Abstract

We calculate the quantum phase diagram of the $XXZ$ chain with nearest-neighbor (NN) $J_1$ and next-NN exchange $J_2$ with anisotropies $\Delta_1$ and $\Delta_2$ respectively. In particular we consider the case $\Delta_1 = -\Delta_2$ to interpolate between the $XX$ chain ($\Delta_i = 0$) and the isotropic model with ferromagnetic $J_2$. For $\Delta_1 < -1$, a ferromagnetic and two antiferromagnetic phases exist. For $|\Delta_i| < 1$, the boundary between the dimer and spin fluid phases is determined by the method of crossing of excitation spectra. For large $J_2/J_1$, this method seems to indicate the existence of a second spin fluid critical phase. However, an analysis of the spin stiffness and magnetic susceptibility for $\Delta_1 = \Delta_2 = 1$ suggest that a small gap is present.
I. INTRODUCTION

In recent years, several interesting quasi one dimensional magnetic systems have been studied experimentally [1–4]. Among them some compounds containing CuO chains with edge sharing CuO$_4$ plaquettes are expected to be described by the $XXZ$ model with an important next-NN exchange $J_2$ in comparison with the NN exchange $J_1$, and the latter can also be negative if the Cu-O-Cu angle is near 90° [4]. In addition, there has been a renewed interest in this $XXZ$ model (which is equivalent to a zig-zag ladder) recently [5–16]. In particular, for the $XX$ chain ($\Delta_1 = \Delta_2 = 0$), field theoretical methods predicted a critical (gapless) phase with incommensurate correlations for $J_2 >> J_1 > 0$. This seems confirmed by recent numerical work [10]. The effects of magnetic field and magnetization jumps (metamagnetism) have also been studied recently [11–14]. Metamagnetism is more likely to occur in nature for ferromagnetic $J_1$, because smaller anisotropies are required [13]. Interestingly, for ferromagnetic small $J_1$ a very small gap with an astronomically large associated correlation length has been found by field theory calculations and seems consistent with density matrix renormalization group (DMRG) calculations [16].

The phase diagram of the model for $\Delta_1 = \Delta_2 > 0$ has been accurately determined by Nomura and Okamoto using the method of level crossings of the excitation spectra, supported by results of conformal field-theory and renormalization group [17]. This method has been also used successfully to determine phase diagrams of electronic models [18], and is related in some cases to jumps in topological numbers determined by Berry phases [19,20]. Using the method of level crossings, the phase diagram has been extended recently to the region $\Delta_1 = \Delta_2 < 0$ [15]. However, to assume that $\Delta_2 < 0$ implies a different sign of the $z$ component of $J_2$ with respect to those of the $x, y$ plane. This is an unrealistic anisotropy (this inconvenient is not present for $J_1$ because the sign of its $x, y$ components can be changed rotating every second spin in the chain by $\pi$ around the $z$ axis). In addition, the above mentioned systems containing CuO chains with edge-sharing plaquettes and Cu-O-Cu angle near 90°, are expected to lie near the isotropic case $\Delta_1 = -1, \Delta_2 = 1$. 

2
In this work we calculate the phase diagram of the system for $\Delta_2 = |\Delta_1|$ and $-1.2 < \Delta_1 < 1.2$ using the method of level crossings. This includes the interpolations between the XX chain and the isotropic cases with ferro- or antiferromagnetic $J_1$.

II. MODEL AND METHOD OF LEVEL CROSSINGS

The model is:

$$H = \sum_i [J_1(S_i^x S_{i+1}^x + S_i^y S_{i+1}^y + \Delta_1 S_i^z S_{i+1}^z) + J_2(S_i^x S_{i+2}^x + S_i^y S_{i+2}^y + \Delta_2 S_i^z S_{i+2}^z)],$$

(1)

where $S_i^\beta$ is the $\beta$ component of the spin-1/2 operator at site $i$.

The basic idea of the method of level crossings is that the properties of a critical phase at low energies and large distances are ultimately determined by a scale invariant fixed point [17]. Then, using conformal field theory one can relate the excitation energy which corresponds to some operator $A_i$ at site $i$ (for example a spin flip $S_i^+$, $S_i^-$), to the dependence of the correlation functions of this operator with distance:

$$E_{A}(L) - E_g(L) = \frac{2\pi v x_A}{L}, \quad \langle A_{i+d} A_i \rangle \sim \frac{1}{d^{2x_A}}.$$  \hspace{1cm} (2)

Here $L$ is the length of the system, $v$ the spin-wave velocity, $E_g(L)$ the ground state energy, and $x_A$ the critical dimension for the excitation $A$. For example if $J_2 = 0$, the XXZ model was exactly solved and its properties are well known [21][22]. The long distance dependence of the main correlation functions is

$$\langle S_{i+d}^+ S_i^- \rangle \sim (-1)^{d-1/K}, \quad \langle S_{i+d}^z S_i^z \rangle \sim (-1)^d r^{-K}$$  \hspace{1cm} (3)

with

$$K = \frac{\pi}{\pi - \arccos(\Delta_1)}$$  \hspace{1cm} (4)

if $|\Delta_1| \leq 1$. For $|\Delta_1| < 1$, the minimum excitation corresponds to a spin flip with wave vector $\pi$. The ground state has total spin projection $S^z = \pm 1$, its wave vector differs from that of
the ground state in $\pi$, and its parity under inversion $P$ is opposite to that of the ground state \[17\]. The matrix element of $S_i^{+(-)}$ between the ground state and the first excited doublet is different from zero. Then, the correlation functions $\langle S_{i+d}^+ S_i^- \rangle$ are the dominant ones at large distances.

At $\Delta_1 = 1$, the above mentioned doublet crosses with the excited state with $S^z = 0$, (with wave vector differing from the ground state in $\pi$, and $P$ and parity under spin reversal $T$ opposite to that of the ground state). Then, for $\Delta_1 > 1$, $\langle S_{i+d}^z S_i^z \rangle$ are the dominant correlations at large distances. At $\Delta_1 = 1$, a gap opens and conformal invariance ceases to be valid, but for a sufficiently small gap so that correlation length is much larger than the size of the system, Eqs. (2) are still expected to hold.

In summary inside a critical phase or near its boundaries, the quantum numbers of the first excited state determine the dominant correlations at large distances, and therefore the crossings of the excited states determine the boundaries.

For small $J_2/J_1$, the use of renormalization group allows to determine the size dependence of the crossings and to extrapolate them very accurately to the thermodynamic limit \[17\].

### III. RESULTS

The phase diagram we obtain in the plane $\alpha = J_2/J_1$ as a function of $\Delta_1$, with $\Delta_2 = |\Delta_1|$ is represented in Fig. 1. The transition between dimer and spin fluid I phases for $\Delta_1 \geq 0$ has been obtained before by Nomura and Okamoto \[17\]. The spin fluid I phase is the well known ground state of the model for $\alpha = 0$, $|\Delta_1| < 1$. The dimer or spin Peierls phase has a spin gap and broken translational symmetry (the unit cell is doubled) in the thermodynamic limit. The first excited state in finite systems has the same quantum numbers $P$ and $T$ as the ground state, but its wave vector differs by $\pi \[17\]$. The new results for the spin fluid I-dimer transition are displayed in Fig. 2. The transition points (open squares) were accurately determined extrapolating the crossing of the first excited state using data for chain lengths $L = 12, 16$ and $20$. As explained earlier \[17\] the crossing point has a $1/L^2$ size dependence.
We have verified this also for negative $\Delta_1$ (see Fig. 3). However, in the region denoted by ? in Fig. 3 (constructed with data for $L = 16$), the first excited state has opposite $P$ and $T$ as the ground state. This is unexpected for the dimer phase. This might be a finite-size effect related with the high degeneracy at the point $\Delta_1 = -\Delta_2 = -1$, $\alpha = 0.25$ \[13,23\]. The other possibility is that a novel phase exists there, but this seems unlikely.

After the transition to the dimer phase, if $\alpha$ is increased further, the crossing of excitation spectra indicates another transition to a phase in which the first excited state has $S^z = \pm 1$ and wave vector $k_c = \pi/2$. We denote this phase as “spin fluid II” (between quotation marks), because, as we discuss below, its nature is not established for all values of $\Delta_i$. For $\Delta_i = 0$, from field theory results one might expect a spin fluid phase for large $\alpha$ \[8\]. One also expects that $k_c$ is actually incommensurate and slightly different from $\pi/2$ \[5,6,8,9\]. However, we are not able to detect this difference using periodic boundary conditions. While the use of twisted boundary conditions has given interesting results concerning this incommensurability \[9\], to implement them in the level crossing method is time consuming and present technical complications, which we avoid in this work.

As shown in Fig. 4, the level crossing for the dimer-spin fluid II transition does not follow a $1/L^2$ dependence, and the extrapolation to the thermodynamic limit is not so accurate as for the dimer-spin fluid I transition. We have used a quadratic extrapolation in $1/L^2$, using the data for $L = 8, 12, 16$ and 20. Field-theoretical results suggest that there is a small gap and therefore no spin fluid phase for $\Delta_1 = \Delta_2 = 1$, and $J_2 >> J_1$ \[6,7,14\]. For $\Delta_1 = -1$, $\Delta_2 = 1$, a tiny gap is predicted with an associated astronomically large length scale \[16\]. A direct extrapolation of the gap from our finite-size results has an error larger or of the order of the gap itself and therefore, it is not able to establish if the gap is open or not. However, in principle we can check if a given phase is a spin fluid phase by other methods. For example, the energy per site should vary with system size as:

\[
e(L) = e(\infty) - \frac{\pi}{6L^2}v_s
\]

where $v_s$ is the spin velocity (or the sum of spin velocities if there were several types of
low-energy excitations). We have checked that Eq. (3) is not satisfied inside the dimer phase. A fit of the energies for $L = 12, 16, 20$ and $24$ with Eq. (3) give an error of $v_s$ which is of the order of $v_s$ itself. Instead, inside both “spin fluid” phases the fit is good. The error in $v_s$ is of order of 0.1% inside spin fluid I, and of order of 1% inside spin fluid II. Within spin fluid I, we also find that several relations derived from conformal field theory hold, and are consistent within them within $\sim 5\%$. The spin velocity can be calculated as:

$$v_1 = \frac{E(2\pi/L) - E(0)}{2\pi/L}, \quad (6)$$

where $E(q)$ is the lowest energy in the $S^z = 0$ sector. The extrapolation of $v_1$ to the thermodynamic limit using a quadratic polynomial in $1/L$ is only slightly less than $v_s$ obtained fitting Eq. (3). Also from the numerical calculation of the susceptibility $\chi$ and spin stiffness $D_s$:

$$\chi_s = \frac{1}{\partial^2_m} = \frac{1}{L[E(1) + E(-1) - 2E(0)]} \quad (7)$$

$$D_s = \frac{L}{2} \frac{\partial^2 E}{\partial \phi^2} \quad (8)$$

where here $E(S^z)$ is the lowest energy for total spin $S^z$, and $\phi$ is a flux opposite for spin up and down, [9] we can obtain $K$ in two independent ways from the relations [22]:

$$\chi_1 = \frac{K}{2\pi v_1}, \quad D_1 = \frac{Kv_1}{4\pi} \quad (9)$$

The correlation exponents obtained from these two equations and Eqs. (3), (7), (8) with $\chi_1 = \chi_s, D_1 = D_s$ also agree within 2% to 10% in the spin fluid phase I. The agreement improves with increasing $\Delta_1$.

A simple analysis based on Eqs. (7), (8), (9) is not possible in the “spin fluid II” phase. Eqs. (3) and (8) suggest that the low energy properties of this phase are given by two free bosonic theories (this is of course true if $J_1 = 0$): $v_s = v_1 + v_2$, with $v_2$ slightly larger than $v_1$ (see Fig. 5(a)). This is in principle reasonable, since if there are two branches of low-energy
excitations, Eq. (8) should give the smallest velocity. Also one expects that Eq. (8) gives the sum of both spin stiffness:

\[ D_s = \frac{K_1 v_1 + K_2 v_2}{4\pi} \]  

(10)

The case of the susceptibility is more delicate. From thermodynamics, the total susceptibility should be the sum of those of both branches. However, our numerical study suggests that when one flips only the spin, it goes to the branch of lowest velocity.

The results of field theory in the case \( J_2 \gg J_1 \) (and also those of the Hubbard ladder for small interchain hopping \[24,25\]) suggest that the effective low-energy theory splits in two sectors, symmetric \( \varphi_+ \) and antisymmetric \( \varphi_- \), and in general, at least the latter is gapped. For \( \Delta_1 = \Delta_2 = 0 \), \( \varphi_+ \) is massless and \( \varphi_- \) has a gap which depends on \( J_2/J_1 \) as a power law \[8,9\]. In the isotropic case \( \Delta_1 = \Delta_2 = 1 \), both sectors have an exponentially small gap \[7\]. These field theory results are inconsistent with the hypothesis of two branches of massless excitations in the “spin fluid II” phase. To check this hypothesis we investigated the consistency of Eqs. (5) with \( v_s = v_1 + v_2 \), (8), (10) and an expression for the total susceptibility, for some values of \( K_1 \) and \( K_2 \) in the above mentioned cases (\( \Delta_1 = \Delta_2 = 0 \), and \( \Delta_1 = \Delta_2 = 1 \)). We do not find reasonable results. For example, eliminating \( K_i \) from these equations, sometimes one negative result arises. The most plausible explanation is that at least one of the modes is gapped, but the system is not large enough to detect it in the size dependence of the energy (Eq. (8) is only valid for sufficiently large \( L \)). In fact, some of our fittings suggest that the magnitude of the slope of \( e \) vs \( 1/L^2 \) is decreasing with system size.

To end this section, we discuss the observed phases for \( 1.2 > |\Delta_i| > 1 \). For \( \Delta_1 < -1 \), the ground state changes from a fully polarized ferromagnet \( (S^z = L/2) \) to \( S^z = 0 \) at the solid squares of Fig. 1. Actually, there is a small region of intermediate \( S^z \) between both phases, but it decreases with system size an seems to disappear in the thermodynamic limit. In the phase with \( S^z = 0 \), the first excited state has wave vector \( \pi/2 \). This fact, a study of correlation functions \[26\] and a trivial analysis of energies in the classical limit
$-\Delta_1 = \Delta_2 \to \infty$, suggests that the phase has long-range AF order of the type $\uparrow\downarrow\downarrow\uparrow\uparrow \ldots$ (denoted as AFII). The same features denoting the presence of the AFII phase, are also found for $\Delta_i > 1$ and large $\alpha$. We expect that for $|\Delta_i| > 1$, a spin wave approximation can describe qualitatively the essential physics.

IV. DISCUSSION

Using the method of level crossings, we have calculated the phase diagram of the $XXZ$ model with next-NN exchange (Eq. (1)) for $\Delta_2 = |\Delta_1|$. For the dimer-spin fluid I transition our results are quite robust and extend previous results [17,15] to the case $1 \leq \Delta_1 = -\Delta_2 < 0$. In this region, the transition takes place near $\alpha \sim 0.3$. For larger values of $\alpha$ the method predicts a transition from the dimer phase to a second spin fluid phase. The transition is at $
alpha = 1.42$ for $\Delta_1 = \Delta_2 = 0$, in qualitative agreement with $\nalpha \sim 1.26$ obtained in Ref. [10]. For these values of $\Delta_1$, field theoretical results predict the existence of this phase [8].

For $\Delta_1 = -1$, a tiny gap with an astronomically large length scale is predicted in Ref. [16]. Such a length is of course much larger than the system sizes we use, and our finite size results are consistent with those of Ref. [16].

For $\Delta_1 = \Delta_2 = 1$, we have tried to interpret the thermodynamic properties of the “spin fluid II” phase as a sum of two independent fluids, but the results are not consistent. We conclude then that at this point, the extrapolation of the level crossings is not reliable and in agreement with other calculations [3,4], the gap persists for large $J_2$.

From the parameters estimated for several compounds near the isotropic limit $\Delta_1 = -\Delta_2 = -1$ : $\text{La}_6\text{Ca}_8\text{Cu}_{24}\text{O}_{41}$ ($\alpha \sim 0.36$), $\text{Li}_2\text{CuO}_2$ ($\alpha \sim .62$) and $\text{Ca}_2\text{Y}_2\text{Cu}_5\text{O}_{10}$ ($\alpha \sim 2.2$) [4] our results indicate that these compounds lie outside the usual spin fluid I phase. They are in the AF2 phase if $\Delta_1 < -1$. If $\Delta_1 \geq -1$, $\text{La}_6\text{Ca}_8\text{Cu}_{24}\text{O}_{41}$ is clearly in the dimer phase. One expects a very small, perhaps unobservable gap for $\text{Ca}_2\text{Y}_2\text{Cu}_5\text{O}_{10}$ and spin-spin correlations with wave vector near $\pi/2$. $\text{Li}_2\text{CuO}_2$ lies in between. The interchain interactions might affect this scenario.
