Abstract

There has been significant interest in the development of multicomponent nanocrystals formed by the assembly of two or more different materials with control over size, shape, composition, and spatial orientation. In particular, the selective growth of metals on the tips of semiconductor nanorods and wires can act to couple the electrical and optical properties of semiconductors with the unique properties of various metals. Here, we outline our progress on the solution-phase synthesis of metal-semiconductor heterojunctions formed by the growth of Au, Pt, or other binary catalytic metal systems on metal (Cd, Pb, Cu)-chalcogenide nanostructures. We show the ability to grow the metal on various shapes (spherical, rods, hexagonal prisms, and wires). Furthermore, manipulating the composition of the metal nanoparticles is also shown, where PtNi and PtCo alloys are our main focus. The magnetic and electrical properties of the developed hybrid nanostructures are shown.

Keywords: synthesis; Hybrid Nanocrystals; Nanowires; Electrical and magnetic properties; MOCVD

The assembly of two or more nanostructured components with precise control over the size, shape, composition, and spatial orientation is desirable not only for the combination of different functionalities, but also for advanced properties that can arise independent of the single-component materials. Engineering hybrid multicomponent nanostructures draws on the vast array of synthetic techniques now at our disposal to assemble nanocrystals with very different properties; a semiconductor nanocrystal can be combined with a metal in such a way that the hybrid structure can be tailored to a specific application.

Non-centrosymmetric hybrid nanocrystals have been prepared from a variety of materials combinations, with the resulting conformations depending on the crystal structure, miscibility, interfacial strain, or selective reactivity of the components (1). In this type of hybrid nanocrystal, both materials are exposed and spatially isolated, allowing for asymmetric assembly or functionalization. This is, in contrast to core/shell structures, where only the outer shell is available for chemical reactions. Semiconductors, for example, often exhibit considerably greater facet-specific chemical reactivity than metals, owing to their anisotropic crystal structures (2). There has been significant interest in the selective growth of metals on the tips of nanorods and wires to couple the electrical and optical properties of semiconductors with the unique properties of various metals. A number of approaches have been used to selectively grow metals on semiconductors through reduction, physical deposition, or photochemistry to give Au and Ag on ZnO (3, 4), Co and Au on TiO₂ (5, 6), and others (7, 8). Here we describe...
our progress on the development of metal-semiconductor heterojunctions focused on Cd and Pb calcogenide interfaces with Au, Pt, and other binary catalytic metal systems.

A number of bimetallic nanoparticle systems, including the Ni_{x}Pt_{1-x} nanocrystals described by Weller and coworkers, have magnetic properties that can be utilized for high-density data storage and other magnetic-based applications (9). Furthermore, bimetallic materials frequently present advanced catalytic behaviors distinct from their constituent metals. For example, NiPt nanoparticles show enhanced activity for oxygen reduction relative to pure Pt (10, 11). The incorporation of semiconductors with bimetallic catalyst particles may be of particular interest for photocatalytic and photovoltaic applications.

Preparation of hybrid nanostructures

**CdSe nanowires**

CdSe nanowires were grown by a previously reported form (12) of the SLS growth mechanism (13). Briefly, cadmium oxide (CdO 99.99%, 0.006 g, 0.047 mmol) was complexed with \( n \)-tetradecylphosphonic acid (\( n \)-TDPA 97%, 0.0270 g, 0.097 mmol) in trioctylphosphine oxide (TOPO 99%, 5 gr) for 90 min at 300°C under N\(_2\) using standard Schlenk technique. The catalyst, a 6 nm thin film of Bi, was thermally evaporated on top of a 2.5 nm sticking layer of Cr on a Si(100) substrate. In a typical film of Bi, was thermally evaporated on top of a 2.5 nm sticking layer of Cr on a Si(100) substrate. The catalyst, a 6 nm thin film of Bi, was thermally evaporated on top of a 2.5 nm sticking layer of Cr on a Si(100) substrate. In a typical synthesis, one or two ~ 0.4 cm\(^2\) Si substrates were added to the Cd-TDPA solution at 270°C. Since the bulk melting point of Bi is 271°C, some of the Bi thin film melts and dewets from the surface of the substrate forming Bi nanoparticle catalysts. Next, 0.25 mL of 2.5 wt% selenium (99.5% powder mesh) dissolved in trioctylphosphine (97%) was injected into the solution. After 5 min of growth time, the solution was cooled and then diluted with 5-10 mL of toluene. The CdSe nanowires suspended in solution were precipitated by addition of methanol followed by centrifugation. The product was stored as a colloidal suspension in toluene.

**Cu\(_{2}\)S nanoprisms**

In a typical synthesis of the hexagonal nanoprisms, 6 mL of a 0.11 M solution of Cu(II)[S\(_2\)CNC\(_4\)H\(_{10}\)]\(_2\) in trioctylphosphine (TOP 97%) is placed on a 6 mm-6 mm Si (100) substrate that has been cleaned by sonication in isopropanol. The substrate is placed onto a glass slide on a hot plate and heated under inert atmosphere (N\(_2\)) to 240–250°C until all solvent has evaporated (about 10 min).

Single-source molecular precursors Cu(II)[S\(_2\)CNC\(_4\)H\(_{10}\)]\(_2\) and was synthesized based on previously published methods (14). Briefly, Cu(II)Cl\(_2\), Pb(II)Cl\(_2\), and sodium diethylidithiocarbamate (Na(I)[S\(_2\)CNC\(_4\)H\(_{10}\)]) were dissolved separately in deionized water (\(R > 18.0\) MU). The metal ion solution was mixed with the dissolved diethylidithiocarbamate ligand solution with a ligand to metal molar ratio of 2:1. The product formed immediately as a precipitate and was vacuum filtered and dried. The molecular precursor was recrystallized once from hot chloroform before use.

**Au growth**

The CdSe wires were decorated with Au according to a method described previously (15). A toluene solution containing gold trichloride (AuCl\(_3\), 12 mg, 0.03 mmol), didodecyl(dimethylammonium) bromide (DDAB, 40 mg, 0.09 mmol), and dodecylamine (DDA, 70 mg, 0.38 mmol) was sonicated for 5 min and then added dropwise to a suspension of nanowires stirring under N\(_2\). The product was precipitated with methanol and separated by centrifugation. The amount of precursor added was varied to give the desired degree of Au overgrowth.

**Pt, PtNi, and PtCo growth**

Decoration of the CdSe wires with Pt, PtNi, and PtCo was achieved as described previously (16). Oleic acid (0.2 mL), oleylamine (0.2 mL), and 1, 2-hexadecanediol (43.0 mg) were heated in diphenyl ether (10 mL) at 80°C under vacuum for 30 min to remove traces of water. Platinum acetylacetonate (32.8 mg) was added to a suspension of CdSe nanowires in 1,2-dichlorobenzene and heated at 65°C for 10 min to promote dissolution of the Pt precursor. The mixture of surfactants and diphenyl ether was purged with nitrogen and heated to 200°C before injecting the Pt precursor and semiconductor wires. After several minutes, the reaction was removed from heat and quenched in a water bath. The product was washed by precipitation with ethanol followed by centrifugation. Either nickel or cobalt acetate was added to the reaction prior to heating to 80°C to promote PtNi or PtCo formation. Control over the binary composition is possible by altering the ratio of the metallic components or by changing the metal to CdSe nanowire ratio.

**GaN and InGaN growth**

GaN and GaN@InGaN core-shell nanowire growth was carried out in a Thomas Swan, Showerhead MOCVD cold-wall reactor. The growth substrates were prepared by drop-casting 40 \(\mu\)L of 0.2 M solution of Ni(NO\(_3\))\(_2\) in ethanol onto a 1 cm\(^2\) c-plane sapphire wafer. For substrates, of 5:1 ratio B. B. International 10 nm gold colloid to ethanol was drop-cast onto wafers. Pure GaN nanowires were grown for 10 min at \(\sim 825°C\). The reactive and carrier gas flows were 600, 41,200, and 400 sccm for ammonia, tri-methyl gallium (TMG), hydrogen, and nitrogen. The TMG bubbler was kept at 5°C and the reactor pressure was 140 Torr. For core-shell wires, the same conditions were used for GaN nanowires with a subsequent step for InGaN deposition. The InGaN shells
were grown for 15 min with temperatures from 700 to 750°C. The reactive and carrier gas flows were 5,000, 1,190, and 1,000 sccm for ammonia, TMG, tri-methyl Indium (TMI), and nitrogen. The TMI bubbler was kept at 18°C and the reactor pressure was 400 Torr.

**Characterization**

The structure and composition of the samples were investigated by TEM and HRTEM (Tecnai G2 S-Twin microscope operated at 200 kV and JEOL 2100-F Field-Emission Analytical Transmission Electron Microscope operated at 200 kV), EDS (Philips CM200/FEG microscope operated at 200 kV, equipped with a Link EDS detector, and a Weiss FESEM Ultra-55 operated at 30 kV), and XRD (Bruker-AXS D8 with a general area detector and Co Kα radiation). Samples were dispersed on carbon coated copper grids for TEM or glass substrates for XRD. Toluene suspensions of the nanowires were prepared for analysis by UV-vis absorption spectroscopy (Shimadzu UV-3,600), and PL spectroscopy was performed using a 532 nm excitation source for disperse samples on TEM grids. Image correlation for PL measurements was performed using the STEM mode on a Weiss FESEM Ultra-55 operating at 30 kV. Magnetic measurements were performed on powder samples of the PtCo-overgrown CdSe nanowires with a SQUID magnetometer (Quantum Design MPMS XL).

**Conductance measurements**

Source and drain electrodes with junctions spanning 20-40 nm were fabricated on silicon wafer test chips using e-beam lithography, followed by deposition of 55 nm of Au on 10 nm of Ti. A film of 10 nm of silicon nitride or aluminum oxide was deposited via atomic layer deposition (ALD) before the electrodes to prevent shorting through the silicon substrate.

The nanorod samples were adsorbed to these predefined Au junctions by submerging the chip in the appropriate µM nanorod-toluene solution and drying with N₂. The details of this process are discussed below. Once fabricated, the current through individual nanorod devices was characterized in a two-terminal geometry as a function of source-drain voltage and temperature. All data reported here were measured in a 10⁻¹⁰ Torr atmosphere with a Janis Research ST-500-2 micromanipulated probe station, chilled with liquid He or N₂ cryogen.

**Properties of hybrid nanostructures**

There has been considerable interest in the selective growth of metals on semiconductors through reduction, physical deposition, or photochemistry. A facile method for the deposition of Au on the tips of CdSe nanorods was developed by one of the co-authors of this paper, based on the reduction of Au by dodecylamine in the presence of didodecyldimethylammonium bromide (DDAB) at room temperature (15). Fig. 1A presents a TEM image of CdSe nanorods decorated with two gold tips. The same process has been shown for CdS nanorods (Fig. 1B) (17). The anisotropic wurtzite crystal structure of CdSe nanorods promotes selective growth of metals at the tips as a result of their higher reactivity that is also responsible for longitudinal growth along the <001> direction to form CdSe nanorods. Initially, when the concentration of Au is low, growth dominates at one of the tips, possibly due to increased interaction with the Se rich facet. Along the <001> axis the nanorods are alternately composed of planes of Se and Cd, the Cd having less reactivity with the Au. As the reaction progresses and the Au concentration increases, the DDAB facilitates an etching process of the CdSe rods that may promote growth at both ends as Se sites are exposed on the other end. However, by increasing the ratio of Au to CdSe nanorods beyond the concentration needed for growth of two tips, another process occurs. In this process, one of the tips dissolves and the other tip grows, resulting in asymmetric heterostructures with single Au tips. This process was explained by an electron-transfer mediated ripening mechanism (18). These methods have also allowed for the selective growth of Au tips on CdSe rods (Fig. 1A) and CdTe tetrapods (Fig. 1C). We have shown that a variety of metals can be grown with high selectivity on the tips of Cd-calcegin endes. In order to increase the application for metal-semiconductor heterostructures, the semiconductor can also be changed to include narrow band-gap Pb and Cu-calcegenide nanocrystals, for example. Metal growth has been demonstrated previously for Au on PbS (7), and we have shown that similar results occur for PbSe (Fig. 1E) and Cu₂S nanocrystals (Fig. 1D). The PbSe nanocrystals shown in Fig. 1E were treated with AuCl₃ in toluene with dodecylamine and DDAB, and at early stages of growth or low Au concentrations the PbSe particles were decorated with multiple Au nucleates (Fig. 1E). At higher Au concentrations or a larger Au to PbSe ratio, a ripening process, similar to that observed for CdSe nanorods (18), resulted in coalescence of the Au nucleates on the PbSe nanocrystals. Growth of Au was expanded to gas phase (MOCVD) grown nanowires (GaN and InGaN) and similar results were obtained as shown in Fig. 1F (19).

Extension of these methods to include Pt and related binary metals is of particular interest for photocatalytic applications where the catalytic activity of Pt is relevant for an extremely large number of reactions that are not accessible with Au. However, previous attempts to reduce Pt on CdSe in this manner were unsuccessful, and the reduction of Au on CdS resulted in the growth of metal clusters over the entire rod, with less selectivity for the tips (17). A high-temperature organometallic method for the synthesis of Pt-CdS, PtNi-CdS, and PtCo-CdS hybrid.
nanostructures with controllable size and composition is described here. There are several advantages inherent in this approach including high selectivity for the tips, an absence of etching that preserves the size of the nanorods, and composition control of the metal tips.

The procedure for the selective growth of Pt on semiconductor nanorods was adapted from a scheme for the synthesis of Ni$_x$Pt$_{1-x}$ nanoparticles developed by Weller and coworkers (9). In order to produce the heterostructures, a mixture of Pt precursor and CdS rods was injected into a coordinating solvent containing stabilizers and a reducing agent at high temperature, the growth of the Pt nanoparticles on CdS nanostructures was first shown in our earlier report (16). Herein, we discuss the growth of the four various compositions of metals on CdSe nanowires (20). We have used the same procedure that was described before to decorate CdSe nanowires with Au, Pt, and bimetal nanoparticles (PtNi, PtCo) as shown Fig. 2. Fig. 2A shows the Au growth on the surface of the CdSe nanowires. The size of the Au particles is controlled by changing the concentration of the Au precursor. The high reactivity of the tips as a result of increased surface energy and imperfect ligand passivation allows for selective chemistry on different facets (2). During the early stages of metal growth, or at a low metal concentration, metal deposition appears to occur preferentially on only one tip of the CdSe nanowires, this observation was clearly shown in the growth of the metal on the CdS (or CdSe) nanorods. This process is not related to the electrochemical ripening seen for the Au tipped semiconductors but rather can be explained by considering that at low metal concentrations, the Se rich facets along the <001> axis are more highly reactive. Alternatively, due to the significant length of the CdSe nanowires relative to the size of the metal particles, each tip may act as an isolated nucleation site independent of the other tip. Thus, at low metal precursor concentrations where some of the rods do not experience metal growth on either tip, the remainder of metal nucleation will most likely occur on only one of the tips. Increasing the amount of metal relative to the concentration of CdSe wires leads to decoration of the nanowires with Au particles, as shown in Fig. 2A. The procedure was expanded to other metal as shown in Fig. 2B-D, which presents TEM images of CdSe nanowires decorated with Pt, PtNi, and PtCo, respectively.

The XRD patterns and the EDS spectra of the four samples shown in Fig. 2 are presented in Fig. 3A, B. The pure CdSe wires and Pt-CdSe agree well with the bulk CdSe wurtzite crystal structure and that for face-centered cubic Pt. The EDS measurements shown in Fig. 3B of the CdSe and Pt-CdSe clearly show the elemental composition of the two samples (Cd, Se, and Pt).

Characterization of the binary metallic heterostructures was performed to determine the composition of the metal tips. The XRD measurements (Fig. 3A) provide evidence for the presence of crystalline CdSe and Pt peak shifted corresponding to a change in lattice constant with alloy formation (9, 21). Furthermore, there was no evidence for pure Ni or Co phases or their respective
oxides. Experimentally we have seen that the Co precursor is not reduced in the absence of Pt under the conditions described here. Selected area EDS measurements on a single tip of the PtNi-CdS hybrids shows the presence of both Pt and Ni in the tip (Fig. 3B), while analysis on a larger number of tips indicates the presence of approximately 25% Ni relative to Pt. These results are of interest because control over the composition of the tips may have a direct effect on the catalytic activity of these materials.

Magnetic characterization of the PtCo-CdSe hybrid nanowires was performed using SQUID magnetometry. Hysteresis loops are presented for the PtCo-CdSe hybrid nanowires for both 300 and 4.2 K in Fig. 4 (22). The lower inset displays temperature-dependent magnetization measurements done in both zero-field cooled and field-cooled modes. The structures exhibit superparamagnetic behavior with a blocking temperature of approximately 30 K, which is typical of nanoscale PtCo particles (23). We thus see that, in this case, the magnetic properties of the PtCo alloys are preserved upon growth onto the CdSe nanowires.

Optical absorption and photoluminescent (PL) measurements of the Au-CdSe hybrid nanowires show significant broadening upon Au growth a concurrent quenching of the photoluminescence indicative of strong coupling between the semiconductor and metal tip. Fig. 4 presents the SEM images (using the STEM detector) of the CdSe nanowires before (4A) and after Au growth (4B). The PL and absorption spectra of the same samples shown in A and B were taken and shown in C and D, respectively.

Electrical measurements of single nanostructures remain a challenging task. The electrical properties of a single semiconductor nanostructure are influenced by various parameters; among these parameters is the interface between the semiconductor nanostructure and the metal electrodes. This interface plays a significant role of determining the overall properties. We have conducted systematic measurements to study the effect of the interface by comparing the electrical response of CdSe nanorods with and without the Au tips (24). The Au-CdSe hybrid nanorods provide a direct two metal-semiconductor interfaces with no surfactant in the middle.

Fig. 5 shows the TEM images CdSe nanorods with (Fig. 5A) and without Au tips (Fig. 5B) and the SEM images of the two Au electrodes that were fabricated as described in the experimental section (Fig. 5C). The absorption spectra of the CdSe sample before and after the growth are shown in Fig. 5D. The broadening of the absorption spectrum of the CdSe-Au sample was discussed earlier in this manuscript.

Measurement of the electrical properties of single nanorods is shown in Fig. 6. The room temperature resistance of various devices is summarized in Fig. 6A. The resistance values obtained for the pure CdSe (red trace) are ranged between $10^{11}$ and $10^{13}$, which is 6-orders of magnitude higher compared to the Au-CdSe (green trace) nanostructures. These results can be shown in the
I-V curve (Fig. 6B), where the resistance the zero-bias is much higher for the CdSe nanorods compared to the Au-CdSe hybrid structure. The improvement of the electrical conductivity by lowering the resistance at the interface opens a wide range of applications in electronics, energy, and others.

**Conclusion**

Hybrid nanostructures could have special interest in catalysis and energy application. We have shown the synthesis of hybrid nanostructures of different materials and various shapes. The electrical properties of individual CdSe nanorods with and without Au tips are shown.
