Abstract. [Purpose] This study report a case of a patient with hemiparetic stroke who showed significantly reduced foot pain when ankle spasticity was reduced using nerve and motor point blocks with 20% ethyl alcohol. [Subject and Methods] A 58-year-old woman with left hemiparesis following intracranial hemorrhage five years previously presented with pain in the left fifth metatarsal head for two years (numeric rating scale [NRS]: 8). Erythema and edema were observed on the lateral aspect of the head of the fifth metatarsal bone. She was diagnosed with a Tailor’s bunion. Spasticity was observed in the left ankle plantar flexor and ankle supinator (Modified Ashworth Scale: 1+). Using 20% ethyl alcohol, a block in the medial and lateral motor branches to the gastrocnemius muscle of the left tibial nerve and the motor point of the left posterior tibialis muscle was performed. [Results] After the alcohol block, spasticity had almost disappeared and foot pain was significantly reduced (NRS: 1). Results from the foot pressure measurement system test showed foot contact pressure was highly distributed to the lateral forefoot pre-block. After the block, the distribution of foot contract pressure was similar to normal distribution. [Conclusion] Clinicians should consider the possibility that spasticity can contribute to foot pain.

Key words: Tailor’s bunion, Spasticity, Alcohol block

INTRODUCTION

Spasticity is a frequent consequence of stroke1, 2). In the lower leg, spasticity usually occurs in ankle plantar flexor and supinator muscles3). This condition alters musculoskeletal position or alignment during walking4). This malposition or malalignment causes mechanical stress to foot joints in the lateral forefoot area, and joints under this stress are likely to be inflamed and painful5). Foot pain causes difficulty in standing and walking, and thus limits daily living activities. Accordingly, management of foot pain is necessary in patients with stroke. The malposition or malalignment of the foot can be managed by the control of spasticity. It was proposed that correcting the malposition or malalignment can reduce abnormal mechanical pressure in specific areas of the foot, which leads to a reduction in foot pain. Of the several options available for the management of spasticity, the clinical usefulness of nerve and motor point blocks with alcohol has been well demonstrated5–7).

In the current study, whether a reduction of ankle spasticity using nerve and motor point blocks with 20% ethyl alcohol can manage foot pain was examined.

SUBJECT AND METHODS

A 58-year-old woman visited the rehabilitation department of a university hospital due to piercing pain (numeric rating scale [NRS]: 8) in the left fifth metatarsal head for two years. Erythema and edema were present on the lateral aspect of the...
The patient provided informed signed consent for participation in the study. The study was approved by the research ethics committee of Yeungnam University Hospital (YUH-16-0425-D7). On the foot X-ray, the fourth and fifth intermetatarsal angle of the left foot was 7.7° (Fig. 1B). She was diagnosed with a Tailor’s bunion. She had a history of intracerebral hemorrhage on the right basal ganglia about five years previously. She had spasticity in the left ankle plantar flexor and ankle supinator. The degree of her spasticity was a Modified Ashworth Scale (MAS) of 1+. The ankle clonus was checked and found to be 2–3 beats. Additionally, slight motor weakness (Medical Research Council: 4+) in the left upper and lower extremities was shown. Other neurological symptoms, including sensory and cognitive deficits, were not present. At first, 0.5 ml of 2% lidocaine with 10 mg triamcinolone acetonide was injected into the tender point of the left fifth metatarsal head area. Two weeks after this injection the NRS score was unchanged.

To evaluate dynamic foot pressure, the foot pressure measurement system (FPMS) (TPScan; BioMechanics, Goyang, Korea) was used. Dynamic foot contact pressure data during gait were recorded on the FPMS floor mat (40.5 × 40.5 cm²) at the middle of the gait test. The foot pressure was presented as a color: red is the highest pressure followed by orange, yellow, green, and blue. Foot contact pressure was evaluated twice before and one-month after the nerve and motor point block procedure. Before the procedure, contact pressure was highly distributed to the lateral forefoot, however, reduced distribution was observed in the medial forefoot and hindfoot (Fig. 2). After the procedure, the distribution of foot contact pressure was found to be similar to that of a normal control (56-year-old female individual).
RESULTS

At the follow-up evaluation, two weeks after the alcohol block, the spasticity in the left ankle plantar flexor and supinator had disappeared (MAS: 0). In addition, ankle clonus was not present. Moreover, the pain in the left fifth metatarsal head was significantly reduced from NRS 8 to NRS 1. At one, two, and three months after the alcohol block the effects on ankle spasticity and foot pain were sustained.

DISCUSSION

In the present study, foot pain related to Tailor’s bunion was reduced after spasticity treatment using nerve and motor point block with 20% ethyl alcohol.

Approximately 65% of all patients with stroke experience spasticity\(^1\). In the lower leg, spasticity occurs most frequently in the ankle plantar flexor and supinator\(^3\). Although the incidence of foot pain in patients with stroke has not been investigated, patients with stroke are prone to have foot pain due to deteriorated musculoskeletal position or alignment induced by spasticity or motor weakness. The Tailor’s bunion or bunionette, which was first described by Davies in 1949\(^11\), is a painful bony prominence on the lateral, dorsolateral, or plantar aspect of the head of the fifth metatarsal bone\(^12\). The conflict between the fifth metatarsal head and footwear has been reported to be the cause of Tailor’s bunions\(^12\). In the present study, the spasticity in the ankle plantar flexor and supinator appeared to cause repeated mechanical stress and chronic irritation in the fifth metatarsal head area, which is thought to induce a Tailor’s bunion.

For the management of foot pain due to Tailor’s bunion, corticosteroids were injected into the tender point of the fifth metatarsal head area; however, the patient’s pain was unresponsive to this injection. It was considered that non-controlled spasticity can lead to continuous mechanical stress or irritation and repeated occurrence of inflammation in the fifth metatarsal head area. Therefore, the spasticity was controlled using a block with 20% ethyl alcohol on the motor branches to the gastrocnemius muscle of the tibial nerve and the motor points of the posterior tibialis muscle. Several previous studies have shown the effectiveness and safety of these procedures. Alcohol acts by denaturing proteins, resulting in the splitting of myelin sheaths. After the block with ethyl alcohol, spasticity in this patient had almost disappeared (from MAS 1+ to MAS 0). Also, the patient received the stretching exercises for the ankle plantar flexors and the ankle supinators. The stretching exercise is known to effectively reduce spasticity\(^13, 14\) by increasing tissue extensibility\(^15\). It was thought that the reduced spasticity in the patient was attributed, at least in part, to the stretching exercises. It is thought that the mechanical stress and irritation in the fifth metatarsal head area during walking were significantly reduced with the disappearance of spasticity in this patient. When the stress and irritation were reduced after the management of spasticity, the pain due to Tailor’s bunion appeared to be significantly reduced.

In addition, the FPMS was used for detailed evaluation of the effect of the 20% ethyl alcohol block. Before the alcohol block, foot pressure during walking was highly concentrated in the lateral forefoot. After the control of spasticity with the alcohol block, increased contract foot pressure in the hindfoot and medial forefoot were observed. This change in pressure distribution is concurrent with the results of several previous studies\(^10, 16, 17\). Using FPMS, it was confirmed that mechanical stress abnormally concentrated on the fifth metatarsal head area was corrected to near normal following the alcohol blocks on the tibial nerve branches and the motor point of the tibialis posterior muscle. The correction of foot contact pressure distribution appears to have contributed to the pain reduction in the fifth metatarsal head area.

In conclusion, the case of a patient with chronic hemiparetic stroke whose pain due to Tailor’s bunion showed relief following the control of spasticity using nerve and motor point blocks with 20% ethyl alcohol was reported. This study showed that deteriorated foot position or alignment induced by spasticity and malposition/malalignment-related foot pain can be successfully managed by nerve and motor point blocks with 20% ethyl alcohol. On the basis of the clinical experience in this study, when clinicians treat foot pain in patients with stroke, they should consider the possibility that spasticity can contribute to the development of foot pain. This is first study to show that management of spasticity can reduce foot pain in a patient with hemiparetic stroke. However, since this study reports a single case, further studies involving a larger number of patients are necessary.
