Heterostructures of microcrystalline cellulose-SiO₂ nanoparticles (MCC-SiO₂) were prepared by adsorption phase reaction technology (APRT). A urea solution served as the adsorption phase in the swelling process of the MCC particles. The thickness of the urea solution layer that adsorbed on the MCC surface was controlled by washing the samples with ethanol 3 times. The urea layer acted as a “micoreactor” to generate SiO₂ nanoparticles through a sol-gel process with tetraethoxysilane (TEOS), and MCC-SiO₂ heterostructures took shape. The morphologies of the heterostructures were controllable by changing the swelling time, thickness of the urea layer and TEOS content. The SiO₂ particles loaded on the MCC surface were almost spherical, with a size of 20-40 nm. These heterostructures were used in tire tread compounds to show their potential as reinforcing fillers. Compared with vulcanizates filled with MCC, those filled with the heterostructures had improved mechanical properties, with a 16.7% increase in tensile strength and a 16.2% increase in tear strength. Furthermore, the heterostructures were found to be a good filler for addressing the “magic triangle” problem in the tire industry. These materials improved the wet-skid resistance and abrasion resistance, and decreased the rolling resistance. These results indicated that MCC-SiO₂ heterostructures are a potential filler for use in the tire industry. SEM photographs showed that the sizes of the MCC-SiO₂ heterostructures were micronized in situ during rubber processing, from 20-90 μm to 1-10 μm, and the interfacial bonding between the heterostructures and the rubber matrix was improved.

Keywords: microcrystalline cellulose, nano-SiO₂, heterostructures, wet-skid resistance, tire tread compounds

INTRODUCTION

Currently, there is a trend of developing environmentally friendly materials, renewable resources and energy, and sustainable techniques to ease the burden of nonbiodegradable petroleum-based materials and meet the demand for environmental protection and resource conservation. Natural polymers have received increasing amounts of attention in the development of environmentally friendly, biocompatible and biodegradable products. Among these materials, cellulose-based materials are the most attractive due to their renewability, biocompatibility, biodegradability, availability, nontoxicity and low cost. Microcrystalline cellulose (MCC) can be prepared from raw cellulose through simple physical methods, such as mechanical disintegration, steam explosion, and chemical methods, such as acid hydrolysis and enzymolysis. MCC is a commercially available product with high crystallinity and strength, but larger sizes (20-90 μm). MCC can be further treated by acid hydrolysis to prepare nanocrystalline cellulose (NCC), rod-like, with 3-5 nm width and 50-500 nm in length. In recent years, there has been an attempt to use MCC and NCC as “green fillers” in plastic and rubber composites.

NCC has satisfactory reinforcing efficiency due to being nano-sized and having high strength, but it is not easily available because of production difficulties and high price. Furthermore, it is difficult to disperse NCC in a...
rubber matrix because of its strong tendency to aggregate, which seriously limits its application in polymer composites. MCC is commercially available, but its use is restricted by its poor reinforcing efficiency resulting from its large size (20-90 μm) and poor compatibility with nonpolar rubber. Many attempts have been made to solve these two problems, such as chemical grafting, esterification and silanization. These chemical methods can improve its compatibility with a polymer matrix, but have little benefit in decreasing the size of MCC. The high cost and complicated process have limited the large-scale application of MCC.

The adsorption phase reaction technique (APRT) is a new microreactor technique to prepare nanocomposites and nanocomposite catalysts, usually using silicate or SiO₂ particles as a nanoparticle carrier. MCC has a strong hydrophilicity and is capable of absorbing a thin water layer to serve as a microreactor where inorganic particles can be generated and loaded on its surface. In our previous work, it was found that rod-like, tube-like and spherical SiO₂ or ZnO particles could be loaded on the surface of MCC (swollen by 8% NaOH solution) by the APRT method. Further studies showed that the crystal form of MCC changed after being swollen by NaOH solution, which decreased the reinforcement in rubber compounds. The rod-like and tube-like SiO₂ or ZnO particles were not helpful in reinforcement because their shapes were destroyed under the force field during rubber processing. In this paper, a urea aqueous solution was used as swelling agent for MCC to avoid the destruction of MCC crystallinity and to control the shapes of nano-SiO₂ particles that were generated on the surface of MCC. The MCC-SiO₂ heterostructures were then used in tire tread compounds, and their effects on the mechanical properties, wet-skid resistance, rolling resistance and abrasion resistance of the tread compounds were investigated.

**EXPERIMENTAL**

**Materials**

Microcrystalline cellulose (20-90 μm in length and 5-20 μm in width) was supplied by Shandong Liaocheng Luxi Medicinal Materials Co., Ltd., China. The urea, ammonium hydroxide (NH₃.H₂O, NH₃ content was 25 wt%), alcohol, and tetraethoxysilane (TEOS), analytically pure, were all purchased from National Pharmaceutical Group Chemical Reagent Co., Ltd., China. The ingredients of the tire tread compounds are listed in Table 1. The elastomers were solution-polymerized styrene butadiene rubber (SSBR2557A, the styrene content was approximately 25%, and butadiene content was approximately 75%), and the emulsion-polymerized styrene butadiene rubber (ESBR1502, the styrene content was approximately 23.5%, and the butadiene content was approximately 76.5%) was supplied by Sinopec Dushanzi Co. Ltd., China. The silica (1165 MP, with a specific surface area of 165 m²/g) was obtained from Solvay Fine Chemical Additives Qingdao Co., Ltd., China. N-1,3-dimethylbutyl-N'-phenyl-p-phenylenediamine (antioxidant 4020) and poly(1,2-dihydro-2,2,4-trimethyl-quinoline) (antioxidant RD) were received from Shanghai Chenguin Chemical Additives Co., Ltd., China. The other ingredients, including [3-(triethoxysilyl)propyl]tetrasulfide (Si69), diphenylguanidine (DPG), sulfur, stearic acid (SA), N-tetraybutyl-2-benzothiazole sulphonamide (TBBS), zinc oxide (ZnO) and wax, industrial grade, were supplied by Sentury Tires Co., Ltd., China.

**Fabrication of MCC-SiO₂ heterostructures**

The entire process included the process of swelling MCC with a urea solution, followed by a sol-gel process using TEOS as a precursor. Briefly, MCC was swollen with an 8 wt% urea solution for a certain time at room temperature and then leached. The swollen MCC was washed with ethanol 3 times to remove the urea solution that was not absorbed firmly by MCC and control the thickness of the adsorption layer. The treated MCC was leached and dispersed again in ethanol and then added dropwise to TEOS ethanol solution by a separating funnel. After reacting at 60 °C for 6 h, 8 mL NH₃.H₂O was added to adjust the pH to 8~9, and then the solution was continually reacted for another 1 h. MCC-SiO₂ heterostructures were obtained after drying at 80 °C in a vacuum oven for 6 h. The entire process is shown in Figure 1.

**Preparation of tire tread compounds**

The elastomers and other ingredients, as listed in Table 1, were mixed in a torque rheometer (Rheomix 3000OS, Haake, Germany) according to the ASTM D3182-07 standard. The feeding order and mixing time of the ingredients were as follows: rubber (2 min), half of the total silica (with half of Si-69, 2 min), the other half of the silica (with remaining Si-69, 2 min) and MCC or MCC-SiO₂ (2 min), and the rest of the components (ZnO, SA, NS, DPG, 4020 and RD, 4 min). The onset temperature of the mixer was 90 °C, with a rotor speed of 70 rev/min. The sulfur was added into an open mill, and sheets with an approximate thickness of 2 mm were obtained.

A rheometer vulcanization machine (MDR-
Microcrystalline cellulose (2000, Alpha, USA) was used to measure the curing time ($t_{90}$) at 160 °C. The oscillating frequency was $1.7 \pm 0.1$ Hz, with an amplitude of $\pm 3.0^\circ$. The vulcanization was carried out at $t_{90}$ in a hydraulic press (HS100T-RTMO, Shenzhen Jiaxin Co. Ltd., China) at 160 °C, and then the vulcanizates were obtained.

### Table 1

| Ingredients          | Control (phr) | MCC-SiO$_2$ (phr) |
|----------------------|--------------|------------------|
| ESRB1502             | 24.00        | 24.00            |
| SSBR2557A            | 104.50       | 104.50           |
| 1165MP               | 60.00        | 60.00            |
| MCC                  | 10.00        | 0                |
| MCC-SiO$_2$          | 0            | 10.00            |
| SA                   | 2.00         |                  |

| Sulfur               | 1.60         |                  |

Figure 1: Fabrication processes for MCC-SiO$_2$ heterostructures (samples named as MS-x-y according to their preparation conditions: MS stands for MCC-SiO$_2$ heterostructures, x – swelling time (12 h, 24 h or 36 h), and y – TEOS usage (20 g, 15 g, 10 g or 5 g))

**Characterization of MCC heterostructures**

**Fourier transform infrared spectroscopy (FT-IR)**

MCC and MCC heterostructures were ground and tableted with KBr powder and then tested using a Fourier infrared transform spectrometer (VERTEX70, Bruker Corporation, Germany) with scanning wavenumbers ranging between 400-4000 cm$^{-1}$.

**Thermogravimetric analysis (TGA)**

A NETZSCH thermogravimetric analyzer (209F1, NETZSCH, Germany) was used to study the mass loss of MCC and MCC-SiO$_2$ heterostructures when heated from 30 to 800 °C, with a heating rate of 20 °C/min. The test was conducted in a nitrogen atmosphere with a flow rate of 50 mL/min.

**Wide-angle X-ray diffractometry (WARD)**

The XRD spectra of the MCC, swollen MCC and MCC-SiO$_2$ heterostructures were obtained with a wide-angle X-ray diffractometer (Ultima IV, Rigaku, Japan), with a Cu Kα source at 40 kV and 40 mA.

**Field-emission scanning electron microscopy (SEM)**

The microstructures of the MCC and MCC-SiO$_2$ heterostructures were investigated by a field-emission scanning electron microscope (JSM-
7500F, JEOL Ltd., Japan). All the samples were sputtered with a layer of platinum before SEM scanning measurements.

Characterization of rubber compounds

Mechanical properties of vulcanizates

An electron tensile testing machine (TUM 1445, Zwick, Germany) was used to measure the physical and mechanical properties of the vulcanizates, including the tensile strength (ASTM D412), the moduli at 100% and 300% elongation (ASTM D412) and the tear strength (ASTM D624). The resilience (ASTM D2632) and shore hardness (ASTM D2240) were investigated according to their respective ASTM standards.

Abrasion resistance

A DIN abrader (GT-7012-D, Gotech Testing Machines Co Ltd., Taiwan) was used to measure the DIN abrasion resistance of the vulcanizates following ASTM D5963. A cylindrical rubber specimen with a diameter of 16 mm and a height of 10 mm was abraded against a rotating cylindrical drum (150 mm in diameter, rotating at approximately 40 rev/min). The specimen was gripped in a steel collet chuck and was clamped tightly into the specimen holder, with a portion of the specimen protruding 2 mm from the clamping aperture with a gauge. The chuck moved at approximately 3 mm/s when the drum rotated at approximately 40 rev/min, and the chuck was parallel to the axis of the drum. After the specimen slid for 120 s, the total loss was tested, and the loss volume of the sample was measured combined with its density.

Dynamic mechanical analysis (DMA)

The dynamic mechanical properties of the vulcanizates were tested by a dynamic mechanical analyzer (EPLEXOR 500N, GABO, Germany) at a constant frequency of 10 Hz. The temperature ranged from -80 to 80 °C, with a heating rate of 3 °C/min. The specimens were 20 mm in length, 4 mm in width and 2 mm in thickness. The loss angle tangent (tanδ) was measured as a function of temperature under identical conditions.

Compression heat build-up

The compression heat build-up measurements were carried out in a flexometer (GT-RH2000, Gotech Testing Machines Inc., China) according to ASTM D623. A cylindrical rubber specimen with a height of 25 mm and a diameter of 17.5 mm was subjected to repeated compression with a frequency of 30 Hz. The compressive loading was 24.5 kilograms, and the onset temperature was 55 ± 1 °C. The internal temperature of the rubber composites was recorded after 25 min. Three specimens were measured for each sample, and the average values were calculated.

RESULTS AND DISCUSSION

Characterization of MCC-SiO₂ heterostructures

Structure of MCC-SiO₂ heterostructures

Figure 2 (a) shows the FT-IR spectra of the MCC and MCC-SiO₂ heterostructures. The peaks at 810 cm⁻¹ and 456 cm⁻¹ for the MCC-SiO₂ sample were caused by the stretching vibration and the deformation vibration of Si-O bonds, respectively, associated with the inorganic Si-O-Si network. In addition, the stretching vibration of Si-O-Si at 1100 cm⁻¹ resulted in a large peak at 1000-1200 cm⁻¹. These results indicated that SiO₂ was successfully loaded on the MCC surface. It is well known that the hydroxyl stretching vibration peak shifts to a lower wavenumber and that the deformation vibration peak shifts to a higher wavenumber if intermolecular hydrogen bonds exist. The band at 3357.9 cm⁻¹ was associated with the stretching vibration of the hydroxyl groups (⁻OH) in the IR spectrum of the MCC, whereas this peak was enhanced and shifted to a lower wavenumber of 3346 cm⁻¹ for the MCC-SiO₂ sample. Furthermore, the band at 1056.9 cm⁻¹ for MCC, attributed to O-H deformation vibration, was enhanced and shifted to 1060.8 cm⁻¹ for the MCC-SiO₂ sample, indicating a strong hydrogen interaction between MCC and SiO₂.

Figure 2 (b) shows the XRD spectra of the MCC, MCC swollen by NaOH, MCC swollen by urea and MCC-SiO₂ (MS-36-15). The XRD spectrum of MCC showed four characteristic peaks: 22.8° (020), 34.6° (004), 14.8° (110) and 16.3° (110), indicating a typical cellulose I crystalline structure. However, the MCC swollen by NaOH exhibited a cellulose II crystalline form, with peaks at 2θ = 14.8°, 20.4° and 22.5°, meaning that most of the cellulose I had transformed into cellulose II. This crystal transformation harms the strength of MCC. Fortunately, the crystal form of the MCC swollen by urea, as well as that of MCC-SiO₂, had not been changed. The crystallinity was calculated by the Segal equation: Cₐ,l = (I₀₀₂-Iₐm)/I₀₀₂*100%, where Cₐ,l, I₀₀₂ and Iₐm represent the percentage of relative

SEM analysis

The vulcanizates were stretched to fracture at room temperature, and the section morphology was observed by SEM. The section was sprayed with a thin layer of platinum before observation.
crystallinity, the maximum intensity of the lattice diffractive angle and the scattering intensity of the amorphous diffraction, respectively; these scattering intensities are located at 2θ values of approximately 22.6° and 18°, respectively. The calculated crystallinity was 84.8% for MCC, 88.58% for urea-swollen MCC, 87.48% for MCC-SiO₂ (MS-12-5), and only 66.41% for NaOH-swollen MCC. The improvement in the crystallinity of the urea-swollen MCC and MCC-SiO₂ was due to the special swelling mechanism of urea. The urea aqueous solution removed the noncrystalline zone, but did not damage the crystalline region. The crystallinity of MCC-SiO₂ decreased slightly compared with that of the MCC swollen by urea because the orderly alignment of MCC molecular chains were disturbed by the strong hydrogen bond interaction between nano-SiO₂ and MCC.32

SiO₂ contents in heterostructures

The TGA curves of MCC-SiO₂ prepared under different conditions were compared with that of raw MCC to determine the thermostability and the number of loaded SiO₂ particles, as shown in Figure 3.

The thermal decomposition temperature of MCC was approximately 350 °C, and the residue tended to zero beyond 400 °C, indicating a complete thermal decomposition of MCC. The thermal decomposition temperature of the MCC-SiO₂ samples was lower than that of MCC because of the remaining NH₃·H₂O in MCC-SiO₂, a catalyst for the thermal decomposition of MCC.

Figure 2: FT-IR (a) and XRD (b) spectra of MCC and MCC-SiO₂

Figure 3: TGA curves of MCC and MCC-SiO₂ heterostructures
The residue of the MCC-SiO$_2$ samples was very different as the swelling time and TEOS concentration changed. The amount of SiO$_2$ loaded on MCC increased with increasing TEOS concentration, but decreased with increasing swelling time. It was clear that the SiO$_2$ load increased with increasing TEOS concentration, but it was difficult to establish that the maximum load of SiO$_2$ was present in the sample with minimum swelling time. The urea did not have enough time to reach and interact with the molecular chains of MCC when the swelling time was 12 h, which resulted in a higher concentration of urea in the absorbed layer of MCC and thus more SiO$_2$ particles generated in this layer.

**Micromorphologies of MCC-SiO$_2$ heterostructures**

The morphologies of the MCC and MCC heterostructures were observed by SEM after drying at 80 °C in a vacuum oven, and SEM and EDS photographs are shown in Figure 4.

It was found that the surface of MCC was smooth, while the surfaces of the heterostructures became rough due to the loading of SiO$_2$ particles. The EDS maps of part of the surface of MS-36-15 in Figure 4 confirmed that SiO$_2$ particles were formed. The loaded SiO$_2$ particles were almost spherical, with a size of 20-30 nm for samples MS-24-15, MS-36-15 and MS-12-5, and 30-40 nm for samples MS-12-15 and MS-12-10. Many aggregates overlapped on the surface of MS-12-15, and only a few aggregates overlapped on the surface of MS-12-10, while the aggregates were almost invisible on MS-24-15, MS-36-15 and MS-12-5. These results indicated that either decreasing TEOS concentration or extending swelling time decreased the number of aggregates and the particle sizes, sharing a similar regularity with the TGA results. Based on the TGA and SEM results, it was expected that MS-24-15, MS-36-15 and MS-12-5 will demonstrate better performance when used in rubber composites.

**Effects of MCC-SiO$_2$ heterostructures on the properties of tire tread compounds**

The effects of MCC (used as received) and the MCC-SiO$_2$ heterostructures on the physico-mechanical and dynamic mechanical
properties, as well as abrasion resistance of the vulcanizates were studied.

**Physico-mechanical properties**

The physical and mechanical properties of the tire tread compounds are shown in Table 2. The sample filled with MCC was used as a control. Compared with the control, the tensile strength, tear strength and elongation at break of the MCC-SiO$_2$ compounds were all improved, in particular, those of MS-36-15, MS-12-10, and MS-12-5. The tensile strength and elongation at break of MS-12-5 were improved by 19.3% and 18.8%, respectively, and the tear strength of MS-12-10 was improved by 16.2%. These results confirmed that the MCC-SiO$_2$ heterostructures had higher reinforcing efficiency than MCC alone. The improvement in the reinforcing efficiency could be attributed to the hybridization effect of nanosized SiO$_2$ particles with microsized MCC. As shown in the SEM images of Figure 4, the samples with regular spherical SiO$_2$ particles and few aggregates had much improved reinforcing efficiency. The large aggregates on MS-12-15 and MS-24-15 easily fell from the surface under the force field of rubber processing, which deteriorated the reinforcing efficiency in the rubber compounds.

**“Magic triangle” of tire tread compounds**

The wet-skid resistance, rolling resistance and abrasion resistance are three important features of a tire. The wet-skid resistance represents the safety of the tire, the rolling resistance represents the fuel savings, and the abrasion resistance represents the serving life. These three properties are well known as the “magic triangle” problem in the rubber industry because they are difficult to improve simultaneously.

The wet-skid resistance and rolling resistance are related to the viscoelastic properties of the rubber compounds and can be characterized by DMA (tanδ-T curves), as shown in Figure 5 (a). The tire tread compounds are expected to have a high tanδ value at 0 °C to ensure a high wet-skid resistance and a low tanδ value at 60 °C to ensure a low rolling resistance. Figure 5 (a) shows that the tanδ values of the MCC-SiO$_2$ (MS-24-15, MS-36-15) samples at 0 °C were significantly improved, with an approximately 52% improvement and a slight decrease at 60 °C. These results indicated that if MCC-SiO$_2$ was used in tire tread compounds, a much higher wet-skid resistance would be achieved, accompanied by a lower rolling resistance. In addition, the transition temperature (Tg) of the MCC-SiO$_2$ vulcanizates shifted to higher temperature compared with the control, indicating that MCC-SiO$_2$ had a strong interaction with the rubber matrix.

Figure 5 (b) shows the curves of storage modulus (E') vs. temperature (T) obtained from DMA data. It is clear that the storage modulus of MCC-SiO$_2$ compounds was much lower than that of the MCC compounds at low temperature (< -20 °C). A low storage modulus is helpful to the safety of the tire when rolling on ice and snow roads.

Figure 5 (c) shows the DIN abrasion resistance of the tire tread compounds. The abrasion loss of all the MCC-SiO$_2$ samples was much lower than that of the control, meaning that the MCC-SiO$_2$ significantly improved the abrasion resistance, especially those of MS-12-10 and MS-12-15. The significant improvement in the DIN abrasion resistance of MS-12-10 and MS-12-15 was attributed to the improvement in the high tensile strength and resilience of the vulcanizates.

### Table 2

| Properties               | Control | MS-12-15 | MS-24-15 | MS-36-15 | MS-12-10 | MS-12-5 |
|--------------------------|---------|----------|----------|----------|----------|---------|
| Tensile strength, MPa    | 15.0    | 15.4     | 16.8     | 17.5     | 17.5     | 17.9    |
| Elongation at break, %   | 437     | 487      | 479      | 491      | 483      | 519     |
| Tear strength, kN.m$^{-1}$| 45.7    | 48.2     | 50.6     | 51.1     | 53.1     | 52.3    |
| 300% modulus, MPa        | 9.94    | 8.63     | 9.46     | 9.68     | 9.24     | 9.67    |
| Resilience, %            | 21      | 20       | 20       | 20       | 24       | 25      |
| Hardness/Shore A         | 67      | 67       | 67       | 68       | 67       | 68      |

Microcrystalline cellulose
Fracture morphologies of vulcanizates

The failure surfaces of the tensile samples were observed by SEM to study the microstructure and dispersion of MCC and MCC-SiO$_2$ in the rubber matrix, and the photographs are shown in Figure 6. The raw MCC particles, with a size of approximately 20-90 µm, had poor interfacial bonding with the rubber matrix, as observed in Figure 6 (a). Most of the MCC particles were pulled out of the rubber matrix, leaving many large holes in the matrix. The stress concentration often appeared in the crack tip and caused damage and failure of the material, which was the main reason for the inferior reinforcing efficiency of MCC. Compared to the raw MCC, the MCC-SiO$_2$ particles exhibited improved interfacial bonding with the rubber matrix, as shown in Figure 6 (b, c). Almost no MCC-SiO$_2$ particles were pulled out, and no separated interface existed, showing strong interaction between the MCC-SiO$_2$ particles and the rubber matrix. In addition, Figure 6 (d) shows that the MCC-SiO$_2$ heterostructures were maintained in the vulcanizates, indicating that nano-SiO$_2$ particles on the MCC-SiO$_2$ surfaces had not been peeled off under the stress field during the rubber processing. In addition to strong interfacial bonding with the rubber matrix, the sizes of the MCC-SiO$_2$ heterostructures were approximately 1-10 µm, as shown in Figure 6 (b), much smaller than those of the MCC particles. The MCC-SiO$_2$ heterostructures were disintegrated into small particles in situ under the strong force field during rubber processing due to the loose structure of swollen MCC. Due to the in situ micronization and the improved interaction with the rubber matrix, the MCC-SiO$_2$ heterostructures had perfect reinforcing efficiency.
CONCLUSION

MCC-SiO$_2$ heterostructures were achieved by loading spherical nano-SiO$_2$ particles on the surface of MCC through APRT combined with sol-gel technology. The aggregation states and sizes of the nano-SiO$_2$ particles were controllable by changing the MCC swelling time and the TEOS concentration. Decreasing the TEOS concentration and extending the swelling time both decreased the number of aggregates and the particle sizes of SiO$_2$, resulting in an improvement in their reinforcing efficiency in the rubber compounds. The vulcanizates filled with MS-36-15 or MS-12-10 had improved tensile strength and tear strength, and especially, improved DIN abrasion resistance. Furthermore, the wet-skid resistance (0 °C tanδ) was significantly improved as the rolling resistance (60 °C tanδ) decreased. These results indicated that MCC-SiO$_2$ heterostructures have great potential to solve the “magic triangle” problem in “green tire” tread compounds. SEM images showed that, compared with raw MCC, the MCC-SiO$_2$ heterostructures were micronized in situ and had improved interfacial bonding with the rubber matrix.
