Abstract
Spatial proteomics is the systematic study of protein sub-cellular localisation. In this workflow, we describe the analysis of a typical quantitative mass spectrometry-based spatial proteomics experiment using the MSnbase and pRoloc Bioconductor package suite. To walk the user through the computational pipeline, we use a recently published experiment predicting protein sub-cellular localisation in pluripotent embryonic mouse stem cells. We describe the software infrastructure at hand, importing and processing data, quality control, sub-cellular marker definition, visualisation and interactive exploration. We then demonstrate the application and interpretation of statistical learning methods, including novelty detection using semi-supervised learning, classification, clustering and transfer learning and conclude the pipeline with data export. The workflow is aimed at beginners who are familiar with proteomics in general and spatial proteomics in particular.

Introduction
Quantitative mass spectrometry based spatial proteomics involves elaborate, expensive and time consuming experimental protocols and considerable effort is invested in the generation of such data. Multiple research groups have described a variety of approaches to establish high quality proteome-wide datasets (see for example\(^1\) for a review, and \(^3\)–\(^5\) for recent examples). However, data analysis is as critical as data production for reliable and insightful biological interpretation. Here, we walk the reader through a typical pipeline for the analysis of such data using several Bioconductor packages for the R statistical programming environment.

The main package to analyse protein localisation data is \textit{pRoloc}, which offers a set of dedicated functions for the analysis of such data. \textit{pRoloc} itself relies on \textit{MSnbase} to manipulate and process quantitative proteomics data. Many other packages are used by \textit{pRoloc} for clustering, classification and visualisation. Support for interactive visualisation is offered by the \textit{pRolocGUI} package.

In this workflow, we will describe how to prepare the spatial proteomics data starting from a spreadsheet containing quantitative mass spectrometry data, through to some essential data processing steps, and finish with different applications of machine learning (Figure 1). We focus on a recent pluripotent mouse embryonic stem cells experiment\(^6\). These data, as well as additional annotated and pre-formatted datasets from various species are readily available in the \textit{pRolocdata} package.

Installation of Bioconductor packages is documented in detail on the Bioconductor installation help page. Below, we show how to install the four main packages used in this workflow:

```r
source("https://bioconductor.org/biocLite.R")
biocLite(c("MSnbase", "pRoloc", "pRolocdata", "pRolocGUI"))
```

![Figure 1. Schematic overview of the pRoloc pipeline from data import, through to data processing, machine learning and data export.](image-url)
This procedure is also applicable to any packages from CRAN as well as GitHub. Once a package has been installed, it needs to be loaded for its functionality to become available in the R session; this is done with the `library` function e.g. to load the `pRoloc` one would type `library("pRoloc")` after installation.

If you have questions about this workflow in particular, or about other Bioconductor packages in general, they are best asked on the Bioconductor support site following the posting guidelines. Questions can be tagged with specific package names or keywords. For more general information about mass spectrometry and proteomics, the readers are invited to read the `RforProteomics` package vignettes and associated papers.

### Reading and processing spatial proteomics data

#### The use-case: predicting sub-cellular localisation in pluripotent embryonic mouse stem cells

As a use-case, we analyse a recent high-throughput spatial proteomics dataset from pluripotent mouse embryonic stem cells (E14TG2a)\(^3\). The data was generated using hyperplexed LOPIT (hyperLOPIT), a state-of-the-art method relying on improved sub-cellular fractionation and more accurate quantitation, leading to more reliable classification of protein localisation across the whole sub-cellular space. The method uses an elaborate sub-cellular fractionation scheme, enabled by the use of Tandem Mass Tag (TMT)\(^9\) 10-plex and application of the MS data acquisition technique named synchronous precursor selection MS\(^3\) (SPS-MS\(^3\))\(^9\), for TMT quantification with high accuracy and precision. Three biological replicates were generated from the E14TG2a experiment, the first was to target low density fractions and the second and third were to emphasise separation of the denser organelles. The intersect of replicates 1 and 2 was treated as a 20-plex dataset for the analysis. As discussed in the publication\(^3\), it has been shown that combining replicates from different gradients can increase spatial resolution\(^10\). The combination of replicates resulted in 5032 proteins common to both experiments.

These, as well as many other data are directly available as properly structured and annotated datasets from the `pRolocdata` experiment package. In this workflow, we will start with a description of how to generate these ad hoc data objects starting from an arbitrary spreadsheet, as produced by many popular third-party applications.

While we focus here on a LOPIT-type dataset, these analyses are relevant for any quantitative spatial proteomics data, irrespective of the fractionation or quantitation (i.e. labelled or label-free) methods.

#### The infrastructure: `pRoloc` and `MSnbase` packages

To make use of the full functionality of the `pRoloc` software one needs to import their data into R and prepare them as an `MSnSet`. The `MSnSet` is a dedicated data structure for the efficient manipulation and processing of mass spectrometry and proteomics data in R. Figure 2 illustrates a simplified view of the `MSnSet` structure; there exists 3 key sub-parts (termed slots) to such a data object: (1) the `exprs` (short for expression data) slot for storing the quantitation data, (2) the `fData` slot (short for feature-metadata) for storing the feature metadata, and finally (3) the `pData` slot (short for pheno-metadata, i.e. sample phenotypic data) for storing the sample metadata.

![Figure 2. Simplified representation of the `MSnSet` data structure](image)
Feature metadata typically contains general annotation about the proteins (accession numbers, description, …), information related to the identification search (confidence scores, number of peptides,…) as well as annotation about known sub-cellular location (see in particular the Markers section) and results from data analysis. The sample metadata would, for example, record what stable isotope labels were used for the respective fraction (when labelled quantitation is used), replicate number, fraction number along the gradient and pooling information.

Another slot of interest is `processingData`, that logs the processing `MSnSet` objects undergo. The processing log can be accessed with the `processingData` function and is displayed under Processing information in the textual object summary when an `MSnSet`’s name is typed in the R console.

## Importing data

There are a number of ways to import quantitation data and create an `MSnSet` instance. All methods are described in the MSnbase input/output capabilities vignette. One suggested simple method is to use the function `readMSnSet2`. The function takes a single spreadsheet file name as input and extracts the columns containing the quantitation data, as identified by the argument `ecol`, to create the expression data, while the other columns in the spreadsheet are appended to the feature metadata slot. By example, in the code chunk below we read in the csv spreadsheet containing the quantitation data from the intersect of replicates 1 and 2 of the mouse map, using the `readMSnSet2` function. The data is as available online with the manuscript (see tab 2 of the xlsx supplementary Dataset 1 in 3, which should be exported as a text-based spreadsheet). It is also available as a csv file in the Bioconductor `pRolocdata` data package, which we make use of below.

To use the `readMSnSet2` function, as a minimum one must specify the file path to the data and which columns of the spreadsheet contain quantitation data. In the code chunk below, we start by identifying the file that we want to use. The `system.file` function is used to return the path to the `extdata` directory from the `pRolocdata` package, which is where our file of interest resides. We then use the `dir` function to list the content of that directory and store the path that matches the file name of interest in the `csvfile`. Note that these two lines are only needed here to locate a file in a package; in a more general use case, the user would define the `csvfile` variable containing the file name of interest directly.

```r
library("MSnbase")
extdatadir <- system.file("extdata", package = "pRolocdata")
csvfile <- dir(extdatadir, full.names = TRUE, pattern = "hyperLIT-SIData-ms\-rep\-2-intersect.csv")
basename(csvfile)
## [1] "hyperLIT-SIData-ms\-rep\-2-intersect.csv.gz"
```

Note that the file is compressed (as indicated by the `.gz`, for gzip, extension), and will be decompressed on-the-fly when read into R.

Next, we need to identify which columns in the spreadsheet contain the quantitation data. This can be done using the `getEcols` function inside R. The spreadsheet deposited by the authors contains two headers, with the second header containing information about where the quantitation data is stored.

We can display the names of the second header by calling the `getEcols` function with the argument `n = 2` (the default value is `n = 1`), to specify that we wish to display the column names of the second line. We also specify the name of the spreadsheet file (defined as `csvfile` above) and the separator that splits cells.

**Figure 3.** A screenshot of the data in the spreadsheet.
It is now easy for one to identify that the quantitation data, corresponding to the 10 TMT isobaric tags, is located in columns 8 to 27. We now have the two mandatory arguments to readMSnSet2, namely the file name (stored in the csvfile variable) and the quantitation column indices. In addition to these, it is also possible to pass the optional argument fnames to indicate which column to use as the labels by which to identify each protein in the sample. Here, we use fnames = 1 to use the UniProt identifiers contained in the first (unnamed) column of the spreadsheet. We also need to specify to skip the first line of the file (for the same reason that we used n = 2 in getEcols above) to read the csv data and convert it to an MSnSet object, named hl (for hyperLOPIT).

hl <- readMSnSet2(csvfile, ecol = 8:27, fnames = 1, skip = 1)
Below, we display a short summary of the data. The data contains 5032 proteins/features common across the 2 biological replicates for the respective 2 × 10-plex reporter tags (20 columns or samples), along with associated feature metadata such as protein markers, protein description, number of quantified peptides etc (see below).

```
## MSnSet (storageMode: lockedEnvironment)
## assayData: 5032 features, 20 samples
##   element names: exprs
## protocolData: none
## phenoData: none
## featureData
##   featureNames: Q9JHU4 Q9QXS1-3 ... Q9Z2R6 (5032 total)
##   fvarLabels: X X.1 ... Cell.Surface.Proteins (25 total)
##   fvarMetadata: labelDescription
## experimentData: use 'experimentData(object)'
## Annotation:
## - - - Processing information - - -
## MSnbase version: 2.1.4
```

Below, we examine the quantitative information along the whole gradient for the first 5 proteins. It is also possible to access specific rows and columns by naming the proteins and TMT tag channels of interest.

```
exprs(hl)[1:5, ]
```

```

The feature metadata is stored in the fData slot and can be accessed by `fData(hl)`. When using `readMSnSet2`, automatically, everything that is not defined as quantitation data by `ecol` or the feature names by `fnames` is deposited to the fData slot.

We see the fData contains 25 columns describing information such as the number of peptides, associated markers, machine learning results etc. To identify the feature variable names we can use the function `fvarLabels`. We see that the first 6 feature variable names contain non-discriminatory label names, so we relabel them to help us identify what feature data information is stored in the associated columns.
fvarLabels(hl)

```

Note that when using the simple readMSnSet2 procedure, the pData slot which is used to store information about the samples/channels is kept empty. As illustrated below, one can use the $ operator to access (or create) individual columns in the metadata slot. It is advised to annotate the channels as well. Below, we annotate the replicate from which the profiles originate and the TMT tag (extracted from the sample/channel names). To do so, we use the sample names that were assigned automatically using the quantiation column names and remove leading `X` and trailing `.1` using the sub function.

```
pData(hl)$Replicate <- rep(1:2, each = 10)
pData(hl)$Tag <- sub("\1\$, ", sub("^X", ", sampleNames(hl))
pData(hl)
```

```
# Replicate Tag
# X126   1 126
# X127N  1 127N
# X127C  1 127C
```
Throughout this workflow we refer to the different columns that are found in the `exprs` (expression data) slot as channels (short for TMT channels). In the frame of LOPIT and hyperLOPIT these channels constitute the relative abundance of each protein (along the rows) in the channel of interest. Each TMT channel originates from fractions collected from the density gradient, or a set of pooled fractions or may be a sample originating from an alternative preparation e.g. such as from the chromatin enrichment performed in Christoforou et al. Information about which gradient fractions were used for which tag should also be stored in the sample metadata `pData` slot.

The sample metadata that is distributed with the `pRolocdata` package for Christoforou's hyperLOPIT experiment and (as above) the quantitation data file, are located in the `extdata` in the `pRolocdata` package on the hard drive.

In the code chunk below we again use the `dir` function to locate the filepath to the metadata `csv` file and then read it into R using `read.csv`. We then append the metadata to the `pData` slot. Information about the gradient fractions used and the associated subcellular fraction densities in each replicate are stored here.

```r
expinfo <- dir(extdatadir, full.names = TRUE, pattern = "hyperLOPIT-SIData-fraction-info.csv")
fracinfo <- read.csv(expinfo, row.names=1, skip = 2, header = FALSE, stringsAsFactors = FALSE)
pData(hl)$Gradient.Fraction <- c(fracinfo[, 1], fracinfo[, 2])
pData(hl)$Iodixonal.Density <- c(fracinfo[, 4], fracinfo[, 5])
```

| Replicate | Tag     | Gradient.Fraction | Iodixonal.Density |

Data processing

**Normalisation.** There are two aspects related to data normalisation that are relevant to spatial proteomics data processing. The first one focuses on reducing purely technical variation between channels without affecting biological variability (i.e. the shape of the quantitative profiles). This normalisation will depend on the underlying quantitative technology and the experimental design, and will not be addressed in this workflow. The second aspect, and more specific to spatial proteomics data, is scaling all the organelle-specific profiles into a same intensity interval (typically 0 and 1) by, for example, dividing each intensity by the sum of the intensities for that quantitative feature. This is not necessary in this example as the intensities for each replicate have already been re-scaled to 1 in Proteome Discoverer v1.4 Thermo Fisher. However, if the data require normalisation, the user can execute the normalise function as demonstrated in the below code chunk.

```r
hl <- normalise(hl, method = "sum")
```

This transformation of the data assures cancellation of the effect of the absolute intensities of the quantitative features along the rows, and focus subsequent analyses on the relative profiles along the sub-cellular channels.

The same `normalise` function (or normalize, both spellings are supported) can also be applied in the first case described above. Different normalisation methods, such as mean or median scaling, variance stabilisation or quantile normalisation, to cite a few, can be applied to accomodate different needs (see `?normalise` for available options).

As previously mentioned, before combination, the two replicates in the `hl` data that we read into R were separately normalised by sum (i.e. to 1) across the 10 channels for each replicate respectively. We can verify this by summing each rows for each replicate:

```r
summary(rowSums(exprs(hl[, hl$Replicate == 1])))
##    Min.    1st Qu.     Median       Mean  3rd Qu.     Max.  
## 0.9970   0.9990   1.0000    1.0000   1.0010   1.0030
summary(rowSums(exprs(hl[, hl$Replicate == 2])))
##    Min.    1st Qu.     Median       Mean  3rd Qu.     Max.  
## 0.9970   0.9990   1.0000    1.0000   1.0010   1.0030
```

We see that some features do not add up exactly to 1 due to rounding errors after exporting to intermediate files. These small deviations do not bear any consequences here.

Combining acquisitions

The spreadsheet that was used to create the `hl` MSnSet included the two replicates within one `csv` file. We also provide individual replicates in the `pRolocdata` package. Below, we show how to combine MSnSet objects and, subsequently, how to filter and handle missing values. We start by loading the `pRolocdata` package and the equivalent replicates using the `data` function.

```r
library("pRolocdata")
data(hyperLOPIT2015ms3r1)
data(hyperLOPIT2015ms3r2)
```

At the R prompt, typing

```r
pRolocdata()
```

will list the 54 datasets that are available in `pRolocdata`.

Combining data is performed with the `combine` function. This function will inspect the feature and sample names to identify how to combine the data. As we want our replicates to be combined along the columns (same proteins, different
sets of channels), we need to assure that the respective sample names differ so they can be identified from one another. The function `updateSampleNames` can be used to do this.

```r
identical(sampleNames(hyperLOPIT2015ms3r1), sampleNames(hyperLOPIT2015ms3r2))
## [1] TRUE
```

```r
hyperLOPIT2015ms3r1 <- updateSampleNames(hyperLOPIT2015ms3r1, 1)
hyperLOPIT2015ms3r2 <- updateSampleNames(hyperLOPIT2015ms3r2, 2)
sampleNames(hyperLOPIT2015ms3r1)
## [1] "X126.1"  "X127N.1" "X127C.1" "X128N.1" "X129N.1" "X129C.1"
## [8] "X130N.1" "X130C.1" "X131.1"
sampleNames(hyperLOPIT2015ms3r2)
## [1] "X126.2"  "X127N.2" "X127C.2" "X128N.2" "X128C.2" "X129N.2" "X129C.2"
## [8] "X130N.2" "X130C.2" "X131.2"
```

In addition to matching names, the content of the feature metadata for identical feature annotations must match exactly across the data to be combined. In particular for these data, we expect the same proteins in each replicate to be annotated with the same UniProt entry names and descriptions, but not with the same coverage of number of peptides or peptide-spectrum matches (PSMs).

```r
fvarLabels(hyperLOPIT2015ms3r1)
## [1] "EntryName"  "ProteinDescription" "Peptides"
## [4] "PSMs"       "ProteinCoverage"  "markers"
fvarLabels(hyperLOPIT2015ms3r2)
## [1] "EntryName"  "ProteinDescription" "Peptides"
## [4] "PSMs"       "ProteinCoverage"  "markers"
```

Below, we update the replicate specific feature variable names and remove the shared annotation. In the first line, we update only the feature variable names 3 to 5 (by appending a 1) and in the second line, we apply the `updateFvarLabels` function to update all feature variable names (by appending a 2).

```r
fvarLabels(hyperLOPIT2015ms3r1)[3:5] <- paste0(fvarLabels(hyperLOPIT2015ms3r1)[3:5], 1)
hyperLOPIT2015ms3r2 <- updateFvarLabels(hyperLOPIT2015ms3r2, "2", sep = "")
fData(hyperLOPIT2015ms3r1) <- fData(hyperLOPIT2015ms3r1)[1:5]
fData(hyperLOPIT2015ms3r2) <- fData(hyperLOPIT2015ms3r2)[3:5]
fvarLabels(hyperLOPIT2015ms3r1)
## [1] "EntryName"  "ProteinDescription" "Peptides1"
## [4] "PSMs1"      "ProteinCoverage1"
fvarLabels(hyperLOPIT2015ms3r2)
## [1] "Peptides2"  "PSMs2"     "ProteinCoverage2"
```

We can now combine the two experiments into a single MSnSet:

```r
combined <- combine(hyperLOPIT2015ms3r1, hyperLOPIT2015ms3r2)
```

```r
combined
## MSnSet (storageMode: lockedEnvironment)
## assayData: 6725 features, 20 samples
## element names: exprs
```
More details about combining data are given in the dedicated *Combining MSnSet instances* section of the *MSnbase* tutorial vignette.

**Missing data**

Missing data are a recurrent issue in mass spectrometry applications, and should be addressed independently of this workflow\[^{11}\]. In 13, we have described how a high content in missing values in spatial proteomics data and their inappropriate handling leads to a reduction of sub-cellular resolution. Missing data can be imputated using *MSnbase*’s `impute` function. The method underlying the imputation method is then determined by a `method` parameter (see `?impute` for available options). To impute missing values using nearest neighbour imputation, one would:

```r
hl <- impute(hl, method = "knn")
```

In our particular case, missing values are indicative of protein groups that were not acquired in both replicates (Figure 4).

We prefer to remove proteins that were not assayed in both replicated experiments. This is done with the `filterNA` function that removes features (proteins) that contain more than a certain proportion (default is 0) missing values. The *Processing information* section summarises how combining and filtering missing values (subsetting) changed the dimensions of the data.

```r
combined <- filterNA(combined)
combined
```

```r
## MSnSet (storageMode: lockedEnvironment)
## assayData: 5032 features, 20 samples
##   element names: exprs

## Combined [6725,20] and [6268,10] MSnSets Mon Dec 5 09:40:22 2016
## MSnbase version: 1.21.7
```
When more than 2 datasets are to be combined and too many proteins have not been consistently assayed, leading to too many proteins being filtered out, we suggest to implement an ensemble of classifiers voting on protein-sub-cellular niche membership over the output of several experiments (see section Supervised machine learning for the description of sub-cellular assignments).

**Quality control**

Data quality is routinely examined through visualisation to verify that sub-cellular niches have been separated along the gradient. Based on De Duve’s principle⁴ proteins that co-localise in a cell, exhibit similar quantitation profiles across the gradient fractions employed. One approach that has been widely used to visualise and inspect high throughput mass spectrometry-based proteomics data is principal components analysis (PCA). PCA is one of many dimensionality reduction methods, that allows one to effectively summarise multi-dimensional data in to 2 or 3 dimensions to enable visualisation. Very generally, the original continuous multi-dimensional data is transformed into a set of orthogonal components ordered according to the amount of variability that they describe. The `plot2D` and `plot3D` methods in pRoloc allows one to plot the principal components (PCs) of a dataset against one another, by default the first two components are plotted on the x- and y-axis for the `plot2D` function, and first three components are loaded for the `plot3D` function, respectively (the `dims` argument can be used to plot other PCs). If distinct clusters are observed, we assume that there is organellar separation present in the data. Although, representing the multi-dimensional data along a limited set of PCs does not give us a hard quantitative measure of separation, it is extremely useful summarising complex experimental information in one figure, to get a simplified overview of the data.

![Figure 4. Heatmap of missing values.](image)

Note that the features are re-ordered to highlight cluster of proteins with similar numbers of missing values.
In the code chunk below we produce a 2-dimensional PCA plot of the mouse stem cell dataset (Figure 5). Each point on the plot represents one protein. We can indeed see several distinct protein clusters. We specify fcol = NULL to ignore feature metadata columns and not annotate any feature (protein) with a colour. We will see later how to use this argument to annotate the PCA plot with prior information about sub-cellular localisation.

```r
library("pRoloc")
plot2D(hl, fcol = NULL, col = "black")
plot2D(hl, method = "hexbin")
```

In the first instance we advise one to visualise their data without any annotation (i.e. with fcol = NULL), before proceeding with data annotation. The identification of well resolved clusters in the data, constitutes an unbiased assessment of the data structure, demonstrating the successful separation of sub-cellular clusters.

It is also useful to visualise the relative intensities along the gradient to identify channels displaying particularly low yield. This can be done using the plotDist and boxplot functions, that plot the protein profiles occupancy along the gradient (we also display the mean channel intensities) and a boxplot of the column intensities. In the two plots displayed on Figure 6, we re-order the TMT channels to pair corresponding channels in the two replicates (rather than ordering the channels by replicate).

**Markers**

In the context of spatial proteomics, a marker protein is defined as a well-known resident of a specific sub-cellular niche in a species and condition of interest. Applying this to machine learning (ML), and specifically supervised learning, for the task of protein localisation prediction, these markers constitute the labelled training data to use as input to a classification analyses. Defining well-known residents, and obtaining labelled training data for ML analyses can be time consuming, but it is important to define markers that are representative of the multivariate data space and on which a classifier will be trained and generated. *pRoloc* provides a convenience function, `addMarkers`, to directly add markers to an MSnSet object, as demonstrated in the code chunk below. These marker sets can be accessed using the `pRolocmarkers()` function. Marker sets are stored as a simple named vector in R, and originate from in-house user-defined sets of markers or from previous published studies\(^1\), which are continuously updated and integrated.

---

**Figure 5.** PCA plot of the mouse stem cell data `hl`. Each dot represents a single protein, and cluster of proteins represent proteins residing in the same sub-cellular niche. The figure on the right bins proteins and represent the bins density to highlight the presence of protein clusters.
## List available marker sets

pRolocmarkers()

## 7 marker lists available:

### Arabidopsis thaliana [atha]:
Id: TAIR, 543 markers

```r
par(mfrow = c(1, 2), # creates a two-panel figure
     las = 2,       # axis labels orientation
     cex.axis = .7) # axis label size
o <- order(hl$Iodixonal.Density)
plotDist(hl[, o], pcol = "#00000001", xlab = "")
lines(colMeans(exprs(hl[, o])), col = "red", type = "b")
boxplot(exprs(hl[, o]))
```

### Drosophila melanogaster [dmel]:
Id: Uniprot, 179 markers

```r
par(mfrow = c(1, 2), # creates a two-panel figure
     las = 2,       # axis labels orientation
     cex.axis = .7) # axis label size
o <- order(hl$Iodixonal.Density)
plotDist(hl[, o], pcol = "#00000001", xlab = "")
lines(colMeans(exprs(hl[, o])), col = "red", type = "b")
boxplot(exprs(hl[, o]))
```

### Gallus gallus [ggal]:
Id: IPI, 102 markers

### Homo sapiens [hsap]:
Id: Uniprot, 872 markers

### Mus musculus [mmus]:
Id: Uniprot, 937 markers

### Saccharomyces cerevisiae [scer_sgd]:
Id: SGD, 259 markers

### Saccharomyces cerevisiae [scer_uniprot]:
Id: Uniprot Accession, 259 markers

These markers can then be mapped to an MSnSet’s `featureNames`. The mouse dataset used here has Uniprot IDs stored as the `featureNames` (see `head(featureNames(hl))) and the names of the vector of the mouse markers stored in `pRoloc` (mmus markers) are also Uniprot IDs (see `head(mrk)`) in the code chunk below, that displays the 6 first markers, so it is straightforward to match names between the markers and the MSnSet instance using the `addMarkers` function.

---

**Figure 6.** Protein profiles and distribution of channel intensities. The red dots represent the mean relative intensity for each channel.
## Use mouse markers

```r
mrk <- pRolocMarkers(species = "mmus")
```

```r
head(mrk)
```

```r
##                  P26039/Q6PB66/P11276
##   "Actin cytoskeleton"  "Mitochondrion"  "Extracellular matrix"
##   "Actin cytoskeleton"  "Mitochondrion"  "Extracellular matrix"
##                  Q6PR54/Q0793/P19096
##   "Nucleus - Chromatin"  "Extracellular matrix"  "Cytosol"
```

## Add mouse markers

```r
hl <- addMarkers(hl, mrk)
```

## Markers in data:  937 out of 5032

```r
## organelleMarkers
##                  40S Ribosome 60S Ribosome Actin cytoskeleton
##                  27          43            13
##                  Cytosol   Endoplasmic reticulum Endosome
##                  43          95             12
##                 Extracellular matrix Golgi apparatus Lysosome
##                  10          27             33
##                 Mitochondrion Nucleus - Chromatin Nucleus - Non-chromatin
##                  383         64             85
##                 Peroxisome Plasma membrane Proteasome
##                  17          51             34
##                  unknown
##                  4095
```

We recommend at least 13 markers per sub-cellular class (see the Optimisation section for details about the algorithmic motivation of this number). Markers should be chosen to confidently represent the distribution of genuine residents of a sub-cellular niche. We generally recommend a conservative approach in defining markers to avoid false assignments when assigning sub-cellular localisation of proteins of unknown localisation. A more relaxed definition of markers, i.e. one that broadly or over-confidently defines markers, risks the erroneous assignment of proteins to a single location, when, in reality, they reside in multiple locations (including the assumed unique location). One can not expect to identify exact boundaries between sub-cellular classes through marker annotation alone; the definition of these boundaries is better handled algorithmically, i.e. after application of the supervised learning algorithm, using the prediction scores (as described in the Classification section, in particular Figure 16).

If the protein naming between the marker sets and the MSnSet dataset are different e.g. the markers are labelled by Uniprot accession numbers and the dataset entries are labelled by Uniprot entry names, one will have to convert and match the proteins according to the appropriate identifier. Sometimes, we find the equivalent entry name, Uniprot ID or accession number is stored in the feature metadata, which makes conversion between identifiers relatively straightforward. If this is not the case however, conversion can be performed using biomaRt, the Bioconductor annotation resources or any conversion softwares available online.

### Adding user-defined marker lists

It is also possible for users to use their own marker list with the addMarkers function. The user needs to create a named vector of marker localisation, or a create a csv file with two columns (one for the protein names, one for the corresponding sub-cellular marker annotation) and pass the vector or file name respectively to the function. As previously mentioned, the protein names of these markers must match some (but not necessarily all) of the MSnSet’s feature names. See ?addMarkers for more details.

In general, the Gene Ontology (GO)⁵, and in particular the cellular compartment (CC) namespace are a good starting point for protein annotation and marker definition. It is important to note however that automatic retrieval of sub-cellular localisation information, from pRoloc or elsewhere, is only the beginning in defining a marker set for downstream analyses. Expert curation is vital to check that any annotation added is in the correct context for the biological question under investigation.
Visualising markers

Having added all the mouse markers to our pData from the pRolocmarkers, we can now visualise these annotations along the PCA plot using the plot2D function and then use the addLegend function to map the marker classes to the pre-defined colours. We also display the data along the first and seventh PCs using the dms argument. Note that these calls to the plot2D function, we have omitted the fcol argument and use of the default “markers” feature variable to annotate the plot. We choose to display PCs 1 and 7 to illustrate that while upper principal components explain much less variability in the data (2.23% for PC7, as opposed to 48.41% for PC1), we see that the mitochondrial (purple) and peroxisome (dark blue) clusters can be differentiated, despite the apparent overlap in the visualisation of the two first PCs (Figure 7).

The data can also be visualised along three PCs using the plot3D function (Figure 8). When produced interactively, the plot can be rotated and zoomed in using the mouse.

**Figure 7.** Annotated PCA plots of the h1 dataset, as produced with plot2D.

**Figure 8.** Using the plot3D function to visualise the h1 dataset along PCs 1, 2 and 7.
par(mfrow = c(1, 2))
plot2D(hl, main = "pRolocmarkers for mouse")
addLegend(hl, cex = .6)
plot2D(hl, dims = c(1, 7), main = "Marker resolution along PC 1 and 7")

The default colours for plotting have been defined so as to enable the differentiation of up to 30 classes. If more are provided, different character symbols (circles, squares, and empty and solid symbols) are used. The colours and the default plotting characters (solid dots for the markers and empty circles for the features of unknown localisation) can of course be changed, as described in the setStockcol manual page.

As demonstrated in 3 and illustrated in the PCA plot (Figure 7), the Golgi apparatus proteins (dark brown) display a dynamic pattern, noting sets of Golgi marker proteins that are distributed amongst other subcellular structures, an observation supported by microscopy. As such, we are going to reset the annotation of Golgi markers to unknown using the fDataToUnknown function. It is often used to replace empty strings (" ") or missing values in the markers definition to a common definition of unknown localisation.

hl <- fDataToUnknown(hl, from = "Golgi apparatus", to = "unknown")
getMarkers(hl)

Another useful visualisation that relies on marker annotation is the representation of the protein profiles occupancy along the gradient using the plotDist function. While the PCA plot enables efficient visualisation of the complete dataset and assessment the relative separation of different sub-cellular niches, comparing profiles of a few marker clusters is useful to assess how exactly they differ (in terms of peak channels, for example). On Figure 9, we plot the profile of the mitochondrial and peroxisome markers to highlight the differences in profiles between these two sets of markers in the channels labelled with tag 129C, as represented above along the 7th PC on the PCA plot on Figure 7.

Figure 9. Mitochondrion and peroxisome protein profiles.
plot3D(hl, dims = c(1, 2, 7))

hlo <- hl[, order(hl$IODixonal.Density)]
plotDist(hlo[fd(hlo)$markers == "Mitochondrion", ],
         pcol = "purple", fractions = "Tag")
title(main = "Marker occupancy profiles along the gradient")
matlines(t(exprs(hlo[fd(hlo)$markers == "Peroxisome", ])),
         lty = 1, col = "darkblue", type = "l")
legend("topleft", c("Mitochondrion", "Peroxisome"),
       lty = 1, col = c("purple", "blue"), bty = "n")

Finally, in addition to plot2D, the plot3D function allows to interactively explore a 3-dimensional plot of the data.

**Features of interest**

In addition to adding annotation using the addMarkers function, one can store specific sets of proteins by using the Features of interest infrastructure from the MSnbase package. If users have specific subsets of proteins they wish to highlight in their data (possibly across multiple experiments) they would first create a FeaturesOfInterest object. For example, if we wanted to highlight a proteins with the accession numbers Q8CG48, Q8CG47, Q8K2Z4, and Q8C156, which are some of the proteins known to form part of the 13S condensin complex, we would create a first create a FeaturesOfInterest object, and subsequently highlight their location on a PCA plot with the highlightOnPlot function.

prots <- c("Q8CG48", "Q8CG47", "Q8K2Z4", "Q8C156")
foi13s <- FeaturesOfInterest(description = "13S consensin proteins",
                          fnames = prots,
                          object = hl)

plot2D(hl)
addLegend(hl, cex = .6)
highlightOnPlot(hl, foi13s)

Users can also create several sets of FeaturesOfInterest object and store them in a FoICollection.

It is also worthy of note that it is possible to search for a specific protein of interest by featureNames or using any identifying information found in the fData columns by using the search box on the pRolocVis application part of the pRolocGUI package (see section on interactive visualisation). This can be handy for quickly searching and highlighting proteins on the fly, the disadvantage here is that proteins can only be searched for a one-by-one basis.

**Replication**

With the aim of maximising the sub-cellular resolution and, consequently, the reliability in protein sub-cellular assignments, we follow the advice in 10 and combine replicated spatial proteomics experiments as described above. Indeed, Trotter et al. have shown a significant improvement in protein–organelle association upon direct combination of single experiments, in particular when these resolve different subcellular niches.

Direct comparisons of individual channels in replicated experiments does not provide an adequate, goal-driven assessment of different experiments. Indeed, due to the nature of the experiment and gradient fraction collection, the quantitative channels do not correspond to identical selected fractions along the gradient. For example, in the table below (taken from hl's pData) TMT channels 127C (among others) in both replicates originate from different sets of gradient fractions (gradient fractions 7 – 9 and 8 – 9 for each replicate, respectively). Different sets of gradient fractions are often pooled to obtain enough material and optimise accurate quantitation.
Figure 10. Highlighting protein features of interest.

Table 1. Differences in gradient fraction pooling.

| Replicate | Tag | Gradient.Fraction | Iodixonal.Density |
|-----------|-----|-------------------|-------------------|
| X127C     | 1   | 127C 8 to 9 (pooled) | 11.00            |
| X127C.1   | 2   | 127C 7 to 9 (pooled) | 10.00            |

The more relevant comparison unit is not a single channel, but rather the complete protein occupancy profiles, which are best visualised experiment-wide on a PCA plot. As such, we prefer to focus on the direct, qualitative comparison of individual replicate PCA plots, assuring that each displays acceptable sub-cellular resolution. Note that in the code chunk below, we mirror the x-axis to represent the two figures with the same orientation. The interactive “compare” application part of the pRolocGUI package is also useful for examining replicate experiments (see the next section interactive visualisation for details).

```r
par(mfrow = c(1, 2))
plot2D(hl[, hl$Replicate == 1], main = "Replicate 1")
plot2D(hl[, hl$Replicate == 2], main = "Replicate 2", mirrorX = TRUE)
```

In addition, the reproducibility can be assessed by performing independent classification analyses on each replicate (see the section on Supervised machine learning below) and comparing the results. Even when the gradient conditions differ (for unexpected technical or voluntary reasons, to maximise resolution when combining experiments), one expects agreement in the most confident organelle assignments.
Interactive visualisation

Visualisation and data exploration is an important aspect of data analyses allowing one to shed light on data structure and patterns of interest. Using the pRolocGUI package we can interactively visualise, explore and interrogate quantitative spatial proteomics data. The pRolocGUI package is currently under active development and it relies on the shiny framework for reactivity and interactivity. The package currently distributes 3 different GUI’s (main (default), compare or classify) which are wrapped and launched by the pRolocVis function.

The main application

In the code chunk below we launch the main app (note, we do not need to specify the argument, app = "main" as it is the default).

```r
library("pRolocGUI")
pRolocVis(h1)
```

As displayed in the screenshot in Figure 12, the main application is designed for exploratory data analysis and is divided into 3 tabs: (1) PCA, (2) Profiles and (3) Table selection. The default view upon loading is the PCA tab, which features a clickable interface and zoomable PCA plot with an interactive data table for displaying the quantitation information. Particular proteins of interest can be highlighted using the text search box. There is also a Profiles tab for visualisation of the protein profiles, which can be used to examine the patterns of proteins of interest. The Table selection tab provides an interface to control data table column selection. A short animation [https://github.com/Lmsimp/bioc-pRoloc-hyperLOPIT-workflow/blob/master/Figures/pRolocVis_pca.gif](https://github.com/Lmsimp/bioc-pRoloc-hyperLOPIT-workflow/blob/master/Figures/pRolocVis_pca.gif) illustrating the interface is available in the manuscript repository16.

The compare application

The compare application is useful for examining two replicate experiments, or two experiments from different conditions, treatments etc. The compare application is called by default if the input object to pRolocVis is an MSnSetList of 2 MSnSets, but it can also be specified by calling the argument app = "compare". For example, in the code chunk below we first create an MSnSetList of replicates 1 and 2 of the hyperLOPIT data, this is then passed to pRolocVis.

```r
data(hyperLOPIT2015ms3r1)
data(hyperLOPIT2015ms3r2)
h1list <- MSnSetList(list(hyperLOPIT2015ms3r1, hyperLOPIT2015ms3r2))
pRolocVis(h1list, app = "compare")
```
Figure 12. A screen shot of clickable interface and zoomable PCA plot of the main app in the pRolocGUI package.

Figure 13. The compare application, main panel.
The comparison app loads the two PCA plots side-by-side. Only common proteins between the two datasets are displayed. As per the main application, proteins can be searched, identified and highlighted on both PCA plots and in the dedicated profiles tab. One key feature of the compare application is the ability to re-map the second dataset onto the PCA data space of the first (reference) dataset (see \texttt{pRolocVis} and the argument \texttt{remap = TRUE}). Using the first dataset as the reference set, PCA is carried out on the first dataset and the standard deviations of the PCs (i.e. the square roots of the eigenvalues of the covariance/correlation matrix) and the matrix of variable loadings (i.e. a matrix whose columns contain the eigenvectors) are stored and then used to calculate the principal components of the second dataset. Both datasets are scaled and centered in the usual way. The first dataset appears on the left, and the second re-mapped data appears on the right. The order of the first (the reference data for remapping) and second dataset can be changed through regeneration/re-ordering of the MSnSetList object.

\textbf{The classify application}

The final application \textit{classify}, has been designed to view machine learning classification results according to user-specified thresholds for the assignment of proteins to its sub-cellular location, as discussed later in the subsection \textit{thresholding} in the \textit{supervised machine learning section}.

\textbf{Novelty detection}

The extraction of sub-cellular protein clusters can be difficult owing to the limited number of marker proteins that exist in databases and elsewhere. Furthermore, given the vast complexity of the cell, automatic annotation retrieval does not always give a full representation of the true sub-cellular diversity in the data. For downstream analyses, such as supervised ML, it is desirable to obtain reliable markers that cover as many sub-cellular niches as possible, as these markers are directly used in the training phase of the ML classification. We find that a lack of sub-cellular diversity in the labelled training data leads to prediction errors, as unlabelled instances can only be assigned to a class that exists in the training data\textsuperscript{17}. In such scenarios, novelty detection can be useful to identify data-specific sub-cellular groupings such as organelles and protein complexes. The phenotype discovery (phenoDisco) algorithm\textsuperscript{17} is one such method and is available in \texttt{pRoloc}. It is an iterative semi-supervised learning method that combines the classification of proteins on existing labelled data with the detection of new clusters.

In addition to extracting new phenotypes, novelty detection methods are also useful for confirming the presence of known or postulated clusters in an unbiased fashion. For example, in \textsuperscript{3} the \texttt{phenoDisco} algorithm was used to confirm the data-specific presence of the nucleus and nucleus sub-compartments. In the code chunk below, we demonstrate how to do this analysis, highlighting some of the optional arguments and parameters available for phenotype extraction and give some advice on how to interpret the output.

As the \texttt{phenoDisco} algorithm is semi-supervised it uses both labelled (markers) and unlabelled data to explore the data structure and find new sub-cellular data clusters. Thus the first step is to define some input labelled data i.e. markers, that the algorithm will use as input for the supervised learning aspect of the algorithm. As described in \textsuperscript{3} we define a set of markers to use as input for the analyses that cover well-known residents from three distinct organelle structures; the mitochondria, plasma membrane and ER, and from three well-known and abundant protein complexes; the proteasome and two ribosomal subunits, 40S and 60S. These input markers are stored in the featureData column of \texttt{hl} where \texttt{fcol = "phenoDisco.Input"}. We can use the convenience accessor function \texttt{getMarkers} to print out a table of the markers contained in this marker set. These initial markers were manually curated using information from the UniProt database, the Gene Ontology and the literature.

\begin{verbatim}
getMarkers(hl, fcol = "phenoDisco.Input")
## organelleMarkers
##                          40S Ribosome
##                                    26
##                          60S Ribosome
##                                    43
## Endoplastic reticulum/Golgi apparatus
##                                    76
##                         Mitochondrion
##                                   261
##                       Plasma membrane
##                                    50
##                          Proteasome
##                                    34
## unknown
##                                  4542
\end{verbatim}
In the code chunk below we show how to run the `phenoDisco` function and return a novelty detection result, according to the specified parameters. The algorithm parameters `times` (number of iterations) and `GS` (minimum number of proteins required to form a new phenotype) are passed to the function, along with the `fcol` to tell the algorithm where the input training data is contained.

```r
# As per Christoforou et al (2016),
hl <- phenoDisco(hl, fcol = "phenoDisco.Input", times = 200, GS = 60)
```

Note: We do not evaluate this code chunk in this document as the algorithm is computationally intensive and best parallelised over multiple workers. This phenoDisco analysis took 24 hours to complete when parallelised over 40 workers.

The argument `times` indicates the number of times we run unsupervised Gaussian Mixture Modelling before defining a new phenotype cluster. The recommended minimum and default value is 100. In the above code chunk we increase the value to `times = 200` as we have found for larger datasets (e.g. 5000+ proteins) a higher `times` is required for convergence. `GS` defines the minimum number of proteins allowed per new data cluster and thus heavily influences what type of new clusters are extracted. For example, if a user is interested in the detection of small complexes they may wish to use a small `GS = 10`, or `GS = 20` etc. If they wish to detect larger, more abundant sub-cellular niches a much higher `GS` would be preferable. Specifying a small `GS` can be more time consuming than using a larger `GS`, and there is a trade off between finding interesting small complexes and those that may not be of interest as we find there is a tendency to find more noise when using a small `GS` compared to using a higher one.

One may also consider increasing the search space for new data clusters by increasing the value of the parameter `G`. This defines the number of GMM components to test and fit; the default is `G = 1:9` (the default value in the `mclust` package¹). One should note that the decreasing the `GS`, and increasing the values of the arguments `times,G`(among other function arguments, see `?phenoDisco`) will heavily influence (increase) the total time taken to run the algorithm. `phenoDisco` supports parallelisation and we strongly suggest you make use of a parallel processing to run these analyses.

The output of running the `phenoDisco` algorithm is an `MSnSet` containing the new data clusters, appended to the `featureData` under the name `pd`. The results can be displayed by using the `getMarkers` function. We see that 5 new phenotype data clusters were found.

```r
hl

##   fvarMetadata: labelDescription
## experimentData: use 'experimentData(object)'
## Annotation:
##   - - - Processing information - - -
## Added markers from 'mrk' marker vector. Mon Dec 5 09:40:24 2016
## Added markers from 'pdres' marker vector. Mon Dec 5 09:40:25 2016
## MSnbase version: 2.1.4
```
We can plot the results using the `plot2D` function (Figure 14). The five new phenotype data clusters can be extracted and examined. In the code chunk below we write the results to a csv file using the `write.exprs` function. We use the argument `fDataCols` to specify which columns of the `featureData` to write.

```r
## Re-order the colours for the phenoDisco output
cl <- getMarkerClasses(hl, "pd")
cols <- getStockcol()[seq(cl)]
ind <- grep("Pheno", cl, invert = TRUE)
cols[ind] <- getStockcol()[seq(cl)][1:length(ind)]
cols[-ind] <- getStockcol()[(seq(cl))[length(ind) + 1]:length(cl)]

## Plot the input and output
par(mfrow = c(1, 2))
plot2D(hl, fcol = "phenoDisco.Input",
       main = "phenoDisco input markers", col = getStockcol()[1:6])
addLegend(hl, fcol = "phenoDisco.Input", cex = .7)
plot2D(hl, fcol = "pd", main = "phenoDisco output", col = cols)
addLegend(hl, fcol = "pd", cex = .7, col = cols)
fData(hl)$pd <- as.character(fData(hl)$pd)
write.exprs(hl, fDataCols = "pd", file = "pd-results.csv", sep = ",")
```

We can also examine each phenotype interactively and visualise their protein profiles by using the `pRolocVis` function in the `pRolocGUI` package. We found that phenotype 1 was enriched in nucleus associated proteins, phenotype 2 in chromatin associated proteins, phenotype 3 in cytosolic and phenotypes 4 and 5 in both lysosomal and endosomal proteins.
Supervised machine learning

Supervised machine learning, also known as classification, is an essential tool for the assignment of proteins to distinct sub-cellular niches. Using a set of labelled training examples i.e. markers, we can train a machine learning classifier to learn a mapping between the data i.e. the quantitative protein profiles, and a known localisation. The trained classifier can then be used to predict the localisation of a protein of unknown localisation, based on its observed protein profiles. To date, this method has been extensively used in spatial quantitative proteomics to assign thousands of proteins to distinct sub-cellular niches.

There are several classification algorithms readily available in pRolo, which are documented in the dedicated pRolo machine learning techniques vignette. We find the general tendency to be that it is not the choice of classifier, but the improper optimisation of the algorithmic parameters, that limits classification accuracy. Before employing any classification algorithm and generating a model on the training data, one must first find the optimal parameters for the algorithm of choice.

Optimisation

In the code chunk below we use a Support Vector Machine (SVM) to learn a classifier on the labelled training data. As previously mentioned, one first needs to train the classifier’s parameters before an algorithm can be used to predict the class labels of the proteins with unknown location. One of the most common ways to optimise the parameters of a classifier is to partition the labelled data into training and testing subsets. In this framework parameters are tested via a grid search using cross-validation on the training partition. The best parameters chosen from the cross-validation stage are then used to build a classifier to predict the class labels of the protein profiles on the test partition. Observed and expected classification results can be compared, and then used to assess how well a given model works by getting an estimate of the classifiers ability to achieve a good generalisation i.e. that is given an unknown example predict its class label with high accuracy. In pRolo, algorithmic performance is estimated using stratified 80/20 partitioning for the training/testing subsets respectively, in conjunction with five-fold cross-validation in order to optimise the free parameters via a grid search. This procedure is usually repeated 100 times and then the best parameter(s) are selected upon investigation of classifier accuracy. We recommend a minimum of 13 markers per sub-cellular class for stratified 80/20 partitioning and 5-fold cross-validation; this allows a minimum of 10 examples for parameter optimisation on the training partition i.e. 2 per fold for 5-fold cross-validation, and then 3 for testing the best parameters on the validation set.

Classifier accuracy is estimated using the macro F1 score, i.e. the harmonic mean of precision and recall. In the code chunk below we demonstrate how to optimise the free parameters, sigma (the inverse kernel width for the radial basis kernel) and cost (the cost of constraints violation), of a classical SVM classifier with a Gaussian kernel using the function svmOptimisation. As the number of labelled instances per class varies from organelle to organelle, we can account for class imbalance by setting specific class weights when generating the SVM model. Below the weights, \( w \) are set to be inversely proportional to the class frequencies.
\[
\begin{align*}
\text{w} & \leftarrow \text{table(getMarkers(hl, verbose = TRUE))} \\
\text{## organelleMarkers} \\
\text{##} & \quad \text{40S Ribosome} \quad \text{60S Ribosome} \quad \text{Actin cytoskeleton} \\
\text{##} & \quad 27 \quad 43 \quad 13 \\
\text{##} & \quad \text{Cytosol} \quad \text{Endoplasmic reticulum} \quad \text{Endosome} \\
\text{##} & \quad 43 \quad 95 \quad 12 \\
\text{##} & \quad \text{Extracellular matrix} \quad \text{Lysosome} \quad \text{Mitochondrion} \\
\text{##} & \quad 10 \quad 33 \quad 383 \\
\text{##} & \quad \text{Nucleus - Chromatin} \quad \text{Nucleus - Non-chromatin} \quad \text{Peroxisome} \\
\text{##} & \quad 64 \quad 85 \quad 17 \\
\text{##} & \quad \text{Plasma membrane} \quad \text{Proteasome} \quad \text{unknown} \\
\text{##} & \quad 51 \quad 34 \quad 4122 \\
\text{w} & \leftarrow \text{1/names(w) != "unknown"} \\
\text{## 100 rounds of optimisation with five-fold cross-validation} \\
\text{params} & \leftarrow \text{svmOptimisation(hl, fcol = "markers",} \\
\text{\quad times = 100, xval = 5,} \\
\text{\quad class.weights = w)} \\
\end{align*}
\]

As mentioned previously, we rely on the default feature variable "markers" to define the class labels and hence do not need to specify it in the above code chunk. To use another feature variables, one needs to explicitly specify its name using the \text{fcol} argument (for example \text{fcol = "markers2"}).

The output params is an object of class GenRegRes; a dedicated container for the storage of the design and results from a machine learning optimisation. To assess classifier performance we can examine the macro F1 scores and the most frequently chosen parameters. A high macro F1 score indicates that the marker proteins in the test dataset are consistently and correctly assigned by the algorithm. Often more than one parameter or set of parameters gives rise to the best generalisation accuracy. As such it is always important to investigate the model parameters and critically assess the best choice. The f1Count function counts the number of parameter occurrences above a certain F1 value. The best choice may not be as simple as the parameter set that gives rise to the highest macro F1 score. One must be careful to avoid overfitting, and choose parameters that frequently provide high classification accuracy. Below, we see that only a sigma of 0.1 produces macro F1 scores above 0.6, but that a cost of 16 is much more frequently chosen than lower values.

\[
\text{f1Count(params, 0.6)} \\
\text{##} & \quad 4 \quad 8 \quad 16 \\
\text{##} & \quad 0.1 \quad 1 \quad 10 \quad 89 \\
\]

The parameter optimisation results can also be visualised as a boxplot or heatmap, as shown in Figure 15. The plot method for GenRegRes object shows the respective distributions of the 100 macro F1 scores for the best cost/sigma parameter pairs, and levelPlot shows the averaged macro F1 scores, for the full range of parameter values. These figures also indicate that values of 0.1 and 16 for sigma and cost consistently deliver better classification scores.

\[
\text{plot(params)} \\
\text{levelPlot(params)} \\
\]

By using the function \text{getParams} we can extract the best set of parameters. Currently, \text{getParams} retrieves the first best set automatically, but users are encouraged to critically assess whether this is the most wise choice (which it is, as demonstrated above).

\[
\text{(best \leftarrow getParams(params))} \\
\text{## sigma cost} \\
\text{##} & \quad 0.1 \quad 16.0 \\
\]

Once we have selected the best parameters we can then use them to build a classifier from the labelled marker proteins.
Classification

We can use the function `svmClassification` to return a classification result for all unlabelled instances in the dataset corresponding to their most likely sub-cellular location. The algorithm parameters are passed to the function, along with the class weights. As above, the `fcol` argument does not need to be specified as we use the labels defined in the default "markers" feature variable.

```r
hl <- svmClassification(hl, params, class.weights = w, fcol = "markers")
```

In the code chunk above, we pass the whole `params` parameter results and, internally, the first pair that return the highest F1 score are returned (using the `getParams` function above). It is advised to always check that these are actually good parameters and, if necessary, set them explicitly, as shown below.

```r
hl <- svmClassification(hl, cost = 16, sigma = 0.1, class.weights = w, fcol = "markers")
```

Automatically, the output of the above classification, the organelle predictions and assignment scores, are stored in the `featureData` slot of the `MSnSet`. In this case, they are given the labels `svm` and `svm.scores` for the predictions and scores respectively. The resultant predictions can be visualised using `plot2D`. In the code chunk below `plot2D` is called to generate a PCA plot of the data and `fcol` is used to specify where the new assignments are located e.g. `fcol = "svm"`.

Additionally, when calling `plot2D` we can use the `cex` argument to change the size of each point on the plot to be inversely proportional to the SVM score. This gives an initial overview of the high scoring localisations from the SVM predictions.

---

**Figure 15.** Assessment of the classification model parameter optimisation.
The adjustment of the point size intuitively confers important information that is more difficult to define formally (we will address in the next section). The classifier (SVM in our case, but this is also valid of other classifiers) defines boundaries based on the labelled marker proteins. These class/organelle boundaries define how non-assigned proteins are classified and with what confidence.

**Thresholding**

It is common when applying a supervised classification algorithm to set a specific score cutoff on which to define new assignments, below which classifications are kept unknown/unassigned. This is important as in a supervised learning setup, proteins can only be predicted to be localised to one of the sub-cellular niches that appear in the labelled training data. We can not guarantee (and do not expect) that the whole sub-cellular diversity to be represented in the labelled training data as (1) finding markers that represent the whole diversity of the cell is challenging (especially obtaining dual- and multiply-localised protein markers) and (2) many sub-cellular niches contain too few proteins to train on (see above for a motivation of a minimum of 13 markers).

Deciding on a threshold is not trivial as classifier scores are heavily dependent upon the classifier used and different sub-cellular niches can exhibit different score distributions, as highlighted in the boxplot below. We recommend users to set class-specific thresholds. In the code chunk below we display a boxplot of the score distributions per organelle (Figure 17).

There are many ways to set thresholds and the choice of method will depend on the biological question and experimental design at hand. One viable approach in the frame of the above experimental design would be to manually set a FDR, say 5%, per organelle. To do this the user would examine the top scoring predictions for each organelle, and then set a threshold at the score at which they achieve 5% of false assignments per organelle. The definition of a false assignment would depend on the information available, for example, validity or lack of validity for the localisation from another experiment as reported in the literature or a reliable database. If such information is not available, one crude method is to set a threshold per organelle by extracting the median or 3rd quantile score per organelle. For example, in the code chunk below, we use the `orgQuants` function to extract the median organelle scores and then pass these scores to the `getPredictions` function to extract the new localisations that meet this scoring criteria. Any sub-cellular predictions that fall below the specified thresholds are labelled as unknown.

![Figure 16. Classification results.](image-url) Colours indicate class membership and point size are representative of the classification confidence.
Figure 17. Visualization of class-specific classification score distribution.

```R
(ts <- orgQuants(hl, fcol = "svm", scol = "svm.scores", mcol = "markers", t = .5))

## ans
##            40S Ribosome            60S Ribosome   Actin cytoskeleton
##                      85                     70                   92

Figure 17. Visualization of class-specific classification score distribution.

```
## First remove the markers
```r
preds <- unknownMSnSet(hl)
```
## Plot a boxplot of the scores of each organelle
```r
par(oma = c(10.5, 0, 0, 0)) ## sets outer margins
boxplot(svm.scores ~ svm, data = fData(preds),
       ylab = "SVM scores", las = 2)
```

| Organelle                      | Cytosol | Endoplasmic reticulum | Endosome |
|--------------------------------|---------|-----------------------|----------|
| Extracellular matrix           | 296     | 478                   | 96       |
| Nucleus - Chromatin            | 27      | 125                   | 523      |
| Nucleus - Non-chromatin        | 320     | 343                   | 39       |
| Plasma membrane                | 313     | 158                   | 2057     |

The organelle threshold (ts above) can also be set manually using an interactive app (see below) or by using a named vector of thresholds, as shown in the putative example below for 4 organelles.
```r
(ts <- setNames(c(0.612, 0.701, 0.81, 0.92), c("PM", "Mito", "Golgi", "ER")))
```

The output of `getPredictions` is the original MSnSet dataset with a new feature variable appended to the feature data called `fcol.pred` (i.e. in our case `svm.pred`) containing the prediction results. The results can also be visualised using `plot2D` function (Figure 18) and extracted by retrieving that specific column from the feature metadata using, for example, `fData(hl)$svm.pred`.
```r
plot2D(hl, fcol = "svm.pred")
```

There is also a dedicated interactive application to help users examine these distributions in the `pRolocGUI` package (Figure 19). This app can be launched via the `pRolocVis` function and specifying the argument

![Figure 18. Results of the localisation predictions after thresholding.](image-url)
app = "classify" along with the relevant fcol, scol and mcol which refer to the columns in the feature data that contain the new assignments, assignment scores and markers respectively (see also fvarLabels(svmres)).

library("pRolocGUI")
pRolocVis(hl, app = "classify", fcol = "svm", scol = "svm.scores", mcol = "markers")

The data is loaded and displayed on a PCA plot and a boxplot is used to display the classifier scores by data class. On the left, there is a sidebar panel with sliders to control the thresholds upon which classifications are made. There are two types of cut-off that the user can choose from: (1) Quantile and (2) User-defined. By default, when the application is launched quantile scoring is selected and set to 0.5, the median. The class-specific score thresholds that correspond to selecting the desired quantile are shown as red dots on the boxplot. The assignments on the PCA plot are also updated according to the selected threshold. The quantile threshold can be set by moving the corresponding quantile slider. If the users wishes to set their own cut-offs, the User-defined radio button must be selected and then the sliders for defining user-specified scores become active and the scores are highlighted on the boxplot by blue dots. For more information we refer users to the pRolocGUI tutorial vignette.

**Transfer learning**

In addition to high quality MS-based quantitative proteomics data, there exist a number of other sources of information that are freely available in the public domain that may be useful to assign a protein to its sub-cellular niche. For example, imaging from immunofluorescence microscopy, protein annotations and sequences, and protein-protein interactions among others, represent a rich and vast source of complementary information. We can integrate this auxiliary information with our primary MS-based quantitative data using a paradigm known as transfer learning (TL). The integration of data between different technologies is one of the biggest challenges in computational biology to date and the pRoloc package provides functionality to do such analyses. We recently developed two TL algorithms using a k-NN and SVM framework and applied them to the task of protein localisation prediction. In this section we will begin with explaining the concept of TL and then show how to apply this in the frame of spatial proteomics and protein localisation prediction.

In TL one typically has a primary task that one wishes to solve, and some complementary (often heterogeneous) auxiliary information that is related to the primary learning objective, that can be used to help solve the primary goal.

![Classification results](image)

**Figure 19.** The classify application enables the interactive exploration of classification score thresholding.
For example, here our primary task is to assign proteins to their sub-cellular niche with high generalisation accuracy from data collected from quantitative MS-based experiments. We have already seen that straightforward supervised ML works well for these types of experiments, however, TL is particularly useful for classes that are not as well separated.

In the example below we extract GO information to use as an auxiliary data source to help solve our task of protein localisation prediction.

Using the functions `setAnnotationParams` and `makeGoSet` we can construct an auxiliary MSnSet of GO terms, from the primary data’s features i.e. the protein accession numbers. All the GO terms associated to each accession number are retrieved and used to create a binary matrix where a 1 (0) at position \((i, j)\) indicates that term \(j\) has (not) been used to annotate protein \(i\). The GO terms are retrieved from an appropriate repository using the `biomaRt` package. The specific Biomart repository and query will depend on the species under study and the type of identifiers. The first step is to construct the annotation parameters that will enable to perform the query, which is done using `setAnnotationParams`. Typing into the R console `par <- setAnnotationParams()` will present two menus, firstly asking you to identify the species of study, and then what type of identifier you have used to annotate the proteins in your MSnSet. It is also possible to pass arbitrary text to match the species e.g. in the code chunk below we pass "Mus musculus", and the identifier type for our data (see `featureNames(hl)`) which is "Uniprot/Swissprot", for the Biomart query.

```
par <- setAnnotationParams(inputs = c("Mus musculus", "UniProt/Swissprot"))
```

Now we have contructed the query parameters we can use the `makeGoSet` function to retrieve and build an auxiliary GO MSnSet as described above. By default, the cellular component terms are downloaded, without any filtering on evidence codes. It is also possible to download terms from the molecular function and biological process GO namespaces, and also apply filtering based on evidence codes as desired, see `?makeGoSet` for more details.

```
gocc <- makeGoSet(hl, params = par, namespace = "cellular_component")
```

The function `makeGoSet` uses the `biomaRt` package to query the relevent database (e.g. Ensembl, Uniprot) for GO terms. All GO terms that have been observed for the 5032 proteins in the hyperLOPIT dataset are retrieved. Users

![Figure 20. Visualisation of the transfer learning parameter optimisation procedure.](image)

Each row displays the frequency of observed weights (along the columns) for a specific sub-cellular class, with large dots representing higher observation frequencies.
should note that the number of GO terms used is also dependent on the database version queried and thus is always subject to change. We find it is common to see GO terms with only one protein assigned to that term. Such terms do not bring any information for building the classifier and are thus removed using the `filterBinMSnSet` function.

gocc <- filterBinMSnSet(hl)

Now that we have generated our auxiliary data, we can use the \( k \)-NN implementation of transfer learning available in \textit{pRolo} to integrate this with our primary MS-based proteomics data using the functions `knn1Optimisation` to estimate the free-parameters for the integration, and `knn1Classification` to do the predictions. We have shown that using transfer learning results in the assignment of proteins to sub-cellular niches with a higher generalisation accuracy than using standard supervised machine learning with a single source of information\(^{23}\).

**TL optimisation**
The first step, as with any machine learning algorithm, is to optimise any free parameters of the classifier. For the \( k \)-NN TL classifier there are two sets of parameters that need optimising: the first set are the \( k \)'s for the primary and auxiliary data sources required for the nearest neighbour calculations for each data source. The second set of parameters (noted by a vector of \( \theta \) weights) that require optimising are the class weights, one per subcellular niche, that control the proportion of primary and auxiliary data to use for learning. A weight can take any real value number between 0 and 1. A weight of \( \theta = 1 \) indicates that all weight is given to the primary data (and this implicitly implies that a weight of \( 1 - \theta = 0 \) is given to the auxiliary data), and similarly a weight of \( \theta = 0 \) implies that all weight is given to the auxiliary data (so 0 is given to the primary source). If we conduct a parameter search and test weights \( \theta = 0, 1/3, 2/3, 1 \) for each class, and if we have, for example 10 subcellular niches, this will result in \( 4^{10} \) different combinations of parameters to test. The parameter optimisation is therefore time consuming and as such we recommend making use of a computing cluster (code and submissing scripts are also available in the supporting information). The markers in the \textit{hl} dataset contain 14 subcellular classes. If we examine these markers and classes on the PCA plot above we can see that in particular the two ribosomes and two nuclear compartments are highly separated along the first two components, this is also evident from the profiles plot which gives us a good indication that these subcellular niches are well-resolved in the hyperLOPIT dataset. Transfer learning is particularly useful for classes that are not as well separated. We find that subcellular niches that are well-separated under hyperLOPIT and LOPIT obtain a class score of 1 (i.e. use only primary data from transfer learning\(^{23}\)). Therefore, for the optimisation stage of the analyses we can already infer a subcellular class weight of 1 for these niches and only optimise over the remaining organelles. This can significantly cut down optimisation time as by removing these 4 classes from the optimisation (and not the classification) we only have \( 4^{10} \) class weight combinations to consider instead of \( 4^{14} \) combinations.

In the example below we remove these 4 classes from the marker set, re-run the `knn1Optimisation` for each data source and then run the `knn1Classification` with the 10 remaining classes. (Note: this is not run live as the \textit{hl} dataset with 10 classes, 707 markers and \( 4^{10} \) combinations of parameters takes around 76 hours to run on the University of Cambridge HPC using 256 workers).

To remove the 4 classes and create a new column of markers in the feature data called `tlmarkers` to use for the analysis:

```r
## create new markers column for tl markers
fData(hl)$tlmarkers <- fData(hl)$markers
fData(gocc)$tlmarkers <- fData(gocc)$markers

## Remove 4 classes
torm <- c("40S Ribosome", "60S Ribosome", "Nucleus - Chromatin", "Nucleus - Non-chromatin")
for (i in seq(torm)) {
  hl <- fDataToUnknown(hl, from = torm[i], fcol = "tlmarkers")
  gocc <- fDataToUnknown(gocc, from = torm[i], fcol = "tlmarkers")
}
getMarkerClasses(hl, fcol = "tlmarkers")

## [1] "Actin cytoskeleton"  "Cytosol"
## [3] "Endoplasmic reticulum"  "Endosome"
## [5] "Extracellular matrix"  "Lysosome"
```
TL optimisation stage 1 Run knnOptimisation to get the best k’s for each data source.

```r
## get best k’s
kopt <- knnOptimisation(hl, fcol = "tlmarkers")
ko <- knnOptimisation(gocc, fcol = "tlmarkers")
```

From examining the parameter search plots as described in section Optimisation, we find the best k’s for both the primary and auxiliary are 3.

TL optimisation stage 2 Run knnTLOptimisation to get the best transfer learning weights for each sub-cellular class.

```r
## Set appropriate parallelisation backend and number of workers for the tl
par <- SnowParam(255L, type = "MFI")

## Now perform tl optimisation
tlopt <- knnTLOptimisation(hl, gocc, fcol = "tlmarkers",
                         length.out = 4, times = 50,
                         xval = 5, k = c(3, 3),
                         BPARAM = par)
```

The results of the optimisation can be visualised using the plot method for tlopt optimisation result:

```r
plot(tlopt)
```

TL classification

Looking at the bubble plot displaying the distribution of best weights over the 50 runs we find that for many of the subcellular niches a weight of 1 is most popular (i.e. use only primary hyperLOPIT data in classification), this is unsurprising as we already know the dataset is well resolved for these classes. We see that the most popular weights for the proteasome and lysosome tend to be towards 0, indicating that these niches are well-resolved in the Gene Ontology. This tells us that we would benefit from including auxiliary GO information in our classifier for these subcellular compartments. The plasma membrane weights are relatively equally spread between using hyperLOPIT and GO data. Using the getParams function we can return the best weights and then use this as input for the classification.

One of the benefits of the algorithm is the ability to manually select weights for each class. In the optimisation above, for time constraints, we removed the two ribosomal subunits and the two nuclear compartments, and therefore in the code chunk below when we extract the best parameters, these subcellular niches are not included. To include these 4 subcellular niches in the next classification step we must include them in the parameters. We define a weight of 1 for each of these niches, as we know they are well resolved in hyperLOPIT. We then re-order the weights according to getMarkerClasses and perform the classification using the function knnTLClassification.

```r
## best parameters for the 10 classes
(bestpar <- getParams(tlopt))
```

|                | Cytosol | Endoplasmic reticulum |
|----------------|---------|-----------------------|
| Actin cytoskeleton | 1.0000000 | 1.0000000             |
| Endosome         | 1.0000000 | 0.6666667             |
| Extracellular matrix | 1.0000000 | 0.3333333             |
| Lysosome         | 0.3333333 |                      |
The results from the classification results and associated scores are appended to the fData slot and named knnl and knnl.scores respectively. Results can be visualised using plot2D, scores assessed and cutoffs calculated using the classify app in pRolocVis, predictions obtained using getPredictions in the same way as demonstrated above for the SVM classifier.

In pRoloc’s transfer learning vignette, we demonstrate how to use imaging data from the Human Protein Atlas via the hpar package as an auxiliary data source.

Unsupervised machine learning

In pRoloc there is functionality for unsupervised machine learning methods. In unsupervised learning, the training data consists of a set of input vectors e.g. protein profiles, ignoring the information about the class label e.g. localisation, other than for annotation purposes. The main goal in unsupervised learning is to uncover groups of similar features within the data, termed clustering. Ordination methods such as PCA also fall into the category of unsupervised learning methods, where the data can be projected from a high-dimensional space down to two or three dimensions for the purpose of visualisation.

As described and demonstrated already above, PCA is a valuable and powerful method for data visualisation and quality control. Another application uses hierarchical clustering to summarise the relation between marker proteins using the mrkHClust function, where the euclidean distance between average class-specific profiles is used to produce a dendrogram describing a simple relationship between the sub-cellular classes (Figure 21). The mrkHClust uses the same defaults as all other function, using the markers feature variable to define marker proteins. In the code chunk, we adapt the figure margins to fully display the class names.

We generally find supervised learning more suited to the task of protein localisation prediction in which we use high-quality curated marker proteins to build a classifier, instead of using an entirely unsupervised approach to look for clusters and then look for enrichment of organelles and complexes. In the latter we do not make good use of valuable prior knowledge, and in our experience unsupervised clustering can be extremely difficult due to poor estimates of the number of clusters that may appear in the data.
Writing and exporting data

An MSnSet can be exported from R using the `write.exprs` function. This function writes the expression values to a text-based spreadsheet. The `fcol` argument can be used to specify which `featureData` columns (as column names, column number or logical) to append to the right of the expression matrix.

In the code chunk below we write the `hl` object to a csv file. The `file` argument is used to specify the file path, the `sep` argument specifies the field separator string, here we use a comma. Finally, as we want to write all the information in the `featureData` to the file, as well as the expression data, we specify `fvarLabels(hl)` that returns all feature variable names, and write the resulting data to the file "hl.csv".

```r
write.exprs(hl, file = "hl.csv", sep = ",", fcol = fvarLabels(hl))
```

Exporting to a spreadsheet however loses a lot of important information, such as the processing data, and the sample metadata in the `phenoData` slot. Other objects, such as parameters from the machine learning optimisation, cannot be represented as tabular data. To directly serialise R objects to disk, one can use the standard `save` function, and later reload the object using `load`. For example, to save and then re-load the parameters from the SVM optimisation,

```r
## To save the parameters as an R object
save(params, file = "svmparams.rda")

## To re-load after saving
load(file = "svmparams.rda")
```

Session information

The function `sessionInfo` provides a summary of all packages and versions used to generate this document. This enables us to record the exact state of our session that lead to these results. Conversely, if the script stops working or if it returns different results, we are in a position to re-generate the original results using the adequate software versions and retrace changes in the software that lead to failure and/or different results.

```r
sessionInfo()

## R version 3.3.2 Patched (2016-11-01 r71616)

We also recommend that users regularly update the packages as well as the R itself. This can be done with the `biocLite` function.

```r
library("BiocInstaller")
biocLite()
```

It is always important to include session information details along with a short reproducible example highlighting the problem or question at hand.

### Conclusions

This workflow describes a step-by-step guide for analysing and interpreting contemporary spatial proteomics data. We described the software architecture, how to import and process data, quality control and visualisation as well as a range of machine learning methods available through the `pRoloc` suite of Bioconductor packages.

### Data and software availability

The software and data presented in this workflow are part of the Bioconductor project. Version numbers for all packages used are shown in the `Session information` section.

The source of this document, including the code necessary to reproduce the analyses and figures is available at: [https://github.com/lmsimp/bioc-pRoloc-hyperLOPIT-workflow](https://github.com/lmsimp/bioc-pRoloc-hyperLOPIT-workflow). An archived version as at the time of publication is available at: DOI 10.5281/zenodo.1970682.

### Author contributions

LMB and LG developed the software presented in this workflow. All authors wrote and approved the manuscript.

### Competing interests

No competing interests were disclosed.

### Grant information

LMB and CMM are supported by a Wellcome Trust Technology Development Grant (grant number 108441/Z/15/Z). KSL is a Wellcome Trust Joint Investigator (110170/Z/15/Z). LG is supported by the BBSRC Strategic Longer and Larger grant (Award BB/L002817/1).

*The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.*

### Acknowledgements

The authors would like to thank Dr. Stuart Rankin from the High Performance Computing Service for his support. Part of this work was performed using the Darwin Supercomputer of the University of Cambridge High Performance Computing Service, provided by Dell Inc. using Strategic Research Infrastructure Funding from the Higher Education Funding Council for England and funding from the Science and Technology Facilities Council.

Breckels et al. have written a very nice piece on analysing appropriate proteomics data for subcellular localisation. I particularly like the "workshop characteristics" of the text. Which allows a novice, but interested reader to work through the analysis stepwise and reproduce the results described therein. The authors took great care in keeping this ideal up during their text and this is also where I have put my greatest reservation to the manuscript in its present form - since a reader cannot work through the code presented in the manuscript, since there at least two situations where a readily available HPC and quite some time is required. This kind of leaves a dent in my impression - however, given this can be resolved as well as some typos - the workflow report is superb.

Major comments:

○ Next to reducing the dimensions of data for visualisation, PCA also offers a way to understand how the variability is distributed across the multidimensional data by providing linear combinations of the variables which then constitute the actual PCs. On that note it would be nice to mention this in Visualising markers section on page 16, where PC7 explains not much variability but due to the correct weighing of the variables we do get a separation between mitochondrial and peroxisome. This then can be further motivated with Figure 9 - where we probably can see that the weights for the fractions where the two localisations differ are larger than otherwise.

○ I was unable to reproduce Figure 13 comparing the two MSnSets. While I was able to look at each set separately using pRolocVis(hlst@x[[I]]), where i is 1 or 2, I only got an error using the code from the manuscript:

```r
> pRolocVis(hlst, app="compare")
Subsetting MSnSetList to their common feature names 5032 features in common
Remapping data to the same PC space
Error in (function (od, vd)  ```
object and replacement value dimnames differ
Error in pRolocVis_compare(object, ...) : object ‘idDT’ not found

When using ‘remap=FALSE’ it actually works, but since this makes barely sense it is of no use - but just as a hint at debugging it.

- You really need to make the results from the phenoDisco classification available too. It is super disappointing that one cannot continue reproducing the code from page 23 on, because it takes 24 hours to compute it using 40 cores...

- The above comment is of course also true for the KNN TL Optimisation on page 33 - this needs to be downloadable, since not everyone has access to Cambridge’s HPC and probably even less have 76 hours to spare.

- Your comment on the increase suitability of classification instead of clustering (when additional information on classes is available) at the bottom of page 35 could be more pronounced - for educational reasons.

Minor comments:
- I was not able to naively reproduce the workflow from the R commands in the article due to an error installing pRolocdata on a Windows machine. On OS X it was smooth.

- On page 10 line 2 there is a ‘to’ missing.

- I never came across the verb imputate in the context of missing values, I guess the proper term is impute.

- On page 11 the image2 function is called after the filterNA function a couple of lines above. This however would result in an only black heat map (since there are no more missing). The image2 function should be called before the filterNA function. Since the reader does not see the chunk options, it could be puzzling.

- For completeness sake there should also be an install.packages(c("hexbin", "rgl")) somewhere to generate the second PCA-plot and the 3D plot. Moreover, Mac users will need to install xquartz to use rgl properly.

- On page 14 the plotting code chunk is off track - in the middle of the marker sets output.

- On page 18: ...wanted to highlight a proteins with the... -> lose the a and later in the sentence there is a ‘create d’ too many.

- Direct comparisons of individual channels in replicated experiments do not provide...

- You may want to consider adding a layout(1) or similar, after changing the mfrow argument of the parameters to accommodate 2 panels, such that the uncanny reader does not get confused.
I would prefer links to referred sections of the text, but that may be personal taste...

Page 23: One should note that the decreasing the GS, and increasing the ... at least one the too many, probably two.

On page 25: We find the general tendancy to be that it is not the choice ... tendency?

On page 28 you refer to ‘...the code chunk below...’ for Figure 17, however, the following code chunk is generating Figure 16 (which is above and btw not referenced in the text). Maybe force your figures a little to float where you want them/refer to them.

On page 28: ...by extracting the median or 3rd quantile score per organelle... do you mean quartile? Otherwise I do not follow.

On page 32: ...package to query the relevent database ... relevant?

On page 32 - there is something wrong with this sentence: To remove the 4 classes and create a new column of markers in the feature data called tlmarkers to use for the analysis:

On page 34: From examining the parameter search plots as described in section Optimisation... search!

On page 36: ...and later reload the object using save. -> that would be ‘load’ then!

On page 38 - I fully agree with the following sentence, but right after the updating comment it kind of seems ‘misplaced’? Maybe add a title like ‘Getting help’?

It is always important to include session information details along with a short reproducible example highlighting the problem or question at hand.

Competing Interests: No competing interests were disclosed.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Author Response 23 May 2018

Laurent Gatto, de Duve Institute, UCLouvain, Belgium

Thank you for your comments. Please find our responses to these inset below.

Next to reducing the dimensions of data for visualisation, PCA also offers a way to understand how the variability is distributed across the multidimensional data by providing linear combinations of the variables which then constitute the actual PCs. On that note it would be nice to mention this in Visualising markers section on page 16, where PC7 explains not much variability but due to the correct weighing of the variables we do get a separation between mitochondrial and peroxisome. This then can be further motivated with Figure 9 - where we
probably can see that the weights for the fractions where the two localisations differ are larger than otherwise.

We have added a paragraph to the 'Visualising markers' section of the manuscript reiterating the purpose of PCA and motivating the choice of looking at PC's 1 and 7. Figure 9 now follows on from this (now Figure 8), along with the corresponding code and an explanation of the `plotDist` function.

I was unable to reproduce Figure 13 comparing the two MSnSets. While I was able to look at each set separately using `pRolocVis(hilst@x[[I]])`, where i is 1 or 2, I only got an error using the code from the manuscript. When using `remap=FALSE` it actually works, but since this makes barely sense it is of no use - but just as a hint at debugging it.

We can not reproduce this error. Have you updated to the latest version of R and the latest version of `pRolocGUI`? If you still get this error message could you please post this as an issue (https://github.com/ComputationalProteomicsUnit/pRolocGUI/issues) on the `pRolocGUI` Github page along with your `sessionInfo()` and we will certainly attempt to solve this.

You really need to make the results from the phenoDisco classification available too. It is super disappointing that one cannot continue reproducing the code from page 23 on, because it takes 24 hours to compute it using 40 cores?

The results are already available as a `RDS` file and stored in `pRolocdata` for users. This is what is called in the manuscript under the hood:

```r
f0 <- dir(extdatadir, full.names = TRUE, pattern = "bpw-pdres.rds")
pdres <- readRDS(f0)
hl <- addMarkers(hl, pdres, mcol = "pd", verbose = FALSE)
```

We have made this code available in the manuscript in an appendix so users can continue to produce the exact plots as they see in this workflow.

The above comment is of course also true for the KNN TL Optimisation on page 33 - this needs to be downloadable, since not everyone has access to Cambridge's HPC and probably even less have 76 hours to spare.

The same as for the `phenoDisco` analysis and `svm`, the TL results are stored as a `RDS` in `pRolocdata` and are loaded in the background. We have added the code required to the appendix so that users can load the results directly.

Your comment on the increase suitability of classification instead of clustering (when additional information on classes is available) at the bottom of page 35 could be more pronounced - for educational reasons.
To address the above comment on suitability we have added a few additional points on the challenges of using clustering for this type of data.

We generally find supervised learning more suited to the task of protein localisation prediction in which we use high-quality curated marker proteins to build a classifier, instead of using an entirely unsupervised approach to look for clusters and then look for enrichment of organelles and complexes. In the latter we do not make good use of valuable prior knowledge, and in our experience unsupervised clustering can be extremely difficult due to (i) the loose definition of what constitutes a cluster (for example whether it is defined by the quantitative data or the localisation information), (ii) the influence of the algorithm assumption on the cluster identification (for example parametric or non-parametric) and (iii) poor estimates of the number of clusters that may appear in the data.

I was not able to naively reproduce the workflow from the R commands in the article due to an error installing pRolocdata on a Windows machine. On OS X it was smooth.

We didn’t experience any Windows-specific problems. If you re-try the installation and please let us know if you still have any issues by opening an issue (https://github.com/lgatto/pRolocdata/issues) or by posting this issue on the Bioconductor Support site (https://support.bioconductor.org).

On page 10 line 2 there is a *to* missing.

In the version have, we currently can’t find the missing ‘to’.

I never came across the verb imputate in the context of missing values, I guess the proper term is impute.

This has been changed to read "We can impute missing data..."

On page 11 the image2 function is called after the filterNA function a couple of lines above. This however would result in an only black heat map (since there are no more missing). The image2 function should be called before the filterNA function. Since the reader does not see the chunk options, it could be puzzling.

This was an editing mistake and has now been rectified.

For completeness sake there should also be an install.packages(c("hexbin", "rgl")) somewhere to generate the second PCA-plot and the 3D plot. Moreover, Mac users will need to install xquartz to use rgl properly.

A footnote has been added here to tell users that the package `rgl` may need to be installed with `install.packages("rgl")` and mac users may need to install xquartz if it's not already installed. LG: this one is still missing.

On page 14 the plotting code chunk is off track - in the middle of the marker sets output.
This has now been rectified.

On page 18: ...wanted to highlight a proteins with the ... -> lose the a and later in the sentence there is a 'create a' too many.

These typos have been rectified.

Direct comparisons of individual channels in replicated experiments do not provide?

You may want to consider adding a layout(1) or similar, after changing the mfrow argument of the parameters to accommodate 2 panels, such that the uncanny reader does not get confused.

We would prefer to keep the code as it is and not introduce more noise with calls to other functions such as 'layout'. The workflow is not aimed at teaching R. Users should have some basic knowledge of R before tackling this tutorial.

I would prefer links to referred sections of the text, but that may be personal taste?

This is a comment for F1000. We cannot control the linking of sections in the final version.

Page 23: One should note that the decreasing the GS, and increasing the ...at least one the too many, probably two.

We have reworded this sentence as requested.

On page 25: We find the general tendency to be that it is not the choice ...tendency?

This typo has been rectified.

On page 28 you refer to '...the code chunk below...' for Figure 17, however, the following code chunk is generating Figure 16 (which is above and btw not referenced in the text). Maybe force your figures a little to float where you want them/refer to them.

We have now referenced Figure 16 in the text and made sure that the code chunks and figures follow inline where they are referenced in the text.

On page 28: ...by extracting the median or 3rd quantile score per organelle? do you mean quartile? Otherwise I do not follow.

Thank you, yes this is a typo and has now been changed to 'quartile'.

On page 32: package to query the relevent database *relevant*

This typo has been rectified.

On page 32 - there is something wrong with this sentence: To remove the 4 classes and create a
new column of markers in the feature data called tlmarkers to use for the analysis:

This sentence is not needed here and so it has now been removed as it essentially reiterates what is said in the above paragraph.

On page 34: From examining the parameter search plots as described in section Optimisation... search!

This typo has been rectified.

On page 36: and later reload the object using save. -> that would be `load` then!

This typo has been rectified.

On page 38 - I fully agree with the following sentence, but right after the updating comment it kind of seems misplaced? Maybe add a title like Getting help?

We have changed the title of this section to ‘Session information and getting help’ to clarify this section of the tutorial.

A pdf version of our replies is also available here.

**Competing Interests:** No competing interests were disclosed.
very detailed and comprehensive and will be useful for others in the field. A few comments:

- Some clearer statement early on would help to clarify for readers what types of data this works with. I know that the authors indicate that the example they use is 10-plex TMT and that it can be used with label-free or other labels, but that is not what I am referring to. Rather, structure of the experiment. That is, that one needs systematic quantitative data on all the different relevant fractions from a cell, as opposed to someone who perhaps did a differential centrifugation experiment to isolate a couple fractions and then wants to apply this (my understanding is that this latter example would not be usable).

- How do the authors recommend collapsing replicates? This could be covered in the section dedicated to the Compare function. Two replicates will (almost) never agree 100% so how are discrepancies handled?

**Competing Interests:** No competing interests were disclosed.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

Author Response 23 May 2018

Laurent Gatto, de Duve Institute, UCLouvain, Belgium

This manuscript describes a Bioconductor workflow for analyzing subcellular proteomics data. It is very detailed and comprehensive and will be useful for others in the field.

Many thanks for your comments, we have responded to them inset below.

Some clearer statement early on would help to clarify for readers what types of data this works with. I know that the authors indicate that the example they use is 10-plex TMT and that it can be used with label-free or other labels, but that is not what I am referring to. Rather, structure of the experiment. That is, that one needs systematic quantitative data on all the different relevant fractions from a cell, as opposed to someone who perhaps did a differential centrifugation experiment to isolate a couple fractions and then wants to apply this (my understanding is that this latter example would not be usable).

From a purely technical point of view, we need a data matrix with features (typically proteins or protein groups) along the rows and sub-cellular fractions along the columns. Given the requirement for complete (or near-complete) quantitative vectors along all fractions to assure best results, a data set that would only contain one quantitation value per fraction would not work. However, separation using differential centrifugation, or any separation that generates organelle-specific separation profiles is a good fit for pRloc. For instance, the type of data generated by methods such as described in Itzhak et al. (2016) are well fitted for our software:

```r
> library(pRloc)
> library(pRolocdata)
> data(itzhak2016stcSILAC)
> ## 6 combined replicates of 5 fractions each
```
How do the authors recommend collapsing replicates? This could be covered in the section dedicated to the Compare function. Two replicates will (almost) never agree 100% so how are discrepancies handled?

Currently, we recommend to visualise different replicates on their own, to confirm that they are of sufficient quality, and then combine them, retaining the proteins that have been quantified over all replicated experiments. This allows to obtain localisation information over all replicated data. We however do not explicitly assess the variability using this approach. This could be done by analysing replicated independently and then compare the coherence of the classification results. Proteins that are only observed in some replicates could be rescued by repeating the analysis using only the relevant (possibly unique) replicate(s).

**Competing Interests:** No competing interests were disclosed.
