Epidemics on Hypergraphs: Spectral Thresholds for Extinction

Desmond John Higham∗Henry-Louis de Kergorlay†

Abstract

Epidemic spreading is well understood when a disease propagates around a contact graph. In a stochastic susceptible-infected-susceptible setting, spectral conditions characterise whether the disease vanishes. However, modelling human interactions using a graph is a simplification which only considers pairwise relationships. This does not fully represent the more realistic case where people meet in groups. Hyperedges can be used to record such group interactions, yielding more faithful and flexible models, allowing for the rate of infection of a node to vary as a nonlinear function of the number of infectious neighbors. We discuss different types of contagion models in this hypergraph setting, and derive spectral conditions that characterize whether the disease vanishes. We study both the exact individual-level stochastic model and a deterministic mean field ODE approximation. Numerical simulations are provided to illustrate the analysis. We also interpret our results and show how the hypergraph model allows us to distinguish between contributions to infectiousness that (a) are inherent in the nature of the pathogen and (b) arise from behavioural choices (such as social distancing, increased hygiene and use of masks). This raises the possibility of more accurately quantifying the effect of interventions that are designed to contain the spread of a virus.

1 Introduction

Compartmental models for disease propagation have a long and illustrious history [2,16], and they remain a fundamental predictive tool [9,13]. For

a stochastic, individual-level model, it has been suggested recently that hyperedge information should be incorporated [8, 15, 17]. Hyperedges allow us to account directly for group interactions of any size, rather than, as in, for example, [11, 18, 21], treating them as a collection of essentially independent pairwise encounters.

In this work we contribute to the modeling and analysis of disease spreading on a hypergraph. We include the case where the number of infected nodes in a hyperedge contributes nonlinearly to the overall infection rate; this covers the so-called collective contagion model setting and a new alternative that we call a collective suppression model. The main contributions of our work are

- a mean field approximation (6)–(7) with a spectral condition for local asymptotic stability of the zero-infection state (Theorem 6.1) and an extension to global asymptotic stability (Theorem 6.4) when the nonlinear infection function is concave,

- for the exact, individual-level model, a spectral condition for exponential decay of the non-extinction probability in the concave case (Theorem 8.1) and a spectral bound on the expected time to extinction (Corollary 8.2),

- extensions of these results to more general partitioned hypergraph models, where distinct infection rates apply to different categories of hyperedge (4),

- results for the non-concave collective contagion model (Theorem 9.1 and Theorem 9.2),

- a complementary condition that rules out extinction of the disease (Theorem 8.5),

- interpretations of these mathematical results: the spectral thresholds for disease extinction naturally distinguish between the inherent biological infectiousness of the disease and behavioural choices of the individuals in the population, allowing us to account for intervention strategies (Section 10).

The manuscript is organized as follows. In section 2 we introduce the traditional graph-based susceptible-infected-susceptible (SIS) model and quote a spectral condition that characterizes control of the disease. We then discuss the generalization to hyperedges, and motivate the use of infection rates that do not scale linearly with respect to the number of infected neighbors. Section 3 formalizes the hypergraph model and shows how it may be simulated. In section 4 we derive a mean field approximation to characterize the behaviour
of the model, and in section 5 we give computational results to illustrate its relevance. Section 6 analyses the deterministic mean field setting and gives a spectral condition for long-term decay of the disease. The result is local for general infection rates and global (independent of the initial condition) for the concave case. This spectral condition generalizes a well-known result concerning disease propagation on a graph. Section 7 provides further computational simulations to illustrate the spectral threshold. The full stochastic model is then studied in section 8, where we extend the analysis in [11] to our hypergraph setting. Here we study extinction of the disease in the case where the nonlinearity in the infection rate is concave. We also derive conditions for non-extinction. In section 9 we extend our analysis to the so-called collective contagion model proposed in [8, 15, 17]. In section 10 we summarize and interpret our results, and discuss follow-on work.

For a review of recent studies of spreading processes on hypergraphs, including the dissemination of rumours, opinions and knowledge, we recommend [3, subsection 7.1.2]. The model that we study fits into the framework of [6]. This work introduced the idea of a nonlinear “infection pressure” from each hyperedge, and derived a mean field approximation that was compared with microscale-level simulation results. In [15], the authors studied this type of model on simplicial complexes of degree up to two (a subclass of the more general hypergraph setting) and also studied a mean field approximation. These authors examined the mean field system from a dynamical systems perspective and analysed issues such as bistability, hysteresis and discontinuous transitions. Similarly, in [8, 17], a hypergraph version was considered. Our work differs from these studies in (a) focusing on the derivation of spectral thresholds for extinction of a disease in both the exact and mean field settings and (b) seeking to interpret the results from a mathematical modelling perspective. We mention that it would also be of interest to develop corresponding thresholds for the mean field models in [6, 8, 15].

2 Stochastic SIS models

2.1 Stochastic SIS model on a graph

Classical ODE compartmental models are based on the assumption that any pair of individuals is equally likely to interact—this is the homogeneous mixing case [2]. If, instead, we have knowledge of all possible pairwise interactions between individuals, then this information may be incorporated via a contact graph and used in a stochastic model. Here, each node represents an individual, and an edge between nodes $i$ and $j$ indicates that individuals $i$
and $j$ interact. For a population with $n$ individuals, we may let $A \in \mathbb{R}^{n \times n}$ denote the corresponding symmetric adjacency matrix, so nodes $i$ and $j$ interact if and only if $A_{ij} = 1$. In this setting, a stochastic SIS model uses the two-state random variable $X_i(t)$ to represent the status of node $i$ at time $t$, with $X_i(t) = 0$ for a susceptible node and $X_i(t) = 1$ for an infected node. Each $X_i(t)$ then follows a continuous time Markov process where the infection rate is given by

$$\beta \sum_{j=1}^{n} A_{ij} X_j(t)$$

and the recovery rate is $\delta$. Here, $\beta > 0$ and $\delta > 0$ are parameters governing the strength of the two effects. In this model, we see from (1) that the current chance of infection increases linearly in proportion to the current number of infected neighbors.

This model was studied in [21, Theorem 1], where it was argued that the condition

$$\lambda(A) \frac{\beta}{\delta} < 1$$

guarantees the disease will die out. Here, $\lambda(A)$ denotes the largest eigenvalue of the symmetric matrix $A$. Further justification for this result may be found, for example, in [11, 18]. We note that (2) gives an elegant generalization of the homogeneous mixing case (where $A$ corresponds to the complete graph).

### 2.2 Why use a hypergraph?

It has been argued [1, 3, 4, 5, 10] that in many network science applications we lose information by recording only pairwise interactions. For example, emails can be sent to groups of recipients, scholarly articles may have multiple coauthors, and many proteins may interact to form a complex. In such cases, recording the relevant lists of interacting nodes gives a more informative picture than reducing these down to a collection of edges.

In the setting of an SIS model, we may argue that individuals typically come together in well-defined groups, for example, in a household, a workplace or a social setting. Such groups may be handled by the use of hyperedges, leading to a hypergraph; these concepts are formalized in the next section.

With a classic graph model, as described in section 2.1, the rate of infection of a node is linearly proportional to the number of infectious neighbors. With a hypergraph we may consider more intricate contagion mechanisms. For example, using the terminology of [17], the collective contagion model is used in [8, 15, 17]). Here, infection only starts spreading within a hyperedge after a certain threshold number of infectious neighbors has been reached. This
type of behaviour is relevant, for example, in an office environment. A small
number of workers may be able to socially distance in way that effectively
eliminates the risk of infection. However, if the number of individuals (size of
the hyperedge) is too large, then the disease may spread.

We mention here that an alternative type of mechanism may also operate,
which we call collective suppression. Imagine that a disease may be contracted
through contact with a surface that was previously touched by an infected
individual. Now suppose that a group of individuals is likely to use the
same physical object, such as a door handle, hand rail, cash machine, or
water cooler. If an infected individual contaminates the object, then further
contamination by other individuals is less relevant. In this case, doubling
the number of common users will increase the risk of infection by a factor
less than two; generally risk grows sublinearly as a function of the size of the
hyperedge.

These arguments motivate us to study the case where the rate of infection
of a node within a hyperdege is dependent on a generic function \( f \) of the
number of infectious neighbors in a hyperedge; this approach was also taken
in [6]. We will be particularly concerned with the case where \( f \) is concave,
since this is tractable for analysis and allows us to draw conclusions about
the collective contagion model.

We note that if \( f \) is the identity, then we recover linear dependence on
the number of infectious neighbors and the hypergraph model is equivalent
to a virus spreading on the clique graph of the hypergraph.

3 SIS on a Hypergraph

3.1 Background

We continue with some standard definitions [7].

**Definition 1.** A hypergraph is a tuple \( \mathcal{H} := (V, E) \) of nodes \( V \) and
hyperedges \( E \) such that \( E \subset \mathcal{P}(V) \). Here, \( \mathcal{P}(V) \) denotes the power set of
\( V \).

We will let \( n \) and \( m \) denote the number of nodes and hyperedges, re-
spectively; that is, \( |V| = n \) and \( |E| = m \). Loosely, a hypergraph generalizes the
concept of a graph by allowing an “edge” to be a list of more than two nodes.

**Definition 2.** Consider a hypergraph \( \mathcal{H} := (V, E) \). The incidence matrix, \( \mathcal{I} \),
is the \( n \times m \) matrix such that \( \mathcal{I}_{ih} = 1 \) if node \( i \) belongs to hyperedge \( h \) and
\( \mathcal{I}_{ih} = 0 \) otherwise.
It is also useful to introduce \( W := \mathcal{I}\mathcal{I}^T \). This \( n \times n \) matrix has the property that \( W_{ij} \) records the number of hyperedges containing both nodes \( i \) and \( j \). In particular, if \( \mathcal{H} \) is a graph then \( W \) is the affinity matrix of the graph.

### 3.2 General infection model

In our context, the nodes represent individuals and a hyperedge records a collection of individuals who are known to interact as a group. As in the graph case introduced in subsection 2.1, we use a state vector \( X(t) \) which follows a continuous time Markov process, where, for each \( 1 \leq i \leq n \), \( X_i(t) = 1 \) if node \( i \) is infected at time \( t \) and \( X_i(t) = 0 \) otherwise. We continue to assume that an infectious node becomes susceptible with constant recovery rate \( \delta > 0 \). However, generalizing (1), we now assume that a susceptible node \( i \) becomes infectious with rate

\[
\beta \sum_{h \in E} I_{ikh} f \left( \sum_{j=1}^{n} X_j(t) I_{jih} \right),
\]

where \( \beta > 0 \) is a constant. In (3), \( f : \mathbb{R}_+ \to \mathbb{R}_+ \) specifies the manner in which the contribution to the overall level of infectiousness from each hyperedge involving node \( i \) is assumed to increase in proportion to the number of infected nodes in that hyperedge. Throughout our analysis we will always assume that \( f(0) = 0 \) and \( f \) is \( C^1 \) in a neighborhood of 0.

If \( f \) is the identity, the rate of infection reduces to \( \beta \sum_{j=1}^{n} W_{ij} X_j(t) \). This gives a weighted version of the infection rate of an SIS model on a graph. As discussed in subsection 2.2, it may be appropriate to choose nonlinear \( f \) in certain circumstances. We note that in [6] the authors have in mind functions which behave like the identity near the origin and have a horizontal asymptote. Instances of such functions are \( x \mapsto \arctan(x) \) and \( x \mapsto \min\{x, c\} \) for some \( c > 0 \). Relaxing these conditions, we may ask more generally in such a setting that the function be concave. On the other hand, the authors in [8, 15] consider a collective contagion model, where infection spreads within a hyperedge only if a certain threshold of infectious vertices is reached in that hyperedge. A collective contagion model may be represented via the function \( x \mapsto c_2 \mathbb{1}(x \geq c_1) \) for some \( c_1, c_2 > 0 \), or \( x \mapsto \max\{0, x - c\} \) for some \( c > 0 \).

### 3.3 Partitioned hypergraph model

We also introduce a more general case where we partition the hyperedges into \( K \) disjoint categories with each category \( 1 \leq k \leq K \) having its own distinct
rate of infection in response to the number infected nodes in a hyperedge, represented by a function \( f_k \). For example, the categories may correspond to different types of housing, workplaces, hospitality venues or sports facilities. We may then represent the infection rate of node \( i \) as

\[
\beta \sum_{k=1}^{K} \sum_{h \in E} I_{ih} f_k \left( \sum_{j=1}^{n} X_j(t) I_{jh}^{(k)} \right),
\]

(4)

where we let \( I_{ih}^{(k)} = 1 \) if \( i \) belongs to hyperedge \( h \) in the category \( k \) and \( I_{ih}^{(k)} = 0 \) otherwise; so \( I^{(k)} \) is the incidence matrix of the subhypergraph consisting of only the hyperedges from category \( k \). We will refer to this as a partitioned hypergraph model.

In this generalized case, a collective contagion model could be defined by first organizing the hyperedges into categories depending on their size, so that category \( k \) is the set of hyperedges of size \( k + 1 \). A collective contagion model may then represented, for example, via the functions \( f_1 : x \mapsto x \), and \( f_k : x \mapsto c_{2,k} \mathbb{1}(x \geq c_{1,k}), k \in \{2, \ldots, K\} \).

4 Mean Field Approximation

A classic approach to studying processes such as (3), where infection rates are random, is to develop a mean field approximation for the expected process

\[
(\mathbb{E}[X_i(t)])_{t \geq 0} = (\mathbb{P}(X_i(t) = 1))_{t \geq 0} =: (p_i(t))_{t \geq 0},
\]

with deterministic rates. In our case, the rate of recovery \( \delta \) is constant, so can remain unchanged. Let us express the rate of infection (3) of a node solely in terms of the expected processes \( \{p_i(t)\}_{i=1}^{n} \). To do this we can substitute the \( X_j(t) \) appearing in (3) by their expected values \( p_j(t) \). The approximate rate of infection for node \( i \) then becomes

\[
\beta \sum_{h \in E} I_{ih} f \left( \sum_{j=1}^{n} p_j(t) I_{jh} \right).
\]

(5)

We arrive at the deterministic mean field ODE

\[
\frac{dP(t)}{dt} = g(P(t)),
\]

(6)

where \( g_i : \mathbb{R}^n \to \mathbb{R} \) is defined by

\[
g_i(P(t)) := \beta \sum_{h \in E} I_{ih} f \left( \sum_{j=1}^{n} p_j(t) I_{jh} \right) (1 - p_i(t)) - \delta p_i(t).
\]

(7)
5 Simulations and Comparison between Exact and Mean Field Models

Let us emphasize that the approximate infection rates in (5) differ in general from the expectation of the random rates in (3). When the function $f$ is concave, however, Jensen’s reverse inequality indicates that the rates in (5) are greater than the expectation of the rates in (3). Hence, in this case the expected quantities $p_i(t)$ are overestimated by (6)–(7). This is fine since we are looking for conditions for the disease to vanish. If $f$ is not concave (e.g., for a collective contagion model), these expected quantities are underestimated and it is not clear a priori whether the exact model is well approximated by the mean field ODE.

In this section we therefore present results of computational simulations in order to gain insight into the accuracy of our mean field approximation.

5.1 Simulation algorithm

Before presenting numerical results, we summarize our approach for simulating the individual-level stochastic model, which is based on a standard time discretization; see, for example, [6]. Using a small fixed time step $\Delta t$, we advance from time $t$ to $t + \Delta t$ as follows. First, let $r \in [0, 1]^n$ be a random vector of i.i.d. values uniformly sampled from $[0, 1]$. For every node $1 \leq i \leq n$,

- when $X_i(t) = 0$, set $X_i(t + \Delta t) = 1$ if $r_i < 1 - \exp \left(-\beta \sum_h I_{th} f \left(\sum_j X_j(t) I_{jh}\right) \Delta t\right)$,

  and set $X_i(t + \Delta t) = 0$ otherwise;

- when $X_i(t) = 1$, set $X_i(t + \Delta t) = 0$ if $r_i < 1 - \exp (-\delta \Delta t)$,

  and set $X_i(t + \Delta t) = 1$ otherwise.

5.2 Computational results

In the simulations we chose $n = 400$ nodes with fixed recovery rate $\delta = 1$. We look at results for different choices of infection strength $\beta$ and $i_0$, the latter denoting the (independent) initial probability for each node to be
infectious. We simulated the mean field ODE using Euler’s method with time step $\Delta t = 0.05$. The largest size of a hyperedge was 5 and we distributed the number of hyperedges for the hypergraph randomly as follows: 300 edges, 200 hyperedges of size 3, 100 hyperedges of size 4 and 50 hyperedges of size 5. To give a feel for the level of fluctuation, the individual-level paths are averaged over 10 runs, each with the same hypergraph connectivity and initial state.

Figures 1, 2 and 3 show results for three concave choices of $f$; respectively,

- $f(x) = \min(x, 3)$,
- $f(x) = \log(1 + x)$,
- $f(x) = \arctan(x)$.

For Figure 4 we used a collective contagion model on a partitioned hypergraph. Assigning each hyperedge to a category in $\{1, 2, 3, 4\}$, where category $k$ contains the hyperedges of size $k + 1$, we chose the following associated functions to determine the infection rates: $f_1(x) := x$, and for $k \in \{2, 3, 4\}$, $f_k(x) := (k - 1)\mathbb{1}(x \geq k - 1)$.

The four figures show the proportion of infectious individuals as a function of time. In these simulations, and others not reported here, we observe that the initial value $i_0$ does not affect the asymptotic behavior of the process: the process vanishes or converges to a non-zero equilibrium depending on the value of $\beta$ but regardless of the value of $i_0$. In Figures 1, 2 and 3 where $f$ is concave, we know that the mean field model gives an upper bound on the expected proportion of infected individuals in the microscale model. We also see that the mean field model provides a reasonably sharp approximation. Moreover, we see a similar level of sharpness in Figure 4 for the collective contagion model, where $f$ is not concave.

A key advantage of the mean field approximation is that it gives rise to a deterministic autonomous dynamical system for which there exists a rich theory to study the asymptotic stability of equilibrium points. This motivates the analysis in the next section.

6 Stability Analysis

We provide below spectral conditions which imply that the infection-free solution $0 \in \mathbb{R}^n$ is a locally or globally asymptotically stable equilibrium of (6)–(7). We will find that local asymptotic stability can be shown with no structural assumptions on $f$. We will also find that global asymptotic stability follows under the same conditions when $f$ is concave. Our conclusions fit into
Figure 1: Here, \( f(x) = \min(x, 3) \). Red dashed line: mean field approximation from (6)–(7). Blue solid line: proportion of infected individuals, \( \sum X_i(t)/n \), from the individual-level stochastic model (3), averaged over 10 runs.

Figure 2: Here, \( f(x) = \log(1 + x) \). Red dashed line: mean field approximation from (6)–(7). Blue solid line: proportion of infected individuals, \( \sum X_i(t)/n \), from the individual-level stochastic model (3), averaged over 10 runs.
Figure 3: Here, $f(x) = \arctan(x)$. Red dashed line: mean field approximation from (6)–(7). Blue solid line: proportion of infected individuals, $\sum_i X_i(t)/n$, from the individual-level stochastic model (3), averaged over 10 runs.

Figure 4: Collective contagion model on a partitioned hypergraph. Red dashed line: mean field approximation from (6) with (9). Blue solid line: proportion of infected individuals, $\sum_i X_i(t)/n$, from the individual-level stochastic model (3), averaged over 10 runs.
a framework that generalizes the graph case \[\mathbb{2}\]: the spectral threshold takes the form

\[\lambda(W)^{c_f\beta\delta} < 1\]

for some constant \(c_f > 0\) depending only on the choice of \(f\).

Throughout this work, to be concrete we let \(\| \cdot \|\) denote the Euclidean norm.

### 6.1 Local asymptotic stability

**Theorem 6.1.** If

\[\lambda(W)^{f'(0)\beta} < 1\]

then \(0 \in \mathbb{R}^n\) is a locally asymptotically stable equilibrium of (6)–(7); that is, there exists a positive \(\gamma\) such that \(\|P(0)\| < \gamma \Rightarrow \lim_{t \to \infty} \|P(t)\| = 0\).

**Proof.** We see that \(g(0) = 0\), so \(0 \in \mathbb{R}^n\) is an equilibrium for (6). It remains to show that this solution is locally asymptotically stable. Appealing to a standard linearization result \[\mathbb{20}\], it suffices to show that every eigenvalue of the Jacobian matrix \(\nabla g(0)\) has a negative real part. We compute

\[
\frac{\partial g_i}{\partial p_{j_0}} = \begin{cases} 
\beta \sum_h I_{ih}I_{j_0h}f'(\sum_j p_j I_{jh})(1 - p_i), & j_0 \neq i, \\
\beta \sum_h I_{ih}I_{j_0h}f'(\sum_j p_j I_{jh})(1 - p_i) - \beta \sum_h I_{ih}f(\sum_j p_j I_{jh}) - \delta, & j_0 = i.
\end{cases}
\]

We see that \(\nabla g(0) = \beta f'(0)W - \delta I\). This matrix is symmetric and therefore has real eigenvalues. Hence, it suffices that the largest eigenvalue of \(\beta f'(0)W\) does not exceed \(\delta\), and the result follows. \(\square\)

**Theorem 6.1** extends to the partitioned model in \[\mathbb{1}\]. In this case \(g_i(P(t))\) in the mean field ODE (6) is defined as

\[g_i(P(t)) := \beta \sum_{k=1}^{K} \sum_{h \in E} X_{ih}^{(k)} f_k(\sum_{j=1}^{n} p_j(t) X_{jh}^{(k)})(1 - p_i(t)) - \delta p_i(t), \quad (9)\]

and we let \(W^{(k)} := X^{(k)}X^{(k)T}\).

**Theorem 6.2.** If

\[\lambda \left( \sum_{k=1}^{K} f_k'(0)W^{(k)} \right)^{\frac{\beta}{\delta}} < 1\]
then \(0 \in \mathbb{R}^n\) is a locally asymptotically stable equilibrium of \(\theta\), with \(g_i\) defined in \(\theta\).

Proof. The proof of Theorem 6.1 extends straightforwardly. We compute

\[
\frac{\partial g_i}{\partial p_{j0}} = \begin{cases} 
\beta \sum_k \sum_h I_{ih}^k f_k'(0)(1 - p_i), & j_0 \neq i, \\
\beta \sum_k \sum_h I_{ih}^k f_k'(0)(1 - p_i) - \beta \sum_k \sum_h I_{ih}^k f_k'(0) - \delta, & j_0 = i,
\end{cases}
\]

\[
\Rightarrow \frac{\partial g_i}{\partial p_{j0}} |_{p=0} = \begin{cases} 
\beta \sum_k W_{ij}^k f_k'(0), & j_0 \neq i, \\
\beta \sum_k W_{ij}^k f_k'(0) - \delta, & j_0 = i,
\end{cases}
\]

and note that

\[
\lambda(\beta \sum_k f_k'(0)W_{ij}^k - \delta I) < 0 \iff \lambda(\sum_k f_k'(0)W_{ij}^k) < \frac{\delta}{\beta}.
\]

6.2 Global asymptotic stability for the concave infection model

We now show that when \(f\) is concave the condition in Theorem 6.1 ensures global stability of the zero equilibrium, and hence guarantees that the disease dies out according to the mean field approximation.

Definition 3. Given a matrix \(A\), define its symmetric version to be

\[
A^{(S)} := (A + A^T)/2.
\]

Lemma 6.3. Suppose that \(A\) and \(B\) are \(n \times n\) real matrices, and suppose that there exists a diagonal matrix \(\Lambda\) such that for all \(i \in \{1, 2, \ldots, n\}\), \(\Lambda_{ii} \geq 0\), and

\[
A = B - \Lambda.
\]

Then the largest eigenvalues of \(A\) and \(B\) satisfy \(\lambda(A) \leq \lambda(B)\), and the largest eigenvalues of \(A^{(S)}\) and \(B^{(S)}\) also satisfy \(\lambda(A^{(S)}) \leq \lambda(B^{(S)})\).
Proof. Let \( x \) be a unit eigenvector associated with \( \lambda(A^{(S)}) \). We have
\[
2\lambda(A^{(S)}) = x^T A x + x^T A^T x = x^T B x + x^T B^T x - 2x^T \Lambda x = \sum_{i,j=1}^{n}(b_{ij} + b_{ji})x_i x_j - 2\sum_{i=1}^{n} \Lambda_{ii} x_i^2 
\leq x^T (B + B^T) x 
\leq \max\{x^T (B + B^T) x \mid x^T x = 1\} = 2\lambda(B^{(S)}).
\]
The inequality \( \lambda(A) \leq \lambda(B) \) may be shown similarly. \( \square \)

**Theorem 6.4.** Suppose \( f \) is concave. If
\[
\lambda(W) \frac{f'(0)}{\beta} < 1,
\]
then \( 0 \in \mathbb{R}^n \) is a globally asymptotically stable equilibrium of (6)-(7); so \( \lim_{t \to \infty} \|P(t)\| = 0 \) for any valid initial condition (that is, with \( 0 \leq p(0)_i \leq 1 \)).

Proof. From the global asymptotic stability result in [14, Lemma 1'] it is sufficient to show that all eigenvalues of the symmetric matrix \( \nabla g(P)^{(S)} \) are strictly less than 0, for all \( P \neq 0 \). We have
\[
\frac{\partial g_i}{\partial p_{j_0}} = \begin{cases} 
\beta \sum_h I_{ih} I_{j_0h} f'(\sum_j p_j I_{jh})(1 - p_i), & j_0 \neq i, \\
\beta \sum_h I_{ih} I_{j_0h} f'(\sum_j p_j I_{jh})(1 - p_i) - \beta \sum_h I_{ih} f(\sum_j p_j I_{jh}) - \delta, & j_0 = i.
\end{cases}
\]

Letting \( B \) denote the \( n \times n \) matrix given by
\[
B_{ij_0} = \begin{cases} 
\beta \sum_h I_{ih} I_{j_0h} f'(\sum_j p_j I_{jh})(1 - p_i), & j_0 \neq i, \\
\beta \sum_h I_{ih} I_{j_0h} f'(\sum_j p_j I_{jh})(1 - p_i) - \delta, & j_0 = i.
\end{cases}
\]

we have \( \nabla g(P) = B - \Lambda \), where \( \Lambda \) is the \( n \times n \) diagonal matrix where for all \( i \in \{1, 2, \ldots\} \), \( \Lambda_{ii} := \beta \sum_h I_{ih} f(\sum_j p_j I_{jh}) \geq 0 \). On the one hand
Lemma 6.3 now yields $$\lambda((\nabla g(P))^{(S)}) \leq \lambda(B^{(S)})$$; on the other hand, note that $$B + \delta I \leq \nabla g(0) + \delta I$$, where we interpret the inequality in a componentwise sense, and where we use $$f'(\sum_j p_j I_{jh}) \leq f'(0)$$, since $$f$$ is concave. Hence

$$B^{(S)} + \delta I \leq \nabla g(0) + \delta I$$, and since $$B^{(S)} + \delta I$$ has only non-negative entries, appealing to the Perron-Frobenius theorem, we have $$\lambda(B^{(S)}) \leq \lambda(\nabla g(0))$$.

Combining these inequalities and using the spectral condition in the statement of the theorem, we deduce that

$$\lambda\left((\nabla g(P))^{(S)}\right) \leq \lambda(\nabla g(0)) = \lambda\left(\beta f'(0)W - \delta I\right) < 0,$$

as required.

A straightforward adaptation of the proof of Theorem 6.4 yields the following global asymptotic stability result for the more general partitioned model.

**Theorem 6.5.** Suppose all $$f_k$$ are concave. If

$$\lambda\left(\sum_{k=1}^{K} f_k(0)W^{(k)}\right) \frac{\beta}{\delta} < 1,$$

then $$0 \in \mathbb{R}^n$$ is a globally asymptotically stable equilibrium of (6), with $$g_i$$ defined in (9).

### 7 Simulations to Test the Spectral Condition

We now show the results of experiments that test the sharpness of our spectral vanishing condition. Here, we used the concave functions $$f(x) = 2 \log(1 + x)$$ (on the left of Figure 5 and in Figure 6) and $$f(x) = \arctan(x)$$ (on the left in Figure 5 and in Figure 7) to construct partitioned models with $$f_1(x) = x$$ and $$f_k(x) = f(x)$$ for all $$k \geq 2$$. We fixed a hypergraph with $$n = 400$$ nodes, 400 edges, 200 hyperedges of size 3, 100 hyperedges of size 4 and 50 hyperedges of size 5. At time zero, each node was infected with independent probability $$i_0 = 0.5$$ and we used a recovery rate of $$\delta = 1$$. In addition to the mean field ODE, we also simulated the microscale model, averaged over 5 runs, using the discretization scheme described in Section 5.2 with $$\Delta t = 0.1$$.

In Figure 5 the asterisks (red) show the corresponding proportion of infected individuals according to the mean field model, $$\sum_i p_i(t)/n$$, at time $$t = 150$$, for a range of different $$\beta$$ between 0 and 0.2: $$\beta \in \{(0.01)k \mid k \in \mathbb{N}\}$$.
The crosses (blue) show the corresponding proportion of infected individuals from the microscale model, \( \sum_{i} X_i(t)/n \), at time \( t = 150 \). The vertical green line represents the critical value \( \beta_c := \delta/\lambda(\sum_{k=1}^{K} f_k'(0)W(k)) \) (we have \( \beta_c \approx 0.0265 \) on the left and \( \beta_c \approx 0.0490 \) on the right).

For the mean field model, we know from Theorem 6.5 that \( \beta < \beta_c \) guarantees global stability of the zero-infection state. We see that \( \beta_c \) also lies close to the threshold beyond which extinction of the disease is lost in the mean field model. For the individual-level stochastic model, Theorem 8.3 below shows that \( \beta < \beta_c \) is also sufficient for eventual extinction of the disease. This is consistent with the results in Figure 5.

Figure 5: Left: infection function based on \( 2 \log(1 + x) \). Right: infection function based on \( \arctan(x) \). For different choices of infection strength \( \beta \) (horizontal axis), we show the proportion of infection individuals at time \( t = 150 \) (vertical axis) for the mean field approximation (6) with (9) in red asterisks and for the individual-level stochastic model (3) in blue crosses. The spectral bound arising from our analysis is show as a green vertical line.

In the left of Figures 6 and 7 we show individual trajectories of the proportion of infected individuals, \( \sum_{i} p_i(t)/n \), according to the mean field model, for a range of \( \beta \) values. For the same range of \( \beta \) values, the plots on the right of these figures show the corresponding proportion of infected individuals from the microscale model, \( \sum_{i} X_i(t)/n \). The curves are colored in red if the spectral vanishing condition \( \beta < \beta_c \) is satisfied. We see qualitative agreement between the mean field and individual-level models, and extinction for the \( \beta \) values below the spectral threshold.

Having derived and tested spectral conditions that concern extinction of
Figure 6: Results with the arctan infection function. Left: proportion of infected individuals using the mean field model. Right: proportion of infected individuals using the individual-level model. From bottom to top, the $\beta$ values used were $\beta \in \{0.02k \mid k \in \{0, \ldots, 10\}\}$. Cases where $\beta$ is below the spectral bound are colored in red.

Figure 7: Results with the arctan infection function. Left: proportion of infected individuals using the mean field model. Right: proportion of infected individuals using the individual-level model. From bottom to top, the $\beta$ values used were $\beta \in \{0.02k \mid k \in \{0, \ldots, 10\}\}$. Cases where $\beta$ is below the spectral bound are colored in red.
the disease at the mean field approximation level, in the next section we study
the microscale model directly.

8 Exact Model

To proceed, we recall our assumption that at time zero each node has the
same, independent, probability, \( i_0 \), of being infectious; so \( \mathbb{P}(X_j(0) = 1) = i_0 \)
for all \( 1 \leq j \leq n \). This implies that \( n i_0 \) is the expected number of infectious
individuals at time zero.

We are interested in the stochastic process \( \sum_i X_i(t) \), which records the
number of infected individuals. Our analysis generalizes arguments in [11],
which considered a stochastic SIS model on a graph with \( f \) as the identity
map.

8.1 Extinction

Our first result shows that the spectral condition arising from the mean
field analysis in Theorems 6.1 and 6.4 is also relevant to the probability of
extinction in the individual-level model.

**Theorem 8.1.** Suppose \( f \) is concave in the hypergraph infection model (3). Then
\[
\mathbb{P} \left( \sum_i X_i(t) > 0 \right) \leq n i_0 \exp \left( (\beta f'(0) \lambda(W) - \delta) t \right).
\]
Hence, if \( \lambda(W) f'(0) \beta / \delta < 1 \) then the disease vanishes at an exponential rate.

**Proof.** Consider the continuous time Markov process \( \{(Y_i(t))_{t \geq 0}\}_{i=1}^{n} \) taking
values in \( \mathbb{N}^n \), with transition of states defined for every \( 1 \leq i \leq n \) and \( t \geq 0 \) by
\[
\begin{align*}
    k & \rightarrow k + 1, \text{ with rate } \beta f'(0) \sum_j W_{ij} Y_j(t), \\
    k & \rightarrow k - 1, \text{ with rate } \delta.
\end{align*}
\]
This new process is introduced here purely for the purpose of analysis. How-
ever, it may be interpreted as a disease model where the state of each individual
is represented by a non-negative integer that indicates severity of infection.
Here, exposure to highly infected individuals raises the chance of an increase
in infection severity.
Suppose also that \( X_i(0) = Y_i(0) \) for all \( 1 \leq i \leq n \). Since \( f \) is concave,

\[
\beta \sum_h I_{ih} f(\sum_j X_j(t) I_{jh}) \leq \beta \sum_h I_{ih} f'(0) \sum_j X_j(t) I_{jh} = \beta f'(0) \sum_{ij} W_{ij} X_j(t),
\]

from which we see that \( Y_i \) stochastically dominates \( X_i \). Hence

\[
\mathbb{P} \left( \sum_i X_i(t) > 0 \right) \leq \mathbb{P} \left( \sum_i Y_i(t) > 0 \right) \leq \sum_i q_i(t),
\]

where \( q_i(t) := \mathbb{E}[Y_i(t)] \). In terms of the Chapman–Kolmogorov Equation, or Chemical Master Equation, \([12]\), we have

\[
\frac{dq_i(t)}{dt} = \beta f'(0) \sum_j W_{ij} q_j(t) - \delta q_i(t).
\]

Letting \( Q(t) = [q_1(t), q_2(t), \ldots, q_n(t)]^T \), this linear ODE system solves to give

\[
Q(t) = \exp \left( t(\beta f'(0) W - \delta I) \right) Q(0).
\]

The matrix \( \exp \left( t(\beta f'(0) W - \delta I) \right) \) is symmetric and has spectral radius \( \exp \left( (\beta f'(0) \lambda(W) - \delta I)t \right) \). Hence, in Euclidean norm,

\[
||Q(t)|| \leq \exp((\beta f'(0) \lambda(W) - I)t)||Q(0)||.
\]

Since \( ||Q(0)|| = \sqrt{n} \), and, by Cauchy–Schwarz,

\[
\sum_i q_i(t) \leq \sqrt{n}||Q(t)||,
\]

the proof is complete.

We deduce, analogously to \([11]\), the following corollary.

**Corollary 8.2.** Suppose \( f \) is concave in the hypergraph infection model \([3]\). Let \( \tau \) denote the time of extinction of the disease and suppose \( \lambda(W) f'(0) \beta < \delta \), then

\[
\mathbb{E}[\tau] \leq \frac{\log n + 1}{\delta - f'(0) \beta \lambda(W)}.
\]
Proof. Using Theorem 8.1

\[ E[\tau] = \int_0^\infty P(\tau > t)dt \]

\[ = \int_0^\infty P(\sum_i X_i(t) > 0)dt \]

\[ \leq \frac{\log n}{\delta - f'(0)} + \int_0^\infty n \exp((\beta f'(0)\lambda(W) - \delta)t)dt \]

\[ \leq \frac{\log n + 1}{\delta - f'(0)\beta\lambda(W)}. \]

\[ \square \]

Likewise the partitioned case yields the following result.

**Theorem 8.3.** Suppose every \( f_k \) is concave in the partitioned hypergraph model with infection rate (4). Then

\[ P\left(\sum_i X_i(t) > 0\right) \leq n i_0 \exp\left(\beta\lambda(\sum_{k=1}^K f'_k(0)W^{(k)}) - \delta\right). \]

Hence, if \( \lambda(\sum_{k=1}^K f'_k(0)W^{(k)})\beta/\delta < 1 \) then the disease vanishes at an exponential rate.

We also have the following analogue of Corollary 7.2 on the expected time to extinction for the partitioned case.

**Corollary 8.4.** Suppose every \( f_k \) is concave in the partitioned hypergraph model with infection rate (4). Let \( \tau \) denote the time of extinction of the disease and suppose \( \lambda(\sum_{k=1}^K f'_k(0)W^{(k)})\beta/\delta < 1 \), then

\[ E[\tau] \leq \frac{\log n + 1}{\delta - \beta\lambda(\sum_{k=1}^K f'_k(0)W^{(k)})}. \]

### 8.2 Conditions that preclude extinction

So far, we have focused on deriving thresholds that imply extinction. In this subsection, following ideas from \[11\], we derive a condition under which the disease will persist.
Note that our analysis does not require the graph associated with $W$ to be connected. The disconnected setting is relevant, for example, when interventions have been imposed in order to limit interactions. We let $\Delta := D - W$ denote the Laplacian, and let $\lambda_c(\Delta) > 0$ denote the smallest non-zero eigenvalue of $\Delta$. We also let $e_{\text{max}}$ denote the size of the largest hyperedge.

**Definition 4.** Given a hypergraph $\mathcal{H}$, a function $f : \mathbb{R}_+ \to \mathbb{R}_+$ and a subset of the nodes $S \subset V$, let

$$E(S, f) := \sum_{i \in S} \sum_{h \in E} I_{ih} f(\sum_{j \in S^c} I_{jh}),$$

where $S^c := V \setminus S$ is the complement of $S$. Also define for integer $1 \leq m \leq \lfloor n/2 \rfloor$

$$\eta(\mathcal{H}, m, f) := \inf \left\{ \frac{E(S, f)}{|S|} \mid 1 \leq |S| \leq m \right\},$$

and let $\eta(\mathcal{H}, m) := \eta(\mathcal{H}, m, \text{Id})$.

Notice that when $S$ consists of those nodes for which $X_i(t) = 0$, we can write the infection transition rate of $\sum_{i=1}^n X_i(t)$ as $\beta E(S, f)$. More generally, $\beta E(S, f)$ may be regarded as the rate at which nodes in the set $S$ may be infected by nodes in the remainder of the network. When $f = \text{Id}$ and $m = \lfloor n/2 \rfloor$, $\eta(\mathcal{H}, m)$ is the Cheeger constant, or isoperimetric number, associated with the weighted graph induced by $W = T^T T$. We may also regard $\eta(\mathcal{H}, m, f)$ as the smallest average infection rate over all subsets consisting of no more than half of the network.

The next theorem gives a probabilistic lower bound on the time to extinction.

**Theorem 8.5.** Recall that $\tau$ denotes the hitting time of the state 0 for the process $(\sum_j X_j(t))_{t \geq 0}$ in the hypergraph model $(\mathcal{H}, f)$. If $f$ is concave and

$$\lambda_c(\Delta) > \left(2 \frac{e_{\text{max}} - 1}{f(e_{\text{max}} - 1)} \right) \frac{\delta}{\beta},$$

then

$$\mathbb{P} \left( \tau > \frac{r^{m+1}}{2m} \right) \geq 1 - \frac{r}{e} (1 + O(r^m)),$$

where $r := \frac{(e_{\text{max}} - 1)\delta}{f(e_{\text{max}} - 1) \beta \eta(\mathcal{H}, m)} < 1$ and $m := \lfloor n/2 \rfloor$. 

21
From standard Cheeger inequalities [19], we know that the Cheeger constant of the graph induced by \( W \) satisfies \( 2\eta(\mathcal{H}, m) \geq \lambda_c(\Delta) \), hence using the assumptions on \( \lambda_c(\Delta) \) in the theorem, we see that \( r < 1 \) indeed.

In order to prove this result, we introduce the following lemma.

**Lemma 8.6.** If \( f \) is concave and non-decreasing, then

\[
\frac{f(e_{\max} - 1)}{e_{\max} - 1} \eta(\mathcal{H}, m) \leq \eta(\mathcal{H}, m, f).
\]

**Proof.** The proof is immediate once we see that by concavity of \( f \), for all \( x \in \{0, \ldots, e_{\max} - 1\} \)

\[
\frac{f(e_{\max} - 1)}{e_{\max} - 1} x \leq f(x).
\]

\( \Box \)

Now, to prove Theorem 8.5 consider the Markov process \((Z(t))_{t \geq 0}\) valued in \(\{0, \ldots, m\}\), with transition of states given by

\[
\begin{align*}
\{ & k \rightarrow k + 1 \text{ with transition rate } k\beta \frac{f(e_{\max} - 1)}{e_{\max} - 1} \eta(\mathcal{H}, m), \\
& k \rightarrow k - 1 \text{ with transition rate } k\delta. \}
\end{align*}
\]

This Markov process is stochastically dominated by \((\sum_{i=1}^{n} X_i(t))_{t \geq 0}\), which has the same downward transition rate, and an upward transition rate that is at least as large:

\[
k\beta \frac{f(e_{\max} - 1)}{e_{\max} - 1} \eta(\mathcal{H}, m) \leq k\beta \eta(\mathcal{H}, m, f) \\
\leq \beta E(S, f),
\]

where \( S := \{ i \in \{1, 2, \ldots, n\} \mid X_i(t) = 0 \} \). Thus, to show Theorem 8.5 it suffices to find a suitable lower bound for \( P(\hat{\tau} > \frac{|r^{-m+1}|}{2m}) \), where \( \hat{\tau} \) is the hitting time of 0 for the process \((Z(t))_{t \geq 0}\). This follows by applying Theorem 4.1 of [11] to the process \((Z(t))_{t \geq 0}\).

## 9 Collective Contagion Models

We now consider the collective contagion models from [8, 15, 17], where infection only starts spreading within a hyperedge once a threshold number
of infectious nodes in that hyperedge has been reached. As discussed in subsection 3.2, collective contagion models can be represented by nonlinear functions of the form \( f(x) := \max\{0, x - c\} \) for some \( c > 0 \), or \( f(x) := c_2 \mathbb{1}(x \geq c_1) \) for some \( c_1, c_2 > 0 \). In these cases it is obvious that the zero-infection state for the mean field approximation is locally asymptotically stable (and, indeed, Theorem 6.1 applies). However, because the functions are not concave, the theory found in Section 8 for the exact model does not directly apply. Nonetheless, we can still derive similar spectral conditions for the vanishing of the disease by finding concave functions which serve as upper bounds for \( f \). For instance using \( c_2 \mathbb{1}(x \geq c_1) \leq \frac{c_2}{c_1} x \mathbb{1}(x \leq c_1) + c_2 \mathbb{1}(x \geq c_1) \), the bounds in Theorem 8.1 and Corollary 8.2 lead to the following result.

**Theorem 9.1.** Suppose that \( f(x) := c_2 \mathbb{1}(x \geq c_1) \) for some \( c_1, c_2 > 0 \). Then

\[
P\left( \sum_i X_i(t) > 0 \right) \leq n i_0 \exp \left( \frac{\beta c_2}{c_1} \lambda(W) - \delta \right).
\]

In particular if \( \lambda(W) < \frac{c_1 \delta}{c_2 \beta} \), then the disease asymptotically vanishes with exponential decay and the extinction time \( \tau \) satisfies

\[
\mathbb{E}[\tau] \leq \frac{\log n + 1}{\delta - \beta \lambda(W) c_2 / c_1}.
\]

Likewise note that \( \max\{0, x - c\} \leq \frac{e_{\text{max}} - 1 - c e_{\text{max}}}{e_{\text{max}} - 1} x \), where we recall that \( e_{\text{max}} \) is the largest size of a hyperedge of \( \mathcal{H} \). Hence we deduce the following result.

**Theorem 9.2.** Suppose that \( f(x) := \max\{0, x - c\} \) for some \( c > 0 \). Then

\[
P\left( \sum_i X_i(t) > 0 \right) \leq n i_0 \exp \left( \beta \frac{e_{\text{max}} - 1 - c}{e_{\text{max}} - 1} \lambda(W) - \delta \right).
\]

In particular if

\[
\lambda(W) < \left( \frac{e_{\text{max}} - 1}{e_{\text{max}} - 1 - c} \right) \frac{\delta}{\beta},
\]

then the disease asymptotically vanishes with exponential decay and the extinction time \( \tau \) satisfies

\[
\mathbb{E}[\tau] \leq \frac{\log n + 1}{\delta - \beta \frac{e_{\text{max}} - 1 - c e_{\text{max}}}{e_{\text{max}} - 1} \lambda(W)}.
\]
10 Discussion

In this work we derived several spectral conditions that control the spread of disease in an SIS model on a hypergraph. The conditions have the general form

$$\beta \lambda(W) c_f / \delta < 1,$$

where $c_f > 0$ is a constant depending on the function $f$ that determines the nonlinear infection rate within a hyperedge.

We note that in the special case where (i) the hypergraph is an undirected graph and hence $W$ becomes the binary adjacency matrix, and (ii) we have linear dependence on the number of infectious neighbors for the infection rate of a node, so $f$ is the identity function, the condition (11) reduces to the well-known vanishing spectral condition studied in, for example, ([11, 18, 21]).

There are two important points to be made about the general form of (11). First, the hypergraph structure appears only via the presence of the symmetric matrix $W \in \mathbb{R}^{n \times n}$. Recall that $W_{ij}$ records the number of times that $i$ and $j$ both appear in the same hyperedge. Such weighted but pairwise information is all that feeds into this spectral threshold. On a positive note, this implies that useful predictions can be made about disease spread on a hypergraph without full knowledge of the types of hyperedge present and the distribution of nodes within them. (For example, when collecting human interaction data it is more reasonable to ask an individual to list each neighbour and state how many different ways they interact with that neighbour than to ask an individual to list all hyperedges they take part in.) However, this observation also raises the possibility that more refined analysis might lead to sharper bounds, perhaps at the expense of simplicity and interpretability.

Our second point is that the new vanishing condition (11) neatly separates three aspects:

(a) The biologically-motivated infection parameter, $\beta$.

(b) The interaction structure, captured in $\lambda(W)$.

(c) The coefficient $c_f$ that arises from modelling the nonlinear infection process. For instance, Theorem 6.1 and Theorem 6.4 have $c_f = f'(0)$. In the collective contagion model case $f(x) = c_2 1(x \geq c_1)$, Theorem 9.1 indicates that we can take $c_f = c_2 / c_1$.

We may view $\beta$ as an invariant biological constant that reflects the underlying virulence of the disease and is not affected by human behaviour. The factor $\lambda(W)$, which arises from the interaction structure, will be determined by regional and cultural issues, including population density, age demographics, and so on.
typical household sizes, and the nature of prevalent commercial and manufacturing activities. Interventions, including full or partial lockdowns, could be modeled through a change in $\lambda(W)$. The third factor, $c_f$, is strongly dependent upon human behaviour and may be adjusted to reflect individual-based containment strategies such as social distancing, mask wearing or more frequent hand washing.

This work has focused on modelling, analysis and interpretation at the abstract level, concentrating on the fundamental question of disease extinction. Having developed this theory, it would, of course, now be of great interest to perform practical experiments using realistic interaction and infection data, with the aim of

- calibrating model parameters,
- testing hypotheses about the appropriate functional form of the infection rate,
- testing the predictive power of the modeling framework, especially in comparison with simpler homogeneous mixing and pairwise interaction versions,
- quantifying the effect of different interventions.
