Abstract. The present study aimed to detect the levels of microRNA (miR)-33a-5p in the renal tissue, serum and urine of patients with primary IgA nephropathy (IgAN), thereby preliminarily exploring the association between the levels of miR-33a-5p and the condition of primary IgAN to provide evidence for the expression of miR-33a-5p in the serum and urine of IgAN patients as a clinical marker. Reverse-transcription quantitative PCR was performed to evaluate the level of miR-33a-5p in IgAN patients according to severity and pathological classification. The results suggested that the levels of miR-33a-5p in the serum, urine and kidney tissues of patients with IgAN were lower than those of the control tissues obtained from cancer patients (0.28±0.25 vs. 1.00±0.45, P<0.05; 0.34±0.28 vs. 1.00±0.53, P<0.05; 0.47±0.27 vs. 1.00±0.38, P<0.05, respectively). Receiver operating characteristic curve analysis suggested that the serum and urine levels of miR-33a-5p may be used as a marker to differentiate renal injury in IgAN patients from healthy individuals. At the same time, according to the estimated glomerular filtration rate (eGFR) and Lee classification of nephropathy, it was determined that with the progression of renal failure and the increase of the pathological grade of kidney tissue, the relative level of miR-33a-5p in kidney tissue also decreased (eGFR <50 ml/min vs. eGFR ≥50 ml/min/1.73 m² group: 0.38±0.27 vs. 1.00±0.34, P<0.001; Lee grade ≤3 group vs. Lee grade ≥3: 1.00±0.48 vs. 0.38±0.45, P<0.05). This result suggested that the levels of miR-33a-5p in serum, urine and kidney tissues decreased with the severity of renal injury and the progression of renal failure in patients with IgAN. Hence, miR-33a-5p detected in the serum and urine may be used as a non-invasive biomarker to reflect the progression of renal injury and renal failure in patients with IgAN.

Introduction

IgA nephropathy (IgAN) is the most common type of primary glomerulonephritis worldwide. In China, it accounts for 30-40% of primary glomerulonephritis cases (1). At 10-20 years after diagnosis, 20-40% of IgAN patients progress to end-stage renal disease (1). IgAN requires to be diagnosed by renal biopsy. However, as renal biopsy is traumatic and patients frequently refuse to undergo the procedure, it cannot be used as a routine means to detect the disease. In the clinic, urinary microalbumin, 24-h urinary protein, serum creatinine and glomerular filtration rate (GFR) are commonly used to evaluate the condition and prognosis of IgAN. However, these indicators have numerous influencing factors, and their sensitivity and specificity are poor.

It has been indicated that certain microRNAs (miRNAs/miRs) have important roles in the pathogenesis, inflammatory response, renal fibrosis and prognosis of IgAN (2,3). miRNAs are expressed not only in tissues and cells but also in plasma and urine (3). Studies have identified that miRNAs are stable in peracid or alkali environments, and may persist after long storage at room temperature, multiple thaws and exposure to certain active RNAses (2,4). In addition, the collection of plasma and urine samples is easy and non-invasive, and is more acceptable as opposed to biopsy for patients (5). Therefore, plasma and urine miRNAs associated with the pathophysiological changes of IgAN may be a novel non-invasive marker for IgAN (6). However, research on miRNAs in IgAN is still in its infancy, and the correlation between the expression of certain miRNAs and the pathological changes and clinical manifestations of IgAN patients requires further study (7,8). It has been indicated that miRNAs in urinary sediment are easy to obtain and may be potential non-invasive biomarkers for IgAN (9). For instance, urinary miR-3613-3p was reported to be downregulated in IgAN patients and correlated with the severity of the disease (8). Hence, exploration of the association between miRNAs and IgAN may provide approaches for the early diagnosis of IgAN.

A recent study has indicated a reduction of miR-33-5p levels in the urine of db/db mice and type 2 diabetes mellitus
patients, and miR-33-5p levels were negatively correlated with albuminuria (10). In the pathogenesis of HIV-associated nephropathy (HIVAN), miR-33-5p was reported to be decreased in subjects with HIV-1 infections. However, whether miR-33-5p is involved in the progression of IgAN has remained elusive.

The present study aimed to detect the expression of miR-33-5p in the renal tissue, serum and urine of patients with primary IgAN, thereby preliminarily exploring the association between the expression of miR-33-5p and the condition of primary IgAN to test the possibility of utilizing the expression of miR-33-5p in the serum and urine of IgAN patients as biomarkers. The present study provides a reference and a novel idea for the utilization of these non-invasive diagnostic markers in the diagnosis of IgAN.

Materials and methods

Patients and samples. A total of 100 patients diagnosed with IgAN by renal biopsy and clinical and laboratory examinations at the Department of Nephrology, the Second Hospital of Jilin University, Changchun, China) between December 2016 and June 2017 were enrolled in the study as the IgAN group. This group comprised 59 males and 41 females, with an average age of 35.55±9.66 years. On the morning of renal biopsy, morning urine and fasting venous blood samples were simultaneously collected, of which 20 patients were enrolled in renal biopsy. The kidney tissue of these patients was collected as control specimens for patients with IgAN. The patients with IgAN were divided into five subgroups according to the Lee classification (11): 24 patients with grade I, 24 patients with grade II, 18 patients with grade III, 17 patients with grade IV and 17 patients with grade V. In the same time window, kidney tissue samples were collected from 20 patients receiving nephrectomy due to upper-tract urothelial carcinoma, including 12 males and 8 females, with an average age of 43.2±7.5 years, at the Second Hospital of Jilin University (Changchun, China) (12). Kidney tissues that were far away (minimum distance, 2 cm) from the tumor tissues and were of normal pathology were selected. Informed consent was obtained from all participants.

The inclusion criteria were as follows: i) Patients agreed to provide renal puncture tissue, plasma and urine samples to be analyzed in the present study and provided written informed consent; ii) age ≥18 years; iii) no previous treatment with glucocorticoids, immunosuppressive agents or kidney transplantation; and iv) kidney pathology indicated with glucocorticoids, immunosuppressive agents or kidney transplantation; and iv) kidney pathology indicated that the deposition of IgA-based IgGs or complements in the mesangial region was strongly positive for IgA under light microscopy (XDS-500D; Shanghai Caikon Optical Instrument Co., Ltd.).

The exclusion criteria were as follows: i) Secondary IgAN caused by allergic purpura, systemic lupus erythematosus, hepatitis B virus infection, cirrhosis, tumors, or inflammatory bowel disease; ii) other kidney diseases, including membranous nephropathy, hypertensive nephropathy and diabetic nephropathy, minimal-change disease diagnosed under electronic microscopy (JEM-1011; JEOL); iii) systemic diseases including diabetes mellitus and connective tissue disease; iv) glomerulus number in renal biopsy tissues <10; v) urinary tract infections; and vi) cases of lactation and pregnancy.

The clinical data of the cohort are listed in Table I. The above-mentioned clinical indicators were determined prior to the renal biopsy in patients with IgAN after admission. The estimated GFR (eGFR) was calculated according to the Chronic Kidney Disease Epidemiology group equation for Chinese individuals (13).

Age- and gender-matched healthy controls were selected at the Second Hospital of Jilin University during the same time window, and their blood and urine were collected. This healthy control group (n=50) included 27 males and 23 females with an average age of 35.07±6.13 years.

RNA extraction. Total RNA was isolated from the serum samples (5 ml, collected in tubes containing EDTA) or urine or tissues using RNAvzol LS or RNAvzol (Vigorous Biotechnology Beijing Co., Ltd.) according to the manufacturer's protocol. The concentration and purity of the RNA samples were determined by measuring the optical density ratio at 260/280 nm.

| Clinical indicator | Value |
|--------------------|-------|
| Sex (male/female, %) | 59/41 (59%/41%) |
| Age (years) | 35.55±9.66 |
| Course of disease (months) | 8.12±3.95 |
| Family history | 26 |
| Scr (µM) | 79.00 (57.75-108.25) |
| eGFR (ml/min/1.73 m²) | 90.67±42.52 |
| BUN (mM) | 5.05 (4.06-9.43) |
| UA (µM) | 339.24±109.71 |
| CYS (mg/l) | 0.98 (0.76-1.69) |
| TP (g/l) | 55.45 (43.65-63.48) |
| ALB (g/l) | 32.59±9.61 |
| GLOB (g/l) | 20.95 (18.75-26.43) |

| Diastolic blood pressure (mmHg) | 82.00 (73.00-100.00) |

Values are expressed as the mean ± standard deviation, median (range) or n. Scr, serum creatinine; eGFR, estimated glomerular filtration rate; BUN, serum urea nitrogen; UA, serum uric acid; CYS, serum cystatin; TP, total blood protein; ALB, serum albumin; GLOB, hemoglobin; T-CHO, serum total cholesterol; TG, serum triglyceride; HDL, serum high-density lipoprotein; LDL, serum low-density lipoprotein; HB, hemoglobin; U-Prot, 24-h urine protein; C3, serum complement C3; C4, serum complement C4; RBC, red blood cell.
Reverse transcription-quantitative (RT-q)PCR. A total of 1 µg of RNA was reverse transcribed using Moloney Murine Leukemia Virus RT enzyme (Applied Biosystems; Thermo Fisher Scientific, Inc.) with specific primers. The protocol used for RT as follows: 72°C for 10 min, 42°C for 60 min, 72°C for 5 min and 95°C for 2 min. To quantify the relative mRNA levels, qPCR was performed using SYBR Green SuperMix (Bio‑Rad Laboratories, Inc.) in an iCycleriQ real‑time PCR detection system. The PCR amplifications were performed in a 10‑µl reaction system containing 5 µl SYBR Green SuperMix, 0.4 µl forward primer, 0.4 µl reverse primer, 2.2 µl double‑distilled H₂O and 2 µl template complementary DNA. Thermocycling conditions were as follows: 95°C for 10 min, followed by 40 cycles of 95°C for 15 sec and 60°C for 1 min. Relative mRNA expression was normalized to U6 using the 2⁻∆∆Cq method (14).

Primer sequences were as follows: miR‑33‑5p‑RT, 5'‑GTC GTA TCC AGT GCA GGG TCC GAG GTA TTC GCA CTG GAT ACG ACT GCA AT‑3'; U6‑RT, 5'‑GTC GTA TCC AGT GCA GGG TCC GAG GTA TTC GCA CTG GAT ACG ACT GCA AT‑3'; miR‑33‑5p, forward 5'‑GCG CGU GCA UUG UAG UUG C‑3'; U6, forward 5'‑GCG CGT CGT GAA GCG TTC‑3'; and universal reverse primer, 5'‑GTG CAG GGT CCG AGG T‑3'.

Statistical analysis. Values are expressed as the mean ± standard deviation. Two‑tailed unpaired Student's t‑tests were used for comparisons between two groups using SPSS version 13.0 (SPSS, Inc.). Receiver operating characteristic (ROC) curves were used to assess the diagnostic accuracy of miR‑33‑5p as a biomarker, and the area under the ROC curve (AUC) was determined with SPSS version 20.0 (IBM Corp). P<0.05 was considered to indicate a statistically significant difference.

Results

Expression of miR‑33a‑5p in blood, urine and kidney tissues. RT-qPCR indicated that the relative levels of miR‑33a‑5p in the serum and urine of the IgAN group (n=100) were significantly lower than those in the healthy control group (n=50) (0.28±0.25 vs. 1.00±0.45, P<0.05; 0.34±0.28 vs. 1.00±0.53, P<0.05; Fig. 1A and B, respectively). Furthermore, the relative expression level of miR‑33a‑5p in kidney tissues of the IgAN group was reduced compared with that in patients who received biopsy due to renal cancer. *P<0.05 vs. healthy controls. IgAN, IgA nephropathy; miR, microRNA.

Blood and urine miR‑33a‑5p levels may differentiate IgAN patients from healthy controls. When the cutoff value was 0.13, the AUC of serum miR‑33a‑5p in IgAN patients was 0.912 (95% CI=0.819‑1.000, P<0.001), with a sensitivity of 88.6% and specificity of 97.4%. The results indicated that serum miR‑33a‑5p could distinguish IgAN patients from normal controls (Fig. 2A). Furthermore, when the cutoff value was 0.18, the AUC of urine miR‑33a‑5p in IgAN patients (n=100) was 0.942 (95% CI=0.858‑1.000, P<0.001), with a sensitivity of 87.8% and specificity of 98.7% (Fig. 2B). These results indicated that serum as well as urine miR‑33a‑5p may be used as diagnostic markers for IgAN patients. The aforementioned results indicated that serum and tissue miR‑33a‑5p could distinguish patients with IgAN from control individuals.

miR‑33a‑5p is decreased along with impaired renal function. The IgAN patients were divided into two groups according to the eGFR, namely <50 ml/min/1.73 m² and ≥50 ml/min/1.73 m² (52 vs. 48 cases). The relative levels of miR‑33a‑5p were decreased in serum, urine and kidney tissues in the eGFR <50 ml/min/1.73 m² group compared with those in the eGFR ≥50 ml/min/1.73 m² group (0.45±0.43 vs. 1.00±0.57, P<0.05; 0.52±0.37 vs. 1.00±0.56, P<0.05; and 0.38±0.27 vs. 1.00±0.34, P<0.001, respectively; Fig. 3).

miR‑33a‑5p is decreased along with enhanced urinary protein level. The IgAN group was divided into a ≤1.5 g/24 h
group and a >1.5 g/24 h group according to the amount of urinary protein (46 vs. 54 cases). The levels of miR-33a-5p in serum, urine and kidney tissues were decreased in the group with a urine protein content of >1.5 g/24 h compared with those in the group with a urine protein content of ≤1.5 g/24 h (0.45±0.39 vs. 1.00±0.53, P<0.05; 0.55±0.42 vs. 1.00±0.61, P>0.05; 0.58±0.49 vs. 1.00±0.74, P>0.05; respectively; Fig. 4). The level of miR-33a-5p in serum was significantly decreased (P<0.05), but there was no significant difference in the urine and kidney tissue levels of miR-33a-5p between the two groups.

miR-33a-5p is decreased with the severity of nephropathy. IgAN patients were divided according to Lee’s classification of nephropathy into grade ≤3 and >3 groups (38 vs. 62 cases). Compared with those in the Lee grade ≤3 group, the miR-33a-5p levels in the serum (1.00±0.45 vs. 0.58±0.37, P<0.05), urine (1.00±0.48 vs. 0.49±0.31, P<0.05)
and renal tissue (1.00±0.48 vs. 0.38±0.25, P<0.05) of IgAN patients with Lee grade >3 were significantly decreased (Fig. 5).

**Discussion**

In the present study, the expression of miR-33a-5p in the renal tissue, plasma and urine of patients with IgAN was compared with those with renal cancer (non-cancerous tissues) and it was explored whether the miRNA expression levels were associated with the degree of pathological damage and clinical manifestations of IgAN patients, thereby evaluating the diagnostic value of miR-33a-5p to distinguish IgAN patients from non-IgAN individuals.

The results indicated that the serum, urine and kidney tissue levels of miR-33a-5p in IgAN patients were lower than those in patients with renal cancer (non-cancerous tissues). ROC analysis indicated that the level of miR-33a-5p in blood and urine may be used as a marker to differentiate IgAN patients from healthy controls. At the same time, according to the eGFR and Lee classification of nephropathy, the level of miR-33a-5p in kidney tissue decreased with the progression of renal failure and the increase of the pathological grade of kidney tissue. This result suggested that the levels of miR-33a-5p in blood, urine and kidney tissues were decreased with the severity of renal injury and the progression of renal failure in patients with IgAN. Hence, detection of miR-33a-5p in blood and urine may be used
as a non-invasive biomarker to reflect the progression of renal injury and renal failure in IgAN patients. However, in the future study, this should be further confirmed via ROC analysis.

However, the reason for the change in serum miR-33a-5p levels and the underlying mechanisms remain elusive. The change may be caused by organ secretion or disease (15,16). It is necessary to further study the expression level of miR-33a-5p in specific renal cell types. Similar to serum, urinary miR-33a-5p originates from extracellular bodies or microbubbles and exists in apoptotic bodies, which are highly stable (3,17). miR-33a-5p in urine may be derived from glomerular ultrafiltration or secreted by renal tubules. However, due to technical limitations, there is currently no way to detect the specific source of these specific miRNAs in urine, which may come from exfoliated renal tubular epithelial cells or urinary epithelial cells (7). In addition, a future study with a large sample size is necessary to further validate the diagnostic value of miR-33a-5p. It is also important to evaluate whether miR-33a-5p acts as a marker or a mediator in the progression of IgAN. In order to determine whether miR-33a-5p is a specific diagnostic biomarker for IgAN, further studies involving other kidney diseases for comparison, including diabetic nephropathy, HIVAN, membranous nephropathy and minimal change disease, are required.

In conclusion, in spite of the above-mentioned limitations, the present study provided novel information regarding the early diagnosis of IgAN. These results suggest that the expression of miR-33a-5p in renal tissue, plasma and urine may be associated with the pathological changes and clinical manifestations of IgAN, providing a reference for the utilization of urine and serum miR-33a-5p as a non-invasive biomarker of IgAN.
