = U_0 + 2\Gamma_0 + U_{LR} + 2U_{CR} \), respectively) are all aligned. It is interesting to see what would happen in other QDM structures when the resonant conditions are changed.

Figure 7 shows the electrical conductance (\( G_e \)), Seebeck coefficient (\( S \)) and power factor (\( \text{PF} \)) of DQD as functions of \( V_g \) at different temperatures. Physical parameters are the same as those for Fig. 5. For DQD, the four \( G_e \) peaks correspond to \( \epsilon_1 = E_0 - t_c \), \( \epsilon_2 = E_0 + t_c - U_{LR} + U_{LR} - \frac{1}{2}\sqrt{(U_0 - U_{LR})^2 + 16t_c^2} \), \( \epsilon_3 = E_0 - t_c - U_{LR} + U_{LR} + \frac{1}{2}\sqrt{(U_0 - U_{LR})^2 + 16t_c^2} \), and \( \epsilon_4 = E_0 + U_0 + 2U_{LR} + t_c \). The \( G_e \) spectrum shows a mirror-symmetry behavior with respect to the middle of the Coulomb gap. Due to the symmetry of QD structure, the PF spectrum also shows the mirror symmetry. The maximum PF occurs at either orbital-depletion \( (N \leq 1) \) or orbital-filling \( (N = 4) \) condition for DQD. Note that unlike \( G_e \) and PF, \( S \) does not show the mirror symmetry.

Figure 8 shows \( G_e \), \( S \) and PF of SCTQD as functions of \( V_g \) at different \( T \). For simplicity, we adopt \( t_{LR} = 0 \) and \( U_{LR} = 0 \), since they are typically much smaller than the corresponding parameters related to the central dot. The \( G_e \) spectrum in Fig. 8 does not show the mirror symmetry as a result of the inhomogeneous interdot Coulomb interactions \( (U_{LC} = U_{CR} \neq U_{LR}) \). The peaks labeled \( \epsilon_n \) \((N = 1, 1, \cdots, 6)\) correspond to the transitions where the total particle numbers in the SCTQD changes from \( N - 1 \) to \( N \) with \( \epsilon_1, \epsilon_2, \) and \( \epsilon_4 \) being more prominent. The first peak comes from electrons tunneling through the empty SCTQD via the resonant level \( \epsilon_1 = E_0 - 2t_c \). The second peak \( (\epsilon_2 = E_0 + 2\sqrt{t_c} + U_{LR}) \) corresponds to charge transport in the presence of another electron localized in one of the two outer dots. Here we have chosen \( U_{LR} = 0 \).

This is verified by examining \( N_{C,\sigma} \), which is negligible until \( eV_g \) is near \( \epsilon_3 \). \( \epsilon_4 = E_0 + U_0 + U_{LC}(U_{CR}) \) corre-
sponds to the injection of an electron into the left (right) dot of SCTQD with all three dots each filled with one electron, while \( \epsilon_5 = E_0 + U_0 + U_{LC}(U_{CR}) + 2t_{eff} \) corresponds to the addition of another electron in either left or right dot to the configuration associated with \( \epsilon_4 \), where \( t_{eff} = t_{LC}t_{CR}/(E_F - (E_C + 2U_{LC} + 2U_{CR})) = 0.9\Gamma_0 \) is the effective hopping strength mediated by the center dot. Therefore, the splitting between \( \epsilon_4 \) and \( \epsilon_5 \) can be observed by increasing \( t_{ij} \). The Seebeck coefficient spectrum can reveal fine structures not resolved in the \( G_e \) spectrum. For example, the \( \epsilon_3 \) and \( \epsilon_6 \) peaks are hardly noticeable in \( G_e \) but clearly observable in \( S \). The peak at \( \epsilon_3 = E_0 + U_{LC} + U_{CR} \) is caused by the charging of the center dot with two outer dots each filled with one electron and \( \epsilon_6 \) describes the charging of SCTQD with a second electron into the center QD with two outer dots each filled with two electrons. In strong contrast to TQDM, both \( G_e \) and PF of SCTQD are very small at the maximum filling condition \((N = 6)\), which occurs at \( eV_p = 250\Gamma_0 \) where \( E_F + U_0 + 2U_{LC} + 2U_{CR} \) is aligned with \( E_F \). This is because the three resonant channels associated states localized at dot L, C, and R (with energies \( E_L + U_0 + 2U_{LC} + 2U_{LR}, E_C + U_0 + 2U_{LC} + 2U_{CR}, \) and \( E_R + U_0 + 2U_{LR} + 2U_{CR} \), respectively) are misaligned, since \( U_{LR} = 0 \) (or \( U_{LR} \ll U_{CR} \) in general). Consequently, charge transport is seriously suppressed for QD molecule with orbital-filling condition, which is expected to be a general feature in serially coupled QDMs with more dots. For the present SCTQD, the maximum PF occurs at the combined \( \epsilon_4 \) and \( \epsilon_5 \) peak as shown in Fig. 8. In this case, the charge transport is enabled via the long distance coherent tunneling mechanism, which means that the localized electron of the left dot can be transferred to the right dot via an effective hopping strength mediated by the central dot.[25] When we consider \( U_{LR} \) or tune \( t_{ij} \) away from \( 3\Gamma_0 \) (not shown here), the maximum PF for SCTQD would occur at the orbital-depletion condition.

IV. SUMMARY

To reveal the QI and orbital filling effects on the charge/heat transport in QDSL and molecule junction system, we have theoretically investigated the TE coefficients of TQDM with a full many-body solution. Our theoretical work can serve as a guideline for the design of nanoscale TE devices. The destructive QI of \( G_e \) is found to be very robust with respect to temperature variation. This implies that it is possible to achieve the destructive QI of \( G_e \) at high temperatures. Furthermore, the Seebeck coefficient can be made large with a vanishingly small electrical conductance when temperature increases. From the results of various QDMs with a few electrons, we have demonstrated that the measurement of Seebeck coefficient, \( S \) is a powerful tool to reveal the many-body effect of nanostructures, since \( S \) is influenced much more than \( G_e \). To achieve maximum power factor in the case of TQDM the orbital-filling situation is preferred \((N = 6)\). However, for SCTQD in general it is preferable to the orbital-depletion situation with \((N \leq 1)\) and likely for serially coupled QDMs with more dots. It is desirable to compare current results including all Green functions and electron correlations with those calculated by the Hartree-Fock approximation (HFA) [22-24] to examine the validity of mean-field approach. Such a comparison for SCTQD has been carried out.[35] We found that HFA works well only for the orbital-depletion situation and high temperatures.

FIG. 1: (a) Electrical conductance ($G_e$) and (b) Seebeck coefficient ($S$) of TQDM as a function of central QD energy ($\Delta C = E_C - E_F$) for different $t_{LR}$ strengths at $E_L = E_R = E_F$, $t_{LC} = t_{CR} = t_c = 3\Gamma_0$ and $k_B T = 1\Gamma_0$. We assume $U_{LC} = U_{CR} = 30\Gamma_0$, $U_{LR} = 10\Gamma_0$, $U_t = U_0 = 100\Gamma_0$ and $\Gamma_L = \Gamma_R = \Gamma = 0.3\Gamma_0$.

FIG. 2: (a) Electrical conductance ($G_e$) and (b) Seebeck coefficient ($S$) of TQDM as a function of central QD energy ($\Delta C = E_C - E_F$) at $t_{LR} = 0.3\Gamma_0$ for different temperatures. Other physical parameters are the same as those of Fig. 1.

FIG. 3: The curves of Fig. 3 are one to one corresponding to those of Fig. 2. The calculation of Fig. 3 only considers the single particle occupation numbers and on-site two particle correlation functions.

FIG. 4: (a) Electron thermal conductance ($\kappa_e$), and (b) Lorenz number ($\kappa_e/(G_e T)$) as a function of central QD energy for different temperatures. The curves of Fig. 4 correspond to those of Fig. 2. $k_0 = k_B^2/e^2$. 
FIG. 5: (a) Total occupation number, (b) electrical conductance \( (G_e) \), and (c) Seebeck coefficient \( (S) \) as a function of QD energy \( (E_l = E_F + 30\Gamma_0 - eV_g) \) at \( \Gamma_{l,j} = 3\Gamma_0 \) and \( U_{l,j} = 30\Gamma_0 \) for different temperatures. Other physical parameters are the same as those of Fig. 1.

FIG. 6: (a) Electrical conductance \( (G_e) \), (b) Seebeck coefficient \( (S) \) and (c) power factor as a function of QD energy \( (E_l = E_F + 30\Gamma_0 - eV_g) \) at \( \Gamma_{l,j} = 3\Gamma_0 \) and \( k_B T = 1\Gamma_0 \) for different interdot Coulomb interactions. Other physical parameters are the same as those of Fig. 5.

FIG. 7: Electrical conductance \( (G_e) \), Seebeck coefficient \( (S) \) and power factor of DQD as functions of QD energy \( (E_l = E_F = E_0 = E_F + 30\Gamma_0 - eV_g) \) for different temperatures. Other physical parameters are the same as those of Fig. 5.

FIG. 8: Electrical conductance \( (G_e) \), Seebeck coefficient \( (S) \) and power factor of SCTQD as functions of QD energy \( (E_l = E_F + 30\Gamma_0 - eV_g) \) for different temperatures. \( U_{LR} = 0 \) and \( t_{LR} = 0 \). Other physical parameters are the same as those of Fig. 5.
