The momentum distribution of relative motion between two nucleons gives information on the correlation in nuclei. The momentum distribution is calculated for both $^6$He and $^6$Li which are described in a three-body model of $\alpha+N+N$. The ground state solution for the three-body Hamiltonian is obtained accurately using correlated basis functions. The momentum distribution depends on the potential model for the $N-N$ interaction. With use of a realistic potential, the $^6$He momentum distribution exhibits a dip around 2$\text{fm}^{-1}$ characteristic of $S$-wave motion. In contrast to this, the $^6$Li momentum distribution is very similar to that of the deuteron; no dip appears because it is filled with the $D$-wave component arising from the tensor force.

I. INTRODUCTION

In this article we study the momentum distribution and the correlation of relative motion of the halo neutrons in two-neutron halo nuclei. The importance of the correlation in nuclei is widely recognized; obviously the correlation plays a vital role in binding a Borromean three-body system which has no pairwise bound states. Recently an experiment using the technique of intensity interferometry has been done in order to extract the spatial correlation function of the two neutrons in the halo nuclei such as $^6$He, $^{11}$Li and $^{14}$Be. In this experiment the momenta of the two neutrons and the core nucleus are measured after the dissociation of the halo nucleus.

Another type of experiment has very recently been performed at RIKEN to probe the spatial correlation in $^6$He and $^6$Li, and the analysis of data is in progress. This experiment utilizes the one-nucleon exchange process in the interaction of these $A=6$ nuclei with a proton. The basic idea is to utilize the well-established one-nucleon exchange process which is observed at the backward angle in the proton-deuteron elastic scattering. Expecting this mechanism to occur in the $A=6$ nuclei, the cross section for the reaction $^6$He($p,\,dn)\alpha$ ($^6$Li($p,\,dp)\alpha$) has been measured under the backward scattering kinematics of the proton and two-nucleon system in $^6$He ($^6$Li). Under the assumption of a quasi-elastic approximation, the cross section is expected to be sensitive to the relative momentum, which is defined through the Wigner distribution function. One well-known formulation of single-nucleon momentum distribution near nuclear surface was performed by Hüfner and Nemes using the Wigner function. Results of calculation are presented in Sec. together with some discussions. Those included are the spectroscopic properties, the two-nucleon correlation functions which reveal “dineutron” as well as “cigar-like” configurations and the comparison of the momentum distributions.

The plan of this paper is as follows. In Sec. we present our three-body model and some of the details on explicitly correlated basis functions which are used to solve the three-body problem. Some formulas needed to compare $^6$He and $^6$Li properties are given in this section with emphasis on the two-nucleon correlation function and the momentum distribution. The latter is best defined through the Wigner distribution function. One well-known formulation of single-nucleon momentum distribution near nuclear surface was performed by Hüfner and Nemes using the Wigner function. Results of calculation are presented in Sec. together with some discussions. Those included are the spectroscopic properties, the two-nucleon correlation functions which reveal “dineutron” as well as “cigar-like” configurations and the comparison of the momentum distributions. We will show that the tensor force which works differently between $^6$He and $^6$Li plays a key role in the momentum distribution around 2$\text{fm}^{-1}$. A conclusion is given in Sec. In Appendix we give a formula to calculate a density matrix or the Wigner function using the correlated basis functions.

II. FORMULATION

A. Three-body Hamiltonian

The wave functions for $^6$He and $^6$Li are determined from variational calculations for the core($\alpha$ particle)+$N+N$ three-body system which is specified by the Hamiltonian

$$H = T_r + T_R + U_1 + U_2 + v_{12}. \tag{1}$$

The subscripts of the kinetic energies $T$ stand for the relative distance vector $r$ between the two nucleons, and the relative distance vector $R$ from the $\alpha$ particle to the center of mass of the two nucleons. The set of Jacobi coordinates $(r, R)$ is called T-type hereafter. The potential $U_1$ is the $N-\alpha$ potential and $v_{12}$ is the $N-N$ potential. The $\alpha$ particle is treated as a structureless particle.

As the two-nucleon potential $v_{12}$, we use a realistic potential, G3RS (Gaussian soft core potential with 3 ranges) case 1 potential [10], which contains central (C), spin-orbit (LS) and tensor (T) terms. In fact, the G3RS potential contains $L^2$ and quadratic $L \cdot S$ terms in even $L$ waves. Their contribution is small; the deuteron energy with (without) these terms is $-2.17 \text{ MeV}$. Thus we ignore these $L$-dependent terms in what follows. The $D$ state probability of the deuteron is $4.8\%$ in the G3RS potential. We use the G3RS potential because its Gaussian radial form makes a numerical calculation much faster than, e.g., the AV8' potential [11]. It is instructive for the study of the $N-N$ correlated motion to compare results of calculation between the realistic potential model and an effective potential model which has a mild short-ranged repulsion. As such an effective potential we employ the Minnesota potential [12], abbreviated to MN, which has no tensor component. This potential renormalizes the effect of the tensor force into the central force and reproduces the binding energy and the root mean square (rms) radius of the deuteron.

As for the $N-\alpha$ potential $U_1$, we adopt a phenomenological potential [13], abbreviated to KKN potential, which is determined so as to simulate the nonlocal potential that derives from a microscopic calculation in an $N+\alpha$ cluster model. The KKN potential is parity-dependent, contains the central and spin-orbit components, and reproduces very well the low-energy $N-\alpha$ scattering phase shifts of $S$ and $P$ waves. The potential is slightly too repulsive in $D$ and $F$ waves [14]. The Coulomb potential for $p-\alpha$ is taken as

$$U^{\text{Coul}}(r) = \frac{2e^2}{r} \text{erf} \left( \frac{\sqrt{4}}{3b^2r} \right), \tag{2}$$

with $\frac{1}{2b^2} = 0.257 \text{ fm}^{-2}$. The KKN potential is deep enough to support an $S$-wave bound state; the state is considered redundant and must be removed in the three-body calculation because no bound states exist for $^3$He and $^5$Li.

B. Variational solution with correlated Gaussians

Trial wave functions for the ground states of $^6$He and $^6$Li are expressed, in $LS$ coupling scheme, as a combination of explicitly correlated Gaussians:

$$\Psi_{JM} = \sum_{i=1}^{K} C_i \chi_i \Psi_{J,M}(\Lambda_i, A_i, u_i), \tag{3}$$

with the basis function

$$\chi_i = (1 - P_{12}) \left\{ e^{-\frac{1}{2} \hat{\mathbf{x}} \cdot \mathbf{A}_i} \left[ \mathcal{Y}_{i} \left( \hat{\mathbf{r}}, \mathbf{x} \right) \chi_S \left( 1, 2 \right) \right] \right\}.$$ \tag{4}

Here the permutation $P_{12}$ ensures the antisymmetry of the valence nucleons.

The basis function is specified by a set of nonlinear parameters, the orbital and spin angular momenta $\Lambda = (LS)$, a $2 \times 2$ positive-definite, symmetric matrix $A$, and a $2 \times 1$ matrix $u$. The symbol $\hat{\mathbf{x}}$ indicates the transpose of a matrix, and the square bracket $\left[ \mathcal{Y}_{i} \chi_S \right]$ denotes the angular momentum coupling. The short-hand notation $\hat{\mathbf{x}} \cdot \mathbf{A}_i$ with $\hat{\mathbf{x}} = (x_1, x_2)$ stands for $A_{11} x_1^2 + 2A_{12} x_1 \cdot x_2 + A_{22} x_2^2$, where the coordinates $x_1$ and $x_2$, called V-type, are the distance vectors of the valence nucleons from the $\alpha$ particle; $x_1 = R - \frac{1}{2} \mathbf{r}$ and $x_2 = R - \frac{1}{2} \mathbf{r}$. The exponential part of the basis function is rotation-invariant. The cross term $A_{12} x_1 \cdot x_2$ describes explicitly the two-nucleon correlation, which is vital to obtain a precise solution in a relatively small basis dimension [13]. The angular part of the basis function is expressed by the solid spherical harmonics, $\mathcal{Y}_{L,M_L} \left( \hat{\mathbf{x}} \right) = u \mathbf{L}_M \mathcal{Y}_{LM_L} \left( \hat{\mathbf{x}} \right)$, specified by a global vector $\hat{\mathbf{x}} = u_1 x_1 + u_2 x_2$. The ratio of $u_1$ to $u_2$ characterizes the coordinate which is responsible for the rotation of the system [13] [16]. (The norm of $u$, $u_1^2 + u_2^2$, simply affects the normalization of the basis function but not the rotation itself, and it may be set to unity.) The isospin part of the system is expressed by $\eta_{TM_T}$. The $p-\alpha$ Coulomb potential and the neutron-proton mass difference give rise to the isospin impurity in $^6$Li, but its effect is rather small [17] [18]. We ignore the neutron-proton mass difference and consider no isospin mixing in the present study. The action of $P_{12}$ on the basis function is simple; it maintains the functional form [17] [19] as follows:

$$P_{12} e^{-\frac{1}{2} \hat{\mathbf{x}} \cdot \mathbf{A}_i} \left[ \mathcal{Y}_{i} \left( \hat{\mathbf{r}}, \mathbf{x} \right) \chi_S \left( 1, 2 \right) \right] \eta_{TM_T} \left( 1, 2 \right),$$ \tag{5}

where the symbol $\hat{\mathbf{r}}$ indicates the interchange of the elements of the matrix, that is, $A_{11} = A_{22}, A_{12} = A_{21}, A_{22} = A_{11}$, and $u_1 = u_2, u_2 = u_1$. A conventional choice for describing the rotational motion is a partial wave expansion, $\left[ \mathcal{Y}_{i} \left( \hat{\mathbf{r}} \right) \right]_{LM_L}$. One introduces a set of important partial waves $(\ell, \ell_z)$ to obtain a converged solution [3] [20]. See also Ref. [17].
for the importance of including high partial waves in the Faddeev calculation for $^6$Li. Our angular function looks quite different from this and it is much simpler than the partial wave expansion. No apparent couplings appear, and the use of the global vector greatly simplifies the calculation of the Hamiltonian matrix elements. The merit of this angular function lies not only in its simplicity but also in its performance. As was compared in Ref. [16], the global vector representation gives results as accurately as the partial wave expansion. Using the decomposition

$$\psi_{LM}(u_1 x_1 + u_2 x_2) = \sum_{\ell=0}^{L} \sqrt{\frac{4\pi(2L+1)!}{(2\ell+1)!(2L-2\ell+1)!}} \times u_1^{\ell} u_2^{L-\ell} \langle \gamma_{\ell L}(x_1) \gamma_{L-\ell}(x_2) \rangle_{L, M, L},$$

the partial waves $(\ell, L, \ell)$ contained in the global vector part are only $(0L), (1L - 1), \ldots, (L0)$. A very important point of our basis function is that other necessary partial wave contributions are brought about by the exp($-A_{12} x_1 - x_2$) term. When the term is expanded as $\sum_{n=0}^{\infty} (-A_{12})^n/n! \langle x_1, x_2 \rangle^n$, each term in the series produces the partial wave components of type, $(x_1 x_2)^{n-\lambda} \psi_{\ell}(x_1) \psi_{\ell}(x_2)$, with $\lambda = n - 2, \ldots, 1$ or 0. When this is combined with $\langle \gamma_{\ell L}(x_1) \gamma_{L-\ell}(x_2) \rangle_{L, M, L}$ coming from the global vector part, it is clear that the basis function can practically contain important partial wave combinations.

We note that the basis function of Eq. (4) has a definite parity $(-1)^\ell$. As the ground states of $^6$He and $^6$Li have a positive parity, this basis function cannot be used for $L=1$. We need to extend the basis function to make it possible to include $L=1$ and a positive parity. This is made possible by replacing $\psi_{LM}(u x)$ by $\langle \gamma_{LM}(u x) \rangle_{LM}$ or $(\gamma_{LM}(u x))_{LM, \ell}$ for the case of two nucleons with $L=1$, this replacement results in a new basis function

$$\psi_{JM}(A = (1S), A, x) = (1 - P_{12}) \times \left\{ e^{-\frac{i}{2} \hat{A} x} \langle J_1(1) J_1(2) \rangle_1 \chi_{S(1, 2)} \rangle_{JM} \hat{P}_{T M} \chi_{T(1, 2)} \right\}.$$

Note that $\langle J_1(1) J_1(2) \rangle_1$ is equal to the vector product $x_1 \times x_2$ within a constant factor. The operation of $P_{12}$ can be done as in Eq. (4), with an extra minus sign coming from this vector coupling.

The set of $\Lambda = (LS)$ included in the present calculation is summarized as follows:

For $^6$He ($J^* = 0^+$), $\Lambda = (00), (11)$.  
For $^6$Li ($J^* = 1^+$), $\Lambda = (01), (10), (11), (21)$.

Here the basis function is given by Eq. (4) for even $L$ and by Eq. (8) for odd $L$, respectively. Note that the two independent $L=1$ basis states exist for $^6$Li.

As noted before, the redundant state of the KKNN potential has to be eliminated; this elimination is a manifestation of the Pauli principle for the motion of the valence nucleons. The requirement is met by imposing that the trial wave function has no overlap with the $0s_{1/2}$ bound state of the KKNN potential:

$$\langle 0s_{1/2} | \gamma_{JM} \rangle = 0 \quad (i = 1, 2),$$

where the radial coordinate of the $0s_{1/2}$ function is $x_i$, and $m_3$ is the third component of the isospin of the nucleon $i$. The $0s_{1/2}$ bound-state wave functions for the neutron and the proton are only slightly different because of the Coulomb potential, and thus we ignore their difference in the present calculation. The exclusion of the $0s_{1/2}$ component is practically achieved by the orthogonal projection method. That is, we add in the three-body Hamiltonian a nonlocal, pseudo potential,

$$\sum_{i=1}^{2} \sum_{m=\pm \frac{1}{2}} |0s_{1/2} m_3(i) \rangle \langle 0s_{1/2} m_3(i)|,$$

and obtain a stable solution for sufficiently large $\gamma$ (typically $10^6$ MeV or larger than that).

To search for good basis functions, we use the algorithm called the stochastic variational method (SVM). The SVM increases the basis dimension one by one by testing a number of candidates that are chosen randomly. Since each basis function is specified by the parameters $(A_{11}, A_{12}, A_{22}, u_1)$ or $(A_{11}, A_{12}, A_{22})$, the candidates are actually generated by giving random numbers to the parameters chosen from physically important multi-dimensional parameter space. In this way we determine about 100-200 basis functions for each $\Lambda$. The SVM works efficiently to take care of both the short-ranged repulsion of the realistic force and the elimination of the redundant states.

C. Transformation of coordinate sets

In the Faddeev method for a three-body system, three sets of T-type Jacobi coordinates are used, and each Faddeev component of the total wave function, expressed in one of the three sets, is expanded in partial waves. To specify the basis function, however, we use the V-type coordinate $x$, which is different from the T-type coordinate. The V-type coordinate is a set of “single particle” (s.p.)-like coordinate, and it is chosen to make it easy to implement the symmetry of the nucleons. See Eq. (5). The s.p. coordinate is useful to represent the individual motion of the nucleons when the correlation term vanishes, i.e., $A_{12}$ is set to zero. For example, the $0^+$ ground state wave function of $^6$He, approximated in $p$-shell harmonic-oscillator configurations, will be expressed in terms of a
It should be evaluated in the Y-type Jacobi coordinate set such as the spin-orbit.

There is one exception. The matrix element for an angular momentum-dependent operator may be only one particular coordinate set.

This flexibility of the basis function enables one to take sufficiently large as in our previous cases [25], ζ

see in Sec. III A that the error is significant. In the present case, however, it is only four, and we will see in Sec. [11A] that the error is significant.

D. Charge and matter radii

The charge radii of ⁶He and ⁶Li can be calculated by taking into account the charge radii of the constituent particles of α and N as follows:

\[ r_c^2(⁶\text{He}) = \frac{1}{9} \langle R^2 \rangle + r_c^2(\alpha) + r_c^2(n), \]  
\[ r_c^2(⁶\text{Li}) = \frac{2}{9} \langle R^2 \rangle + \frac{1}{12} \langle r^2 \rangle + \frac{2}{3} r_c^2(\alpha) + \frac{1}{3} r_c^2(n) + \frac{1}{3} r_c^2(p). \]  

The charge radii of the constituent particles are \( \sqrt{r_c^2(\alpha)}=1.671\text{ fm} \) [24], \( \sqrt{r_c^2(\alpha)}=0.875\text{ fm} \), and \( r_c^2(n)=-0.1161\text{ fm}^2 \) [24]. Equations (13) ensures one to deduce model-independent information on the \( \langle R^2 \rangle \) value from the experimental charge radius of ⁶He. This will be discussed later. We can extend Eq. (13) to a core+n+n system:

\[ r_c^2(\text{core}+n+n) = \left( \frac{2}{A} \right)^2 \langle R^2 \rangle + r_c^2(\text{core}) + \frac{2}{Z} r_c^2(n), \]  

where \( A \) is the mass number of the system. In a ⁶Li+n+n three-body model for ¹¹Li, the recent data on the charge radii of ⁹,¹¹Li [28, 24] allow us to deduce \( \sqrt{\langle R^2 \rangle}=5.95(3)\text{ fm} \).

It is also interesting to calculate the point matter radius which is defined by an rms radius for the point nucleon distribution. The point matter radii of ⁶He and ⁶Li are calculated by

\[ r_m^2(⁶\text{He}, ⁶\text{Li}) = \frac{2}{9} \langle R^2 \rangle + \frac{1}{12} \langle r^2 \rangle + \frac{2}{3} r_m^2(\alpha), \]  

where \( r_m^2(\alpha) \) is the mean square matter radius of the α particle and its value can be given by \( r_m^2(\alpha)=r_c^2(\alpha)−r_c^2(p)−r_c^2(n) \) under the isospin symmetry that the protons and the neutrons in the α particle have the same mean square radius. In what follows we use \( \sqrt{r_m^2(\alpha)}=1.464\text{ fm} \). Using Eqs. (13) and (16) enables us to relate the matter radius of ⁶Li to its charge radius:

\[ r_m^2(⁶\text{Li}) = r_c^2(⁶\text{Li}) − r_c^2(n) − r_c^2(p). \]  

The matter radius of ⁶Li is thus expressed by only measurable quantities.

E. Electric quadrupole moment

The electric quadrupole moment operator is

\[ \hat{Q} = \sqrt{\frac{16\pi}{5}} \sum_i e_i \mathcal{Y}_{20}(r_i - X), \]  

where \( e_i \) is the nucleon charge and X is the center of mass coordinate of the system. This operator can be
simplified, in the $\alpha+n+p$ model of $^6\text{Li}$, to
\[ \hat{Q} = \hat{Q}_r + \hat{Q}_R = \sqrt{\frac{16\pi}{5}} \left\{ \frac{1}{4} Y_{20}(r) + \frac{2}{3} Y_{20}(R) \right\}. \] (19)

Here use is made of the fact that the $\alpha$ particle has spin zero and the two valence nucleons have good isospin. The operator $\hat{Q}_r$ is the same as the quadrupole moment operator for the deuteron, while the second term $\hat{Q}_R$ corresponds to the quadrupole moment operator for the relative motion between the $\alpha$ particle and the center of mass of the $np$ system.

F. Two-nucleon correlation function

We define the two-nucleon correlation function by
\[ \rho(x_1, x_2) = \frac{1}{2J+1} \sum_M \langle \Psi_{JM} | x_1 x_2 \rangle \langle x_1 x_2 | \Psi_{JM} \rangle_{ST}. \] (20)

Here $\langle \ldots \rangle_{ST}$ indicates that the integration is to be performed over the spin and isospin coordinates. Because of the average procedure over the $z$ component of the total angular momentum, the two-nucleon correlation function becomes scalar, that is, it is a function of $x_1, x_2$ and $\theta$, the angle between $x_1$ and $x_2$: $\rho(x_1, x_2) = \rho(x_1, x_2, \theta)$. The normalization of the total wave function $\Psi_{JM}$ is expressed as $\int \int \rho(x_1, x_2, \theta) 8\pi^2 x_1^2 x_2^2 \sin \theta dx_1 dx_2 d\theta = 1$.

G. Momentum distribution

The momentum and spatial density distributions of a quantum-mechanical system are obtained through the Wigner phase-space distribution function $W$. The Wigner function is concisely expressed in terms of the density matrix as
\[ \rho(r, k) = \int W(r, k) dk. \] (23)

The density distribution for the $N-N$ relative motion is given by the diagonal element of the density matrix
\[ \rho(r) = \rho(r, r) = \int W(r, k) dk, \] (24)

and the momentum distribution for the $N-N$ relative motion is obtained by
\[ \rho(k) = \int W(r, k) dr. \] (25)

These distributions are normalized as $\int \rho(r) dr = 1$, and $\int \rho(k) dk = 1$. A formula to calculate the density matrix and the momentum distribution is given in Appendix.

III. RESULTS AND DISCUSSIONS

The input parameters we use are $\hbar^2/m_N = 41.47$ MeV fm$^2$, $m_\alpha = 4m_N$, and $e^2 = 1.440$ MeV fm, where $m_N$ and $m_\alpha$ are the masses of the nucleon and the $\alpha$ particle, respectively. The $u$ parameter of the MN potential is set to $u=1$ otherwise mentioned. No spin-orbit component of the MN potential is included.

A. Spectroscopic properties

In a single channel calculation with a specific $\Lambda=(LS)$, neither (00) nor (11) channel produces a bound state of $^6\text{He}$ below the $\alpha+n+n$ threshold. The case of $^6\text{Li}$ is different, depending on the $N-N$ potential. When using the MN potential, the $\Lambda=(01)$ channel gives a bound state, whereas in the case of the G3RS potential no single-channel calculation produces a bound state below the three-body threshold. This difference between the two potential models is due to the tensor force which plays no role in the single (01) channel but gains energy through the coupling with different channels. This mechanism is similar to binding the neutron and the proton in the deuteron with the realistic force.

Full calculations which couple all possible $\Lambda$ channels of Eq. 5 give the results listed in Table II. The calculation has been performed in the $Y$-type coordinates. The basis dimension $K$ is 400 for $^6\text{He}$ and for $^6\text{Li}$ with the MN potential, while it is increased to 600 for $^6\text{Li}$ with the G3RS potential. The ground states of $^6\text{He}$ and $^6\text{Li}$ obtained with the G3RS potential are both underbound by 400-500 keV, while the MN potential underbinds $^6\text{He}$ by more than 500 keV but overbinds $^6\text{Li}$ by 200 keV. The underbinding of $^6\text{He}$ with the MN potential is partly due to the fact that the $^1S_0$ potential is too repulsive to reproduce the experimental $^1S_0$ phase shifts. The common lack of the binding energies in the case of the G3RS potential can be explained by at least three effects: One is the deficiency of the attraction in the $D$ and $F$ waves of the KKNN potential as discussed in Refs. 14, 32. According to the latter the energy gain of $^6\text{He}$ which is
TABLE I: Properties of the ground states of $^6\text{He}$ and $^6\text{Li}$. Energy and length are given in MeV and fm. The $L^2$ and quadratic $L\cdot S$ terms of the G3RS potential are neglected. See text for the MMN potential. The Coulomb potential is included in the term $\langle U_1^C + U_2^C \rangle$. Experimental data: $E=-0.975$, $\sqrt{r_c}=2.054(14)$ \[30\] for $^6\text{He}$; $E=-3.70$, $\sqrt{r_c}=2.55(4)$ \[31\] or 2.540(30) \[21\], $\sqrt{r_c}=2.42(4)$ for $^6\text{Li}$.

| $P(01)$ | -       | -      | 91.7    | 90.3  | 100   | 95.2 | -    |
| $P(21)$ | -       | -      | 1.0     | 5.0   | -    | 4.8  | -    |

Table I lists the decomposition of the energy into the expectation values of the various pieces of the Hamiltonian, the radii and the probability $P(\mathit{LS})$ in % of finding the $\Lambda=(\mathit{LS})$ component. Let $E_r$ and $E_R$ denote respectively the energy for the relative motion of the two nucleons and the energy for the relative motion between the $\alpha$ particle and the center of mass of the two nucleons. They are defined by

$$E_r = \langle T_r \rangle + \langle v_{12}^S \rangle + \langle v_{12}^T \rangle + \langle v_{12}^S \rangle,$$

$$E_R = \langle T_R \rangle + \langle U_1^T + U_2^T \rangle + \langle U_1^LS + U_2^LS \rangle.$$ (25)

In the case of $^6\text{He}$, the G3RS and MN potentials give very similar results for these energies: $(E_r,E_R)=(7.03, -7.49)$ MeV for G3RS and $(7.10, -7.52)$ MeV for MN. Even each of the expectation values is close to each other as well. The tensor and spin-orbit forces between the two neutrons play a minor role. In contrast to $^6\text{He}$, both the potentials exhibit quite different features in binding $^6\text{Li}$. The partial energies are $(E_r,E_R)=(3.32, -6.63)$ MeV for G3RS and $(4.14, -8.05)$ MeV for MN, so that the difference between the two is modest. However, the content of $E_r$ in particular is quite different between them because of the tensor force and the short-ranged repulsion. In G3RS the large positive value of $\langle T_r \rangle$ is balanced by the tensor contribution $\langle v_{12}^T \rangle$. Though this is similar to the case of the deuteron, we see from the values of $\langle T_r \rangle$ and $\sqrt{\langle r_c^2 \rangle}$ that the $np$ pair in $^6\text{Li}$ is more compressed obtained by correcting the potential strength is, however, only a few tens of keV. Next is the effect of three-body forces $^3\text{He}$ though a conclusive statement on their magnitude remains open. The third effect to be considered is the distortion of the $\alpha$ core to $3N+N$ partition or the clustering of the $A=6$ nuclei into $^3\text{H}+^3\text{H}$ (for $^6\text{He}$) and $^3\text{H}+^3\text{He}$ (for $^6\text{Li}$). The coupling of the $\alpha+N+N$ three-body configuration to the distorted configuration produces some energy gain. A recent microscopic calculation indicates that the two configurations actually have rather large overlap and that the energy gain is of order of few hundreds keV in $^6\text{He}$ $^3\text{He}$.

We here remark on the accuracy of the present calculation by comparing to other calculations. For $^6\text{He}$ calculated with the MN potential, our ground state energy, $-0.421$ MeV, is in excellent agreement with the value $-0.422$ MeV obtained by the hyperspherical coordinate method $^33$. If the calculation is done in the V-type coordinates, (which is not correct as mentioned in Sec. II C), the ground state energy of $^6\text{He}$ would go down to $-0.749$ MeV; the result is again consistent with the values obtained by a Lagrange-mesh calculation $^24$ and a hybrid T+V model calculation $^24$. The corresponding energy for the $^6\text{Li}$ ground state would be $-4.68$ MeV, instead of $-3.91$ MeV calculated correctly in the Y-type coordinates. These results clearly show that the correct treatment of the coordinates is important in such light systems as $^6\text{He}$ and $^6\text{Li}$.

| $^6\text{He}$ ($0^+$) | $^6\text{Li}$ ($1^+$) | $d$ ($1^+$) |
|----------------------|----------------------|-------------|
than the one in the deuteron. In spite of these differences the $P(LS)$ values of $^6$Li are rather similar in the two potentials except for the $(LS)=(21)$ channel which is largely determined through the tensor coupling to the dominating channel of $(LS)=(01)$. As will be discussed later, the $^6$Li quadrupole moment is very sensitive to this coupling. The spin-triplet channels occupy about 95%.

The $^6$Li charge radius calculated using the G3RS potential agrees with the experimental value determined from the electron scattering [31] and the isotope shift in lithium [29], but the MN potential gives the charge radius which is small by at least 0.1 fm. This failure of the MN potential is due to that the $\sqrt{(R^2)}$ value is predicted to be too small. As Eq. (17) shows, the use of the G3RS or MN potential predicts too large matter radius $r_m$($^6$Li) = 2.42(4) fm, which is consistent with that determined from the analysis of proton elastic scatterings, $r_m$($^6$Li) = 2.45(7) fm [32, 33].

The theoretical value calculated with the G3RS potential is 2.39 fm, in agreement with experiment.

Now we turn to the case of $^6$He. The charge radius of $^6$He has recently been measured by laser spectroscopy technique [30]. Our theoretical value agrees fairly well with the experimental value. Using the observed charge radius of $^6$He in Eq. (13), we can deduce the “experimental” value of $\sqrt{(R^2)}$, which turns out to be 3.726(69) fm. Our value of 3.78 fm is very consistent with this value considering that the fact that the calculated binding energy is small by 500 keV. The rms matter radius of $^6$He extracted from the proton elastic scattering is $r_m$($^6$He) = 2.30(7) fm [37], which is, however, smaller than the value (2.48 $\pm$ 0.03 fm) deduced from the interaction cross section analysis [38]. The theory with the G3RS or MN potential predicts too large matter radius for $^6$He; this overestimation is related to that the calculated binding energy is too small, leading to a too large value for $\sqrt{(R^2)}$. Since the attraction of the MN potential is weak in the $1S_0$ channel, we repeated the calculation by increasing the strength of its longest range part from −91.85 to −91.85 $\times$ 1.07 MeV so as to reproduce the binding energy. This potential is called MMN, and its result is listed in Table I. As expected, the rms matter radius now decreases from 2.63 to 2.49 fm, which is consistent with the values of the interaction cross section measurement as well as the fully microscopic three-cluster calculations [18, 34].

The electric quadrupole moment of $^6$Li is a long-standing problem. The $^6$Li quadrupole moment is negative and small, −0.08178(164) $\text{fm}^2$ [39], while the deuteron quadrupole moment is 0.2860(15) $\text{fm}^2$ [40]. Thus it is known that the $\alpha+n+p$ model which assumes (0s)$^4$ $\alpha$-cluster gives the wrong sign even when the tensor force is included [6]. See also Ref. [41]. Though we do not attempt to solve this enigmatic issue, we just show the result of the present model in Table II. As expected, the $^6$Li quadrupole moment obtained with the G3RS potential turns out to be positive (0.164 $\text{fm}^2$). Interestingly, the quadrupole moment with the MN potential becomes −0.295 $\text{fm}^2$; this happens because the large negative contribution of $Q_R$ is not canceled by the $Q_r$ value. This contrast between the two potential models is mainly due to the different contribution of the cross terms between the $(LS)=(01)$ and $(LS)=(21)$ components of the $^6$Li ground state wave function. See the parenthetic values in Table II. The mixing of these components is due to the tensor force. Therefore the failure of the $^6$Li quadrupole moment indicates that we have to consider the effect of the tensor force between the core and the valence nucleons. It should be noted that a variational Monte Carlo calculation gives the quadrupole moment of −0.23(9) $\text{fm}^2$ [42].

**TABLE II:** Electric quadrupole moments of $^6$Li and the deuteron in $\text{fm}^2$.

|        | $^6$Li (1+) | d (1+) |
|--------|-------------|--------|
| MN     | −0.295      | 0.164  | 0.264 |
| G3RS   | −0.396      | 0.088  |       |
| G3RS   | −0.094      | 0.160  |       |
| G3RS   | −0.260      | −0.034 | 0.264 |
|        | (−0.302)    | (−0.072) |       |

B. Two-nucleon correlation function

Figure II plots the density distributions $\rho(r)$ (normalized to unity) of the two-nucleon relative motion in $^6$He, $^6$Li and the deuteron. The densities calculated using the G3RS potential (right panel) show central dips due to the short-ranged repulsion, but beyond $r=1.5$ fm they are similar to those calculated with the MN potential (left panel). The density of $^6$He reaches furthest in the distance, and as a result its density around $r=1$ is considerably smaller than that of $^6$Li. Comparing the densities between $^6$Li and the deuteron, we see that the $np$ relative motion in $^6$Li shrinks compared to that of the deuteron (see also the $\sqrt{(R^2)}$ value in Table II).

The correlated motion of the valence nucleons reflects on the two-nucleon correlation function $\rho(x_1, x_2, \theta)$. Before discussing the correlated motion, we first examine the function $\rho(x_1, x_2, \theta)$ which is generated from an “uncorrelated” basis function $\Phi$ for $^6$He. For this purpose we take a combination of the two $p$-shell harmonic-oscillator functions [11],

$$\Phi = \sqrt{1-C^2}\Phi_0 + C\Phi_1,$$

and determine $(a_0, a_1, C)$ so as to maximize the overlap,
\[ \langle \Phi | \Psi_{00} \rangle^2 \], with the \(^6\)He ground-state wave function \( \Psi_{00} \) obtained using the G3RS potential. The resulting values are \( a_0=0.163 \text{ fm}^{-2} \), \( a_1=0.194 \text{ fm}^{-2} \), and \( C=0.402 \), leading to \( \langle \Phi | \Psi_{00} \rangle^2 = 0.75 \). The simple wave function \( \Phi \) has a surprisingly large overlap with the realistic wave function \( \Psi_{00} \). Though the overlap is fairly large, \( \Phi \) includes no corelated configurations and indeed the energy calculated with \( \Phi \) is high (8.77 MeV). The two-nucleon correlation function \( \rho(x_1, x_2, \theta) \) calculated from \( \Phi \) becomes a function of \( \cos^2 \theta \), so that \( \rho(x, x, \theta) \) multiplied by \( 8 \pi^2 x^4 \sin \theta \) is symmetric with respect to \( \theta=90^\circ \). See Fig. 2. An asymmetry with respect to \( \theta=90^\circ \) would indicate the presence of correlation in the \( A=6 \) nuclei.

Now let us discuss the two-nucleon correlation function which derives from the dynamical calculation with the G3RS potential. The MN potential gives similar two-nucleon correlation function. Figure 3 displays the contour maps of \( 8 \pi^2 x^4 \sin \theta \rho(x, x, \theta) \) for \(^6\)He and \(^6\)Li. In both the cases we clearly see asymmetric patterns with two distinct peaks: In \(^6\)He the highest peak is located at \((x, \theta)=(2.9, 26^\circ)\) with a height of 0.07 fm\(^{-2}\), while in \(^6\)Li the highest peak is located at \((x, \theta)=(3.2, 24^\circ)\) with a height of 0.13 fm\(^{-2}\). Here \( x \) is given in fm. The peak in \(^6\)Li called the deuteron-like correlation is about twice higher than that called the dineutron-like correlation in \(^6\)He. Comparing Fig. 3 with Fig. 2 we learn that the two-nucleon interaction enhances the asymmetric pattern. Another lower peak which shows up at larger angles is called a cigar-like correlation. It corresponds to the geometry that the two nucleons sit on the opposite sides of the core. This type of peak is located at \((x, \theta)=(2.3, 136^\circ)\) for \(^6\)He and at \((x, \theta)=(2.4, 136^\circ)\) for \(^6\)Li, respectively. Their heights are both 0.03 fm\(^{-2}\), which is about half of the peak height in Fig. 2.

C. Projection to dineutron- and cigar-like configurations

In Sec. III B we discussed the two-nucleon correlated motion from the viewpoint of the asymmetric appearance of the dineutron- and cigar-like peaks. Here we ask a question of how the two peaks appear in relation to the density or rms distance distribution of the two nucleons. We expect that the dineutron-like peak in \(^6\)He is formed from those components of the wave function which have smaller rms distance, whereas the cigar-like peak is constructed from the rest of the components.

As Eq. (3) shows, the wave function is given as a combination of \( K \) independent, nonorthogonal basis functions. By taking a suitable linear transformation of these \( K \) bases, we can obtain an orthonormal set \( \Xi_{JM}(\mu) \),

\[
\Xi_{JM}(\mu) = \sum_{i=1}^{K} W_{\mu i} \Psi_{JM}(\Lambda_i, A_i, \mu_i), \tag{27}
\]

with the condition \( \langle \Xi_{JM}(\mu) | \Xi_{JM}(\mu') \rangle = \delta_{\mu \mu'} \). It is convenient for the present purpose to choose the coefficients \( W_{\mu i} \) in such a way that they diagonalize the squared dis-
He

\[ \langle \Xi_{JM}(\mu)|r^2|\Xi_{JM}(\mu') \rangle = (r^2)_\mu \delta_{\mu,\mu'}. \] (28)

By arranging the eigenvalues \( (r^2)_\mu \) in increasing order \( (\mu=1,2,\ldots,K) \), we display in Fig. 4 the distribution of the rms distance in the case of \(^6\)He, where \( K=400 \) and the minimum and maximum eigenvalues of \( \sqrt{(r^2)_\mu} \) are 0.223 and 40.7 fm, respectively. The fact that the eigenvalues cover the wide region from small to large distances indicates that the SVM basis selection is efficiently performed to take into account the short-ranged correlation as well as the asymptotic behavior. We can see that the basis states \( \Xi_{JM}(\mu) \) of the first 320 members give rather uniform distribution of \( \sqrt{(r^2)_\mu} \) up to about 12 fm, while the rest of the basis states cover the eigenvalues of larger rms distances.

We define two projectors which are orthogonal complements to each other:

\[ P_S = \sum_{\mu=1}^{K} |\Xi_{JM}(\mu)\rangle \langle \Xi_{JM}(\mu)|, \]
\[ P_L = \sum_{\mu=K+1}^{K} |\Xi_{JM}(\mu)\rangle \langle \Xi_{JM}(\mu)|, \] (29)

with \( P_S + P_L = 1 \). The projector \( P_S \) projects into the subspace spanned by those \( \Xi_{JM}(\mu) \) which have smaller \( (r^2)_\mu \) values, while \( P_L \) is the projector into the rest which is spanned by the basis states with larger rms values. The total wave function is decomposed into two orthogonal components, “small” and “large”, using the projectors

\[ \Psi_{JM} = P_S \Psi_{JM} + P_L \Psi_{JM} \equiv \Psi_S + \Psi_L. \] (30)

For the sake of simplicity, we choose \( \kappa \) in Eq. (29) such that \( |\langle \Psi_S|\Psi_{JM}\rangle|^2 \) is as close as to 0.5. It turns out that \( \kappa=88 \) and the corresponding rms eigenvalue is \( \sqrt{(r^2)_\kappa} = 3.47 \) fm.

It is now possible to decompose the expectation value of an operator \( \mathcal{O} \) into three terms, that is, small, large

\[ \langle r^2 \rangle_{\mathcal{O}} = \langle \Psi_S|\langle r^2|\Psi_{JM}\rangle|\Psi_S\rangle + \langle \Psi_L|\langle r^2|\Psi_{JM}\rangle|\Psi_L\rangle. \]
and their interference terms:

\[
\langle \Psi_{JM} | \mathcal{O} | \Psi_{JM} \rangle = \langle \Psi_S | \mathcal{O} | \Psi_S \rangle + \langle \Psi_L | \mathcal{O} | \Psi_L \rangle + \{ \langle \Psi_S | \mathcal{O} | \Psi_L \rangle + \langle \Psi_L | \mathcal{O} | \Psi_S \rangle \}. \tag{31}
\]

We apply this decomposition to the two-nucleon correlation function to see how the contour map of \(^6\text{He}\) (Fig. 3) is constructed. Plotted in Fig. 5 are those contributions to the contour map which are calculated with \(\Psi_S\) and \(\Psi_L\), respectively. The contribution of the interference term is found to be small and can be safely ignored. Comparing this decomposition with the full contour map of \(^6\text{He}\) in Fig. 3 we can safely conclude that the dineutron-like correlation is generated by the small component \(\Psi_S\) and the cigar-like correlation by the large component \(\Psi_S\).

### D. Momentum distribution

Though the contour map discussed in Secs. III B and III C shows some correlation effects, it is not clear how the correlated features in \(^6\text{He}\) and \(^6\text{Li}\) are observed experimentally. Comparative experiments of the intermediate energy proton elastic scatterings on \(^6\text{He}\) and \(^6\text{Li}\) have been performed in order to elucidate the matter densities of both the nuclei, but the analysis of the experimental data is confronted with some ambiguities because the scattering is confined to extremely forward angles. As mentioned in the Introduction, the measurement of the momentum distribution in a special arrangement seems to be accessible in the inverse kinematics, providing data which are sensitive to the different structures of \(^6\text{He}\) and \(^6\text{Li}\).

It is well-known that the momentum distribution of the np relative motion in the deuteron shows different behavior in the S- and D-wave contributions. As displayed in the right panel of Fig. 6 the S-wave contribution to the momentum distribution is peaked at lower momentum and has a dip at \(k \sim 2\text{ fm}^{-1}\). The D-wave component of the deuteron, however, fills the dip. This characteristics of the distribution is supported by experiment [42]. In contrast to this, the momentum distribution (left panel) obtained with the MN potential does show a dip because it has no D-wave component, and in addition the momentum distribution decreases quickly with increasing \(k\) because the short-ranged repulsion is not as strong as the G3RS potential. To compare with experiment at \(k\) higher than \(2\text{ fm}^{-1}\), however, it is important to include meson exchange currents and isobar currents dominated by the \(\Delta\) excitation. See Ref. [44] and Fig. 9.

The momentum distributions of \(^6\text{He}\), \(^6\text{Li}\) and the deuteron are compared in Fig. 7 for the G3RS (right panel) and MN (left panel) potentials. The realistic potential of G3RS gives the momentum distributions characterized as follows: The momentum distribution of \(^6\text{Li}\) is very similar to that of the deuteron, but the momentum distribution of \(^6\text{He}\) differs from them, showing a clear dip at \(k \sim 2\text{ fm}^{-1}\). These features are understood from the difference in the partial wave contents of the N-N relative motion; \(^6\text{Li}\) contains the D-wave component as the deuteron does, whereas \(^6\text{He}\) is dominated by the S-wave component. The most distinctive difference between \(^6\text{He}\) and \(^6\text{Li}\) appears around \(k \sim 2\text{ fm}^{-1}\). In this region, however, the momentum distribution becomes by four or more order of magnitude smaller than that at \(k \sim 0\); this may make it hard to measure the cross section experimentally. If the measurement of the momentum distribution is possible in this region, one can learn the role of the tensor force acting between the valence nucleons, provided that the meson exchange currents and the isobar excitations are still not so important.

Figure 8 compares the momentum distributions of \(^6\text{He}\) corresponding to the three different wave functions, those obtained with G3RS and MN, and the uncorrelated one defined in Eq. (23). Both the G3RS and MN distributions are similar up to the dip region. Beyond \(k \sim 2\text{ fm}^{-1}\) the momentum distribution of G3RS surpasses that of MN, which is due to the difference in the short-range correlation involved in the two wave functions. The uncorrelated wave function gives the momentum distribution which is quite different from those of the correlated wave functions even at \(k \sim 1\text{ fm}^{-1}\).

In Sec. III C we decomposed the ground state wave function of \(^6\text{He}\) into \(\Psi_S\) and \(\Psi_L\), and confirmed that the dineutron-like peak is produced by the small component \(\Psi_S\), while the cigar-like peak by the large component \(\Psi_L\). The interference term was small. One might expect that the momentum distribution may as well be decomposed into low and high momentum components. Namely, \(\Psi_L\) may contribute to the momentum distribution at small \(k\), while \(\Psi_S\) to the high momentum component. We examine this expectation in Fig. 9 by analyzing the momentum distribution of \(^6\text{He}\) obtained with the G3RS potential. The left panel shows the partial momentum distributions, \(\rho_L\) calculated with \(\Psi_L\) and \(\rho_S\) calculated with \(\Psi_S\), respectively. The right panel compares the full momentum distribution \(\rho\) with the incoherent sum of \(\rho_L + \rho_S\), so that the difference between \(\rho\) and \(\rho_L + \rho_S\) is the contribution of the interference terms of Eq. (31). We see that the contribution of the interference terms can be neglected for \(k < 1\text{ fm}^{-1}\). However, the interference contribution becomes important for \(k > 1\text{ fm}^{-1}\). In the momentum region where the interference can be ignored, the momentum distribution is dominated by \(\Psi_L\) for \(k < 0.5\text{ fm}^{-1}\) and by \(\Psi_S\) for \(0.5 < k < 1\text{ fm}^{-1}\).

### IV. CONCLUSIONS

To study the correlation and the momentum distribution of the two-nucleon relative motion in the ground states of \(^6\text{He}\) and \(^6\text{Li}\), we have described these states in a three-body model of \(\alpha + N + N\) where the \(\alpha\) particle is assumed to be an inert core. We used a parity-dependent \(\alpha\)-N potential which reproduces the low-energy S- and P-wave phase shifts, and two different types of N-N in-
interactions as the potential acting between the two valence nucleons. One is a realistic potential which contains the tensor and spin-orbit forces and the other is an effective potential which includes no tensor component. These were used to compare how much the different $N-N$ potentials affect the correlation and the momentum distribution.

We have obtained the solution of the three-body problem by approximating the $^6$He and $^6$Li ground state wave functions in terms of a combination of explicitly correlated Gaussian basis functions. The use of the global vectors to describe a nonspherical orbital motion facilitates the calculation of the matrix elements much easier than the partial wave expansion, and moreover provides us with a solution of high accuracy.

The energies and rms radii of $^6$He and $^6$Li are compared to experiment. The energies calculated with the realistic $N-N$ potential are underbound by 400-500 keV in both the cases. The charge radii of $^6$He and $^6$Li and the matter radius of $^6$Li are in fair agreement with the observed values. The $^6$He matter radius is predicted to be larger than experiment; the result is due to the underbinding of the calculated ground state of $^6$He. We have analyzed the two-neutron correlated motion in $^6$He in order to identify how the dineutron and cigar-like configurations are related to the two-neutron relative distance distribution.

The momentum distributions of the $N-N$ relative motion have been compared between $^6$He and $^6$Li. The distributions obtained with the effective potential show the pattern characteristic of $S$-wave dominance and fall rapidly as the momentum increases. In the case of the realistic potential, the momentum distribution in $^6$Li is very similar to that of the deuteron. That is, both the $S$- and $D$-waves contribute to the momentum distribution which monotonically decreases with an increasing momentum. In contrast to this, the $^6$He momentum distribution is dominated by the $S$-wave, showing a clear dip at $k \sim 2\text{fm}^{-1}$. The most prominent difference in their momentum distributions thus shows up around $k=2\text{fm}^{-1}$. The difference between $^6$He and $^6$Li is primarily due to whether or not the tensor force plays an important role.

FIG. 5: Decomposition of the two-nucleon correlation function of $^6$He into the small (left panel) and large (right panel) components. The G3RS potential is used. The difference between any two neighboring contour levels is $0.01\text{fm}^{-2}$.

FIG. 6: Momentum distributions of the deuteron calculated with the G3RS and MN potentials. Data are taken from Ref. [44].
The aim of this appendix is to show a method of calculating the density matrix, so that it is sufficient to show how the density matrix is evaluated. We first express the basis functions in the T-type coordinates \((z_1, z_2)\) as discussed in Sec. II C, (in this appendix we use \((z_1, z_2)\) instead of \((r, R)\) to simplify the notation), and write the general form of the orbital part of the correlated Gaussians as
\[
G_{LM_L}(A, \ell_1, \ell_2, z_1, z_2) = \exp \left(-\frac{1}{2} \kappa A z \right) [\chi_{L}(z_1) \chi_{L}(z_2)]_{LML}. \tag{32}
\]
The density matrix \(\rho\) which we consider here reads as
\[
\rho(z_1, z_1') = \frac{1}{2J + 1} \sum_M |\langle G_{L}(A', \ell_1', \ell_2', z_1', z_2) \rangle|_{LM_L} | \langle G_{L}(A, \ell_1, \ell_2, z_1, z_2) \rangle|_{LM_L}. \tag{33}
\]
where the integration in the matrix element has to be performed for \(z_2\) as well as the spin coordinates.
Performing the integration over the spin coordinates yields
\[
\rho(z_1, z_1') = \delta_{LL'} \delta_{SS'} \frac{1}{2L + 1} \sum_{M_L} \langle \chi_{L}(z_1) \chi_{L}(z_2) \rangle_{LML} | \langle \chi_{L}(z_1') \chi_{L}(z_2') \rangle_{LML}|. \tag{34}
\]
Writing the angular part of the right-hand side of Eq. (34) explicitly we obtain
\[
\frac{1}{2L + 1} \sum_{M_L} |\langle \chi_{L}(z_1) \chi_{L}(z_2) \rangle_{LML} | \langle \chi_{L}(z_1') \chi_{L}(z_2') \rangle_{LML}|^* = (-1)^{\ell_1' + \ell_2'} \frac{1}{\sqrt{2L + 1}} \sum_{\lambda} \left[ \frac{\ell_1 \ell_2 L}{\ell_1' \ell_2' L} \right] \left[ \frac{\lambda}{\lambda} \lambda 0 \right] C(\ell_2 \ell_2' ; \lambda) z_2^{2n}
\]
\[
\times \left[ \langle \chi_{L}(z_1) \chi_{L}(z_1') \rangle \chi_{L}(z_2) \right]_{00}, \tag{35}
\]

ACKNOWLEDGEMENTS

The authors thank T. Suda for his interest and valuable discussions. They thank D. Baye for useful discussions on the three-body calculations. This work was in part supported by Japan-Belgium Bilateral Joint Research Project of Japan Society for the Promotion of Science and a Grant for Promotion of Niigata University Research Projects (2005-2007).

APPENDIX: CALCULATION OF THE MOMENTUM DISTRIBUTION

The aim of this appendix is to show a method of calculating the momentum distribution for the correlated Gaussians. As discussed in Sec. II C, the momentum distribution is calculated from the density matrix, so that it is sufficient to show how the density matrix is evaluated. We first express the basis functions in the T-type coordinates \((z_1, z_2)\) as discussed in Sec. II C, (in this appendix we use \((z_1, z_2)\) instead of \((r, R)\) to simplify the notation), and write the general form of the orbital part of the correlated Gaussians as
\[
G_{LM_L}(A, \ell_1, \ell_2, z_1, z_2) = \exp \left(-\frac{1}{2} \kappa A z \right) [\chi_{L}(z_1) \chi_{L}(z_2)]_{LML}. \tag{32}
\]
The density matrix \(\rho\) which we consider here reads as
\[
\rho(z_1, z_1') = \frac{1}{2J + 1} \sum_M |\langle G_{L}(A', \ell_1', \ell_2', z_1', z_2) \rangle|_{LM_L} | \langle G_{L}(A, \ell_1, \ell_2, z_1, z_2) \rangle|_{LM_L}. \tag{33}
\]
where the integration in the matrix element has to be performed for \(z_2\) as well as the spin coordinates.
Performing the integration over the spin coordinates yields
\[
\rho(z_1, z_1') = \delta_{LL'} \delta_{SS'} \frac{1}{2L + 1} \sum_{M_L} \langle \chi_{L}(z_1) \chi_{L}(z_2) \rangle_{LML} | \langle \chi_{L}(z_1') \chi_{L}(z_2') \rangle_{LML}|. \tag{34}
\]
Writing the angular part of the right-hand side of Eq. (34) explicitly we obtain
\[
\frac{1}{2L + 1} \sum_{M_L} |\langle \chi_{L}(z_1) \chi_{L}(z_2) \rangle_{LML} | \langle \chi_{L}(z_1') \chi_{L}(z_2') \rangle_{LML}|^* = (-1)^{\ell_1' + \ell_2'} \frac{1}{\sqrt{2L + 1}} \sum_{\lambda} \left[ \frac{\ell_1 \ell_2 L}{\ell_1' \ell_2' L} \right] \left[ \frac{\lambda}{\lambda} \lambda 0 \right] C(\ell_2 \ell_2' ; \lambda) z_2^{2n}
\]
\[
\times \left[ \langle \chi_{L}(z_1) \chi_{L}(z_1') \rangle \chi_{L}(z_2) \right]_{00}, \tag{35}
\]

FIG. 7: Momentum distributions, calculated from the G3RS and MN potentials, of the valence nucleons in \(^6\)He and \(^6\)Li.

FIG. 8: Momentum distributions of the valence nucleons in \(^6\)He for the three different wave functions.

of mixing the \(D\)-state probability between the \(N\)-\(N\) relative motion. We hope that this prediction will be tested experimentally.
where \([ \ ]\) is the 9\(j\) symbol in unitary form and \(C\) is the coefficient to couple two spherical harmonics with a same argument:

\[
C(\ell_2 \ell_2'; \lambda) = \sqrt{\frac{(2\ell_2 + 1)(2\ell_2' + 1)}{4\pi(2\lambda + 1)}} \langle \ell_2 \ell_2' 0 | 0, \lambda 0 \rangle. \tag{36}
\]

Note that \(2n \equiv \ell_2 + \ell_2' - \lambda\) is non-negative and even, otherwise the coefficient \(C(\ell_2 \ell_2'; \lambda)\) vanishes. Thus the integration over \(z_2\) in Eq. (34) is performed as

\[
\int \exp \left( -\frac{1}{2} a z_2^2 - k \cdot z_2 \right) z_2^{2n} \times \left[ [\mathcal{Y}_\ell(z_1) \mathcal{Y}_{\ell_1}(z_1')] Y_{\lambda}(z_2) \right]_{00} \, dz_2 \\
= 4\pi(-1)^\lambda \left[ Y_{\lambda}(z) \right]_{00} \times \frac{\pi}{2} \left( \frac{(2n)!}{\alpha^{n+\lambda+\frac{1}{2}}} \right) L_n^{(\lambda+\frac{1}{2})} \left( -\frac{Z^2}{2\alpha} \right) \exp \left( \frac{Z^2}{2\alpha} \right), \tag{37}
\]

where \(L_n^{(\lambda+\frac{1}{2})}\) is the associated Laguerre polynomial, and

\[
a = A_{22} + A_{22}', \quad Z = A_{12} z_1 + A_{12}' z_1'. \tag{38}
\]

Using the formula (30) the coupling of three \(\mathcal{Y}\)'s in Eq. (37) is reduced to

\[
\left[ [\mathcal{Y}_\ell(z_1) \mathcal{Y}_{\ell_1}(z_1')] Y_{\lambda}(z_2) \right]_{00} = \sum_k \sqrt{\frac{4\pi(2\lambda + 1)!}{(2k + 1)!(2\lambda - k + 1)!}} A_{12}^{\lambda-k} \times \sum_{\mu} \frac{k - \lambda - k \mu}{\mu} \times z_1^{k+\ell_1} z_1^{\lambda-k+\ell_1'} \left[ Y_{\mu}(z_1) Y_{\mu}(z_1') \right]_{00}, \tag{39}
\]

with

\[
[Y_{\mu}(z_1) Y_{\mu}(z_1')]_{00} = (-1)^\mu \frac{\sqrt{2\mu + 1}}{4\pi} \times \sum_{\kappa=0}^{\left[ \frac{\mu}{2} \right]} (-1)^\kappa \frac{(2\mu - 2\kappa - 1)!!}{(\mu - 2\kappa)!!} \left( \frac{z_1 \cdot z_1'}{z_1 z_1'} \right)^{\mu-2\kappa}, \tag{40}
\]

where \(\left[ \frac{\mu}{2} \right]\) is the largest integer less than or equal to \(\frac{\mu}{2}\).

Combining Eqs. (34)–(40), we obtain the density matrix as a combination of terms

\[
z_1^{2p} z_1^{2p'} (z_1 \cdot z_1')^q \exp \left( -\beta z_1^2 - \beta' z_1'^2 - \gamma z_1 \cdot z_1' \right), \tag{41}
\]

where \(p, p', q\) are all non-negative integers.

To calculate the momentum distribution we just replace \((z_1, z_1')\) with \((r + \frac{1}{2}s, r - \frac{1}{2}s)\) in the density matrix, multiply \(e^{ik \cdot s}\) and integrate over \(r\) and \(s\). Renaming \((r, s)\) as \((z_1, z_2)\) again, the integration results in the following form

\[
\int e^{-\frac{1}{2} k_B z_1 z_1'} z_1^{2n_1} z_2^{2n_2} (z_1 \cdot z_2)^{n_3} \, dz_1 dz_2, \tag{42}
\]

which can be performed analytically, where \(B\) is a \(2 \times 2\) symmetric matrix, \(k_B = k - k \cdot z_2\) and \(n_1, n_2\) and \(n_3\) are all non-negative integers.
