(Dated: October 8, 2015)

We present a new dynamic off-equilibrium method for the study of continuous transitions, which represents a dynamic generalization of the usual equilibrium cumulant method. Its main advantage is that critical parameters are derived from numerical data obtained much before equilibrium has been attained. Therefore, the method is particularly useful for systems with long equilibration times, like spin glasses. We apply it to the three-dimensional Ising spin-glass model, obtaining accurate estimates of the critical exponents and of the critical temperature with a limited computational effort.

Monte Carlo simulations combined with finite-size scaling (FSS) methods are, at present, the most successful tool for the identification of continuous transitions and the determination of the critical parameters. In this approach there are two main obstacles to a precise determination of the critical parameters. In one side, scaling corrections, related to the subleading relevant renormalization-group (RG) operators, may mask the asymptotic critical behavior, which shows up only when the system size $L$ becomes large. On the other side, the Monte Carlo dynamics becomes increasingly slow as the critical point is approached, so that thermalization and equilibration autocorrelation times become large as $L$ increases, hampering large-$L$ simulations. These problems are particularly serious in systems with quenched disorder. They occur, for instance, when studying the paramagnetic-glassy transition in the $\pm J$ Ising model with random ferromagnetic and antiferromagnetic couplings, which represents a standard theoretical laboratory to understand the effects of quenched disorder and frustration. Its Hamiltonian is given by \[ H = -\sum_{\langle xy \rangle} J_{xy} \sigma_x \sigma_y, \] (1)

where the sum runs over all nearest neighbors $\langle xy \rangle$ of a cubic lattice, $\sigma_x = \pm 1$ are Ising spins, and $J_{xy}$ are quenched random couplings that take the values $\pm 1$ with equal probability. At the transition and, even worse, in the low-temperature phase, the standard Metropolis dynamics is very slow, so that equilibration becomes very difficult, even for relatively small systems. Moreover, equilibration times depend strongly on the disorder realization, so that a sample-by-sample analysis is needed to guarantee that all measurements are obtained from well-equilibrated samples \[. \] At present, even by using dedicated machines \[, \] it seems impossible to go much beyond sizes $L = 30-40$.

In this work we discuss a dynamic method to determine the critical temperature and the critical exponents. We will discuss it in the context of the $\pm J$ Ising model, but the method and the results are completely general, so it can be applied to the study of any continuous transition in pure or disordered systems. The method, which does not require the system to be in equilibrium, has two advantages. First, the difficult and time consuming (at least in disordered systems) task of verifying equilibration is no longer needed. Second, we can stop the simulation much before equilibrium has been reached, saving a considerable amount of computing time. The method we discuss is somewhat different from previous off-equilibrium methods (see, e.g., Refs. \[4,12 \] and references therein). Indeed, in most of those works it is generally assumed that $L$ is so large that finite-size effects are negligible, a condition that is easily satisfied in pure systems but not in the random case. On the contrary, we will use the finite-size dependence of physical observables to estimate the critical parameters. Our method is essentially an off-equilibrium generalization of the usual Binder crossing method.

As in FSS equilibrium computations, we begin by considering a RG invariant quantity $U(t, L, \beta)$ as a function of the Monte Carlo time $t$, inverse temperature $\beta$, and system size $L$. According to RG, for $L$ and $t$ large and close to the critical point $\beta_c$, $U(t, L, \beta)$ scales as \[13–18\]

\[ U(t, L, \beta) = f_R(tL^{-z}, \epsilon) + u_\omega(\beta)L^{-\omega} g_R(tL^{-z}, \epsilon) + \ldots \] (2)

where next-to-leading scaling corrections have been neglected. Here $\omega$ is the leading correction-to-scaling exponent, $u_\omega(\beta)$ the associated nonlinear scaling field satisfying $u_\omega(\beta) \neq 0$, $\epsilon = u_\beta(\beta)L^{1/\nu}$, where $u_\beta \approx \beta - \beta_c$ is the temperature nonlinear scaling field which parametrizes the distance from the critical point. Equation (2) depends also on the dynamic critical exponent $z$, which represents an additional parameter to be determined. To avoid any reference to $z$, we now reparametrize the time evolution in terms of the correlation length $\xi$, or, better, in terms of the RG invariant ratio $R_\xi = \xi/L$. When us-
ing an initial disordered configuration, $\xi$ is an increasing function of $t$, any function of $t L^{-\xi}$ can be equivalently reexpressed in terms of $R_\xi$, so that we write

$$U(t, L, \beta) = \hat{f}_U(R_\xi, \epsilon) + u_\omega(\beta) L^{-\xi} \hat{g}_U(R_\xi, \epsilon) + \ldots,$$

which is defined for $R_\xi \leq R_{\xi, eq}(\epsilon)$, where $R_{\xi, eq}(\epsilon)$ is the equilibrium value of $R_\xi$ for the given $\epsilon$. Equation (3) is the basic relation we use to compute critical temperature and exponents. Indeed, ignoring scaling corrections, close to the critical point Eq. (3) can be expanded in $\epsilon$, obtaining

$$U(t, L, \beta) = \hat{f}_U(R_\xi, \epsilon) + (\beta - \beta_c) L^{1/\nu} \hat{f}_U(R_\xi, \epsilon) + \ldots$$

At fixed $R_\xi$, the quantity $U(t, L, \beta)$ behaves exactly as in the equilibrium case: $\beta_c$ is determined as the crossing point and $\nu$ is obtained by computing the slope at $\beta_c$. However, in this formulation equilibration is not a needed. Equation (3) is valid for any value of $R_\xi$, so one might think of choosing a small value for such a parameter, reducing significantly the length of the runs. However, one must not forget that the method is intrinsically a finite-size method; hence, it can only work if finite-size effects are not too tiny, and this, in turn, requires $R_\xi$ to be not too small. Mathematically, these considerations can be understood by considering Eq. (4). The method is expected to be precise if the coefficient $\hat{f}_U^\prime(R_\xi, 0)$ is not too small. Such a coefficient depends on $R_\xi$ and it is expected to increase with $R_\xi$. In particular, it is expected to be very small for $R_\xi$ small, so that, if one chooses a small value of $R_\xi$, the crossing becomes undetectable, unless statistical errors are very tiny. Hence, $R_\xi$ should be chosen small, but still large enough to have a reasonable sensitivity of the results on system sizes.

To validate the method, we apply it to the determination of the critical point and of the critical exponents in the ±J Ising model. We perform large-scale simulations on cubic lattices of volume $L^3$, with $8 \leq L \leq 64$, considering five values of $\beta$ between 0.880 and 0.910. Statistics is a crucial factor in the analysis and hence we consider a very large number $N_s$ of samples for each $L$ and $\beta$. Typically, $N_s$ varies between $3 \cdot 10^5$ and a few million. Only for $L = 48, 64$ is $N_s$ smaller: $N_s = 6 \cdot 10^4, 10^4$ in these cases. Essentially all runs end when the system is still out of equilibrium. In most of the cases, data extend only up $R_\xi \approx 0.5$, in some cases even less (at equilibrium $R_\xi = 0.652(3)$ at the critical point). Simulations were performed on a small GPU cluster using a very efficient asynchronous multispin coding technique [19]. In each run we simulate together $32k$ different disorder realizations with four replicas for each disorder realization. The value of $k$ is tuned for each $L$ to have the best performance of the GPUs. As a result, one spin flip takes 2.9 ps (essentially for all sizes) on the GTX Titan, the fastest GPU we have. The simulations presented here took approximately 3.1 CPU years of the GTX Titan GPU.

To apply Eq. (2) we must define the quantities $U$. We consider 5 different Binder cumulants defined in terms of the overlap between two different replicas $q_\epsilon = \sigma_x^{(1)}(\epsilon) \sigma_x^{(2)}(\epsilon)$. Moreover, we must somehow parametrize the scaling functions $\hat{f}_U(R_\xi, \epsilon)$ and $\hat{g}_U(R_\xi, \epsilon)$. Since the data belong to a small temperature interval, we use the expansion (4) to first order in $\epsilon$. We have also performed some analyses using a second-order approximation, without observing significant differences. As for the correction-to-scaling function, we have verified that we can assume it to be independent of temperature. Finally, we should make approximations for the nonlinear scaling fields. Relying on the analysis of Refs. [20, 21], we set $u_\beta(\beta) = \beta - \beta_c$ and $u_\omega(\beta) = 1$, neglecting the additional corrections. Given the small temperature interval we consider, these approximations should hold quite precisely. Hence, each $U(t, L, \beta)$ was fitted to

$$U(t, L, \beta) = P_1(R_\xi) + P_2(R_\xi)(\beta - \beta_c) L^{1/\nu} + P_3(R_\xi) L^{-\omega},$$

with $P_1(R_\xi)$, $P_2(R_\xi)$, and $P_3(R_\xi)$ polynomials of degree 6, 3, and 3, respectively. The fit of the five renormalized couplings is quite complex, as we take $\omega$, $\beta_c$, $\nu$, and the coefficients of the polynomials as free parameters. As a whole, there are 78 free parameters that must be optimized. In the fits we have not taken into account the time correlations among data at the same $\beta$ and $L$, so that statistical errors (computed using the jackknife method) are not a priori optimal. To verify that such neglect is not relevant for the final estimates, we have performed some fits of a single cumulant taking time correlations into account. The corresponding estimates and error bars are essentially equal to those obtained without including statistical correlations.

As usual in this type of analyses, the most difficult issue is the estimation of the systematic errors due to the neglected correction terms. This is very important here, since the attainable values of $L$ are quite small. We have thus performed fits with several types of cuts. We perform fits including each time only data satisfying $L \geq L_{\min}$, $\xi \geq \xi_{\min}$, and $R_\xi \geq R_{\xi, \min}$, considering several values for $L_{\min}$, $\xi_{\min}$, and $R_{\xi, \min}$. Results obtained by taking $3 \leq \xi_{\min} \leq 5$, $8 \leq L_{\min} \leq 12$, and $0 \leq R_{\xi, \min} \leq 0.4$ show some scatter, which is somewhat larger than statistical errors, indicating that the neglected systematic effects may be as important as the statistical ones. The most crucial parameter is $\xi_{\min}$. When such a parameter is increased from 3 to 4, the exponent $\omega$ decreases sharply, by more than one error bar, while $\beta_c$ increases. Such a systematic drift occurs also when $\xi_{\min}$ is further increased to 5, but now the change is much less than one error bar. Therefore, the results we quote correspond to fits with $\xi_{\min} = 4$. For such a value of $\xi_{\min}$ we obtain $\beta_c = 0.911(2)$, $0.916(4)$, $0.909(4)$ for $L_{\min} = 8, 10, 12$ and $R_{\xi, \min} = 0$, and $\beta_c = 0.911(2)$, $0.909(2)$, $0.909(3)$ for $R_{\xi, \min} = 0, 0.2, 0.4$ and $L_{\min} = 8$. 
The estimates of $\beta$ by fixing $L$ analogously, we can estimate the effect of the neglected next-to-leading scaling corrections.

No systematic trends can be observed, all estimates being consistent within errors. Except for one estimate, all results (with their errors) we are quoting here lie in the interval $0.906 \leq \beta_c \leq 0.913$. Therefore, we take $\beta_c = 0.910(4)$ as our final estimate. The error, which is twice the error affecting the results with $L_{\text{min}} = 8$, is somewhat subjective and should take into account the effect of the neglected next-to-leading scaling corrections. Analogously, we can estimate $\omega$ and $\nu$ obtaining

$$\omega = 1.3(2), \quad \nu = 2.47(10).$$

The estimates of $\omega$ are strongly correlated with those of $\beta$: the larger $\beta$, the smaller $\omega$ is. If $\beta_c = 0.906$, fits keeping $\beta_c$ fixed give $\omega \approx 1.5$, while $\omega \approx 1.1$ is obtained by fixing $\beta_c = 0.914$. The exponent $\nu$ is instead much less correlated with $\beta_c$, changing at most by $\pm 0.03$ when $\beta_c$ varies by $\pm 0.004$.

To show the quality of the results, in Fig. 1 we report $\Delta U_4$, defined by

$$\Delta U_4(\beta, L, R_\xi) = U_4(\beta, L, R_\xi) - P_3(R_\xi)L^{-\omega},$$

versus $\epsilon$. We consider $R_\xi = 0.25, 0.35$, and 0.45. Very good scaling is observed, confirming the correctness of the scaling Ansatz and the accuracy of the estimates of the critical exponents. Note also that the data lie on an essentially straight line, validating our choice of expanding $f_U(R_\xi, \epsilon)$ to first order in $\epsilon$. From the figure, we can also clarify why a large number of samples, of order $10^6$, is needed to estimate the critical parameters. For instance, $U_4$ at $R_\xi = 0.35$ varies by 0.04 within our temperature interval. Therefore, the temperature dependence of the data can be observed only if the errors on $U_4$ are significantly less than $10^{-2}$, for instance, if they are equal to $10^{-3}$. Since errors scale as $a/\sqrt{N_s}$ with $a \approx 1$ for all values of $L$, a $10^{-3}$ error is obtained by taking $N_s \approx 10^6$. Note that this requirement is not specific of the off-equilibrium method we use. Also equilibrium analyses require $N_s$ to be large [20, 21].

It is interesting to compare these results with previous ones, see Table I (older estimates are summarized in Ref. 23). For the critical-point position, our estimate $T_c = 1/\beta_c = 1.099(5)$ agrees within errors with the estimates $T_c = 1.102(3)$ and $T_c = 1.109(10)$ of Refs. 3, 21, obtained from the analysis of equilibrium results. Our error is larger than that reported in Ref. 3, but note that our final error includes a subjective estimate of the systematic error. Had we reported only the statistical error for $L_{\text{min}} = 8$, we would have obtained the same accuracy. The estimates of $\nu$ are also consistent, while our final estimate of $\omega$ is slightly larger, though still consistent within error bars, than previous ones. The off-equilibrium estimates of Ref. 11 are consistent with ours, but less precise. Previous dynamic estimates of $T_c$ are instead not consistent. It is now clear that the reported errors are underestimated, as a consequence of the neglect of the subleading scaling corrections in the analyses.

The method we have discussed represents a significant improvement with respect to equilibrium analyses. Indeed, since the scaling variable is $tL^{-z}$, the time needed to extend Metropolis runs from any value of $R_\xi$ to equilibrium scales as $L^z$, i.e., as $L^{7}$ given that $z \approx 7$ for the Ising spin glass. Therefore, the advantage is very large and increases rapidly with $L$. To make a fair comparison with equilibrium studies, we should, however, take into account that in those studies one combines the parallel-tempering method [24] with the Metropolis or heat-bath algorithm. It is not clear how equilibration times scale for this combined algorithm, and in particular, how long it takes to thermalize the hard samples. However, the results reported in Ref. 3 are consistent with a sample-dependent time that scales as $L^2$ for the samples that equilibrate fast and as $L^3$ for those that are slower. The off-equilibrium method is still significantly faster. A more direct comparison can be obtained by using the results published in Ref. 3. In our simulations at the critical point, runs extending up to $R_\xi \approx 0.5$ require $2.5 \cdot 10^6$, $16 \cdot 10^6$ Metropolis sweeps for $L = 24$ and 32, respectively. In the parallel-tempering simulations for $L = 32$ of Ref. 3, the number of iterations discarded for thermalization varies between $8 \cdot 10^6$ and $500 \cdot 10^6$ (on average $13 \cdot 10^6$) sweeps. Taking into account that 22 systems at different temperature are simulated together, our simulations are shorter by a factor of 10 at least. If one were stopping the off-equilibrium runs at $R_\xi = 0.40$, one would gain an additional factor of 3 for this value of $L$. 

In spite of the significant improvement with respect to equilibrium studies, the computing time needed for a simulation scales as $L^2$ even off-equilibrium, since we
need to collect data at fixed \( R_\xi \) for all values of \( L \). This requirement makes our method not suitable to investigate large system sizes. Since errors are independent of system size as a consequence of the absence of self-averaging, the Monte Carlo time needed to obtain the same statistical sizes as a consequence of the absence of self-averaging, the large system sizes. Since errors are independent of system requirement makes our method not suitable to investigate linear scaling field associated with the magnetic field, see Fig. 2: Plot of \( U_4 \) and \( R_\xi \) versus \( tL^{-4} \) for \( \beta = 0.910 \). We set \( z = 6.80 \).

The analysis we have performed for the renormalized couplings can be extended to the susceptibility. The finite-time scaling behavior can now be written as

\[
\ln \chi = (2 - \eta) \ln L + P_1(R_\xi) + (\beta - \beta_c) L^{1/\nu} P_2(R_\xi) + L^{-\omega} P_3(R_\xi) + P_4(\beta). 
\]

where the last term \( P_4(\beta) \) is the contribution of the nonlinear scaling field associated with the magnetic field, see Ref. [20, 21] for a discussion. A good parametrization is obtained by taking \( P_1(R_\xi), P_2(R_\xi), P_3(R_\xi) \) as polynomials of degree 6, 3, 3, respectively, as before. For the \( P_4(\beta) \), we set \( P_4 = a_4 \beta \). We obtain the final estimate \( \eta = -0.39(1) \), which is fully consistent with those of Refs. [3, 21].

Finally, we estimate \( z \) by requiring data to satisfy the general scaling form [2]. We obtain \( z = 6.80(15) \), where the error should be quite conservative. The scaling behavior of \( R_\xi \) and \( U_4 \) is shown in Fig. 2. Scaling corrections are clearly visible, but large \( L \) data appear to fall onto a single universal curve as \( L \) increases. The value we obtain is in agreement with the estimate of Refs. [8, 11] at \( T = 1.1 \). Instead, it is larger than those of Refs. [3, 6, 12]. However, note that in all these works no scaling corrections, crucial to control possible systematic errors, were included in the analyses (they play a fundamental role in the derivation of our result).

Let us now summarize our results. We have presented a new dynamic off-equilibrium method suitable for the determination of the critical temperature and of the critical exponents. Such a method represents a significant improvement with respect to previous ones. In particular, there is no need for \( L \) to be large enough to avoid finite-size effects—thus, a source of systematic errors is absent—nor does it require an a priori knowledge of the critical temperature. We have used the method to determine critical exponents and temperature for the \( \pm J \) Ising model. With a relatively modest investment of computing time, thanks also to a very efficient GPU multispin code, we obtain results that have a comparable precision with that of the estimates of Ref. [3], which are the most precise equilibrium estimates available today. The method is completely general and can be applied to any pure or disordered system.

### TABLE I: Estimates of \( T_c \) and of the critical exponents by off-equilibrium methods. Results of Refs. [3, 21] are obtained in equilibrium simulations. The exponents \( \beta \) and \( \gamma \) are related to \( \nu \) and \( \eta \) by \( \beta = \nu (1 + \eta)/2 \), \( \gamma = \nu (2 - \eta) \).}

| \( T_c \)  | \( \nu \)  | \( \eta \)  | \( \omega \)  | \( z \)  | \( \beta \)  | \( \gamma \)  | \( z\nu \) |
