The Optimal Hard Threshold for Singular Values is $4/\sqrt{3}$

Matan Gavish, Student Member, IEEE, and David L. Donoho, Member, IEEE

Abstract—We consider recovery of low-rank matrices from noisy data by hard thresholding of singular values, in which empirical singular values below a threshold $\lambda$ are set to 0. We study the asymptotic mean squared error (AMSE) in a framework, where the matrix size is large compared with the rank of the matrix to be recovered, and the signal-to-noise ratio of the low-rank piece stays constant. The AMSE-optimal choice of hard threshold, in the case of an $n$-by-$n$ matrix in white noise of level $\sigma$, is simply $(4/\sqrt{3})\sigma \lambda \approx 2.309\sigma \lambda$ when $\sigma$ is known, or simply $2.858 \cdot y_{\text{med}}$ when $\sigma$ is unknown, where $y_{\text{med}}$ is the median empirical singular value. For nonsquare, $m$ by $n$ matrices with $m \neq n$ the thresholding coefficients $4/\sqrt{3}$ and $2.858$ are replaced with different provided constants that depend on $m/n$. Asymptotically, this thresholding rule adapts to unknown rank and unknown noise level in an optimal manner: it is always better than hard thresholding at any other value, and is always better than ideal truncated singular value decomposition (TSVD), which truncates at the true rank of the low-rank matrix we are trying to recover. Hard thresholding at the recommended value to recover an $n$-by-$n$ matrix of rank $r$ guarantees an AMSE at most $3\sqrt{r}$. In comparison, the guarantees provided by TSVD, optimally tuned singular value soft thresholding and the best guarantee achievable by any shrinkage of the data singular values are $5\sigma \sqrt{r}$, $6\sigma \sqrt{r}$, and $2\sigma \sqrt{r}$, respectively. The recommended value for hard threshold also offers, among hard thresholds, the best possible AMSE guarantees for recovering matrices with bounded nuclear norm. Empirical evidence suggests that performance improvement over TSVD and other popular shrinkage rules can be substantial, for different noise distributions, even in relatively small $n$.

Index Terms—Singular values shrinkage, optimal threshold, low-rank matrix denoising, unique admissible, scree plot elbow truncation, quarter circle bulk, edge.

I. INTRODUCTION

Suppose that we are interested in an unknown $m$-by-$n$ matrix $X$, thought to be either exactly or approximately of low rank, but we only observe a single noisy $m$-by-$n$ matrix $Y$, obeying $Y = X + \sigma Z$. The noise matrix $Z$ has independent, identically distributed, zero-mean entries. The matrix $X$ is a (non-random) parameter, and we wish to estimate it with some bound on the mean squared error (MSE).

The default estimation technique for our task is Truncated SVD (TSVD) [2]; Write

$$Y = \sum_{i=1}^{m} y_i u_i v_i'$$

for the Singular Value Decomposition of the data matrix $Y$, where $u_i \in \mathbb{R}^m$ and $v_i \in \mathbb{R}^n$, $i = 1, \ldots, m$ are the left and right singular vectors of $Y$ corresponding to the singular value $y_i$. The TSVD estimator is

$$\hat{X}_r = \sum_{i=1}^{r} y_i u_i v_i'$$

where $r = \text{rank}(X)$, assumed known, and $y_1 \geq \cdots \geq y_m$. Being the best approximation of rank $r$ to the data in the least squares sense [3], and therefore the Maximum Likelihood estimator when $Z$ has Gaussian entries, the TSVD is arguably as ubiquitous in science and engineering as linear regression [4]–[9].

When the true rank $r$ of the signal $X$ is unknown, one might try to form an estimate $\hat{r}$ and then apply the TSVD $\hat{X}_{\hat{r}}$. Extensive literature has formed on methods to estimate $\hat{r}$: we point to the early [9], [10] (in Factor Analysis and Principal Component Analysis), the recent [11]–[13] (in our setting of Singular Value Decomposition), and reference therein. It is instructive to think about rank estimation (using any method), followed by TSVD, simply as hard thresholding of the data singular values, where only components $y_i u_i v_i'$ for which $y_i$ passes a specified threshold, are included in $\hat{X}$. Let $\eta_{H}(y_i; \tau) = y_i 1_{[y_i \geq \tau]}$ denote the hard thresholding nonlinearity, and consider Singular Value Hard Thresholding (SVHT)

$$\hat{X}_\tau = \sum_{i=1}^{m} \eta_{H}(y_i; \tau) u_i v_i'.$$

In words, $\hat{X}_\tau$ sets to 0 any data singular value below $\tau$.

Matrix denoisers explicitly or implicitly based on hard thresholding of singular values have been proposed by many authors, including [12]–[20]. As a common example of implicit SVHT denoising, consider the standard practice of estimating $\hat{r}$ by plotting the singular values of $Y$ in decreasing order, and looking for a “large gap” or “elbow” (Figure 1, left panel). When $X$ is exactly or approximately low-rank and the entries of $Z$ are white noise of zero mean and unit variance, the empirical distribution of the singular values of the $m$-by-$n$ matrix $Y = X + \sigma Z$ forms a quarter-circle bulk whose edge lies approximately at $(1 + \sqrt{\beta}) \cdot \sqrt{\sigma_1}$, with $\beta = m/n$ [21].
only data singular values that are larger than the bulk edge are noticeable in the empirical distribution (Figure 1, right plot). Only data singular values that are larger than the bulk edge are noticeable in the empirical distribution (Figure 1, right plot). Since the singular value plot “elbow” is located at the bulk edge, the popular method of TSVD at the “elbow” is an approximation of bulk-edge hard thresholding, $\hat{X}_{(1+\sqrt{m})/\sqrt{n}}$.

A. Questions

Let us measure the denoising performance of a denoiser $\hat{X}$ at a signal matrix $X$ using Mean Square Error (MSE),

$$\left\| \hat{X}(Y) - X \right\|_F^2 = \sum_{i,j}(\hat{X}(Y)_{i,j} - X_{i,j})^2.$$ 

The TSVD is an optimal rank-$r$ approximation of the data matrix $Y$, in MSE. But this does not necessarily mean that it is a good, or even reasonable, estimator to the signal matrix $X$, which we wish to recover. We may wonder:

- **Question 1.** Assume that rank$(X)$ is unknown but small. Is there a singular value threshold $\tau$ so that SVHT $\hat{X}_\tau$ successfully adapts to unknown rank and unknown noise level, and performs as well as TSVD would, had we known the true rank$(X)$?

As we will see, it is convenient to represent the threshold as $\tau = \lambda_4 \sqrt{n_\sigma}$, where $\lambda$ is a parameter typically between 1 and 10. Recently, S. Chatterjee [17] proposed that one could have a single universal choice of $\lambda$; that in setting more general, but similar, to our setting, any $\lambda > 2$ would give near-optimal MSE, in a qualitative sense; and he specifically proposed $\lambda = 2.02$, namely $\hat{X}_{2.02 \sqrt{n_\sigma}}$ as a universal choice for SVHT, regardless of the shape $m/n$ of the matrix, and regardless of the underlying signal matrix $X$ or its rank. While the rule of [17] was originally intended to be ‘fairly good’ across many situations not reducible to the low-rank matrix in i.i.d noise model considered here, $\hat{X}_{2.02 \sqrt{n_\sigma}}$ is a specific proposal, which prompts the following question:

- **Question 2.** Is there really a single threshold parameter $\lambda_4$ that provides good performance guarantees for MSE? Is that value 2.02? Is it really independent of $m$ and $n$?

Finally, note that singular value hard thresholding is just one strategy for matrix denoising. It is not a-priori clear whether

the whole idea of only ‘keeping’ or ‘killing’ empirical singular values based on their size makes sense. Could there exist a shrinkage rule $\eta : [0, \infty) \rightarrow [0, \infty)$, that more smoothly transitions from ‘killing’ to ‘keeping’, which leads to a much better denoising scheme? We may wonder:

- **Question 3.** How does optimally tuned SVHT compare with the performance of the best possible shrinkage of singular values, at least in the worst-case MSE sense?

B. Optimal Location for Hard Thresholding of Singular Values

Our main results imply that, in a certain asymptotic framework, there are simple and convincing answers to these questions. Following Perry [13] and Shabalin and Nobel [22], we adopt an asymptotic framework where the matrix grows while keeping the nonzero singular values of $X$ fixed, and the signal-to-noise ratio of those singular values stays constant with increasing $n$.

In this asymptotic framework, for a low-rank $n$-by-$n$ matrix observed in white noise of level $\sigma$, $\tau_n = \frac{4}{\sqrt{3}} \sqrt{n_\sigma}$ is the optimal location for the hard thresholding of singular values. For a non-square $m$-by-$n$ matrix with $m \neq n$, the optimal location is

$$\tau_n = \frac{4}{\sqrt{3}} \sqrt{n_\sigma} \approx 2.309 \sqrt{n_\sigma},$$

where $\beta = m/n$. The value $\lambda_4(\beta)$ is the optimal hard threshold coefficient for known $\sigma$. It is given by formula (11) below and tabulated for convenience in Table I. We found that P. Perry’s PhD thesis [13] proposes a threshold which can be shown to be equivalent to (3).

C. Answers

Our central observation is as follows.

When a data singular value $y_i$ is too small, then its associated singular vectors $u_i, v_i$ are so noisy that the component $\langle y_i u_i, v_i \rangle$ should not included in $\hat{X}$.

In our asymptotic framework, which models large, low-rank matrices observed in white noise, the cutoff

| $\beta$ | $\lambda_4(\beta)$ | $\beta$ | $\lambda_4(\beta)$ |
|--------|-------------------|--------|-------------------|
| 0.05   | 1.5066            | 0.10   | 1.5816            |
| 0.15   | 1.6466            | 0.60   | 2.0533            |
| 0.20   | 1.7048            | 0.70   | 2.1299            |
| 0.25   | 1.7580            | 0.75   | 2.1561            |
| 0.30   | 1.8074            | 0.80   | 2.1883            |
| 0.35   | 1.8337            | 0.85   | 2.2197            |
| 0.40   | 1.8974            | 0.90   | 2.2505            |
| 0.45   | 1.9389            | 0.95   | 2.2802            |
| 0.50   | 1.9786            | 1.00   | 2.3094            |
below which \( y_i \) is too small is exactly \((4/\sqrt{3})\sqrt{n}\sigma\) (for square matrices).

**Answer to Question 1:** Optimal SVHT dominates TSVD. Optimally tuned SVHT \( \hat{X}_r \) is always at least as good as TSVD \( \hat{X}_r \), in terms of AMSE (Theorem 2). Unlike \( \hat{X}_r \), the optimal SVHT \( \hat{X}_r \) does not require knowledge of \( r = \text{rank}(X) \). In other words, it adapts to unknown low rank while giving uniformly equal or better performance. For square matrices, the TSVD provides a guarantee on worst-case AMSE that is \( 5/3 \) times the guarantee provided by \( \hat{X}_r \) (Table II).

**Answer to Question 2:** Optimal SVHT dominates every other choice of Hard Threshold. In terms of AMSE, optimally tuned SVHT \( \hat{X}_r \) is always at least as good as SVHT \( \hat{X}_r \) at any other fixed threshold \( \tau = \lambda \sqrt{n}\sigma \) (Theorem 1). It is the asymptotically minimax SVHT denoiser, over matrices of small bounded rank (Theorems 3 and 4) and over matrices of small bounded nuclear norm (Theorem 5). In particular, the parameter \( \lambda = 2.02 \) is noticeably worse. For square matrices, \( \hat{X}_{2,02} \) provides a guarantee for worst-case AMSE that is \( 4.26/3 \approx 1.4 \) times the guarantee provided by \( \hat{X}_r \) (Table II).

**Answer to Question 3:** Optimal SVHT compares adequately to the optimal shrinker. Optimally tuned SVHT \( \hat{X}_r \) provides a guarantee on worst-case asymptotic MSE that is \( 3/2 \) times (for square matrices) the best possible guarantee achievable by any shrinkage of data singular values (Table II).

These are all rigorous results, within a specific asymptotic framework, which prescribes a certain scaling of the noise level, the matrix size, and the signal-to-noise ratio as \( n \) grows. But does AMSE predict actual MSE in finite-sized problems? In Section VII we show finite-\( n \) simulations demonstrating the effectiveness of these results even at rather small problem sizes. In high signal-to-noise, all denoisers considered here perform roughly the same, and in particular the classical TSVD is a valid choice in that regime. However, in low and moderate SNR, the performance gain of optimally tuned SVHT is substantial, and can offer 30\%-80\% decrease in AMSE.

### D. Optimal Singular Value Hard Thresholding—In Practice

For a low-rank \( n \)-by-\( n \) matrix observed in white noise of unknown level, one can use the data to obtain an approximation of the optimal location \( \tau_\alpha \). Define

\[
\hat{\tau}_\alpha \approx 2.858 \cdot y_{\text{med}},
\]

where \( y_{\text{med}} \) is the median singular value of the data matrix \( Y \). The notation \( \hat{\tau}_\alpha \) is meant to emphasize that this is not a fixed threshold chosen a-priori, but rather a data-dependent threshold. For a non-square \( m \)-by-\( n \) matrix with \( m \neq n \), the approximate optimal location when \( \sigma \) is unknown is

\[
\hat{\tau}_\alpha = \omega(\beta) \cdot y_{\text{med}}.
\]

The optimal hard threshold coefficient for unknown \( \sigma \), denoted by \( \omega(\beta) \), is not available as an analytic formula, but can easily be evaluated numerically. We provide a Matlab script for this purpose [1]; the underlying derivation appears in Section III-E below. Some values of \( \omega(\beta) \) are provided in Table IV. When a high-precision value of \( \omega(\beta) \) cannot be computed, one can use the approximation

\[
\omega(\beta) \approx 0.56\beta^3 - 0.95\beta^2 + 1.82\beta + 1.43.
\]

The optimal SVHT for unknown noise level, \( \hat{X}_{\hat{\tau}_\alpha} \), is very simple to implement and does not require any tuning parameters. The denoised matrix \( \hat{X}_{\hat{\tau}_\alpha} (Y) \) can be computed using just a few code lines in a high-level scripting language. For example, in Matlab:

\[
\begin{align*}
\beta &= \text{size}(Y,1) / \text{size}(Y,2); \\
\omega &= 0.56*\beta^3 - 0.95*\beta^2 + \ldots \\
&\quad 1.82*\beta + 1.43; \\
[U \ D V] &= \text{svd}(Y); \\
y &= \text{diag}(Y); \\
y'(y < \omega * \text{median}(y)) &= 0; \\
\hat{X}_\alpha &= U * \text{diag}(y') * V';
\end{align*}
\]

Here we have used the approximation \(5\). We recommend, whenever possible, to use a function \( \omega(\beta) \) such as the one we provide in the code supplement [1], to compute the coefficient \( \omega(\beta) \) to high precision.

In our asymptotic framework, \( \tau_\alpha \) and \( \hat{\tau}_\alpha \) enjoy exactly the same optimality properties. This means that \( \hat{X}_{\hat{\tau}_\alpha} \) adapts to unknown low rank and to unknown noise level. Empirical evidence suggest that their performance for finite \( n \) is similar. As a result, the answers we provide above hold for the threshold \( \hat{\tau}_\alpha \) when the noise level is unknown, just as they hold for the threshold \( \tau_\alpha \) when the noise level is known.

### II. Preliminaries and Setting

Column vectors are denoted by boldface lowercase letters, such as \( v \), their transpose is \( v' \) and their \( i \)-th coordinate is \( v_i \). The Euclidean inner product and norm on vectors are denoted by \( \langle u, v \rangle \) and \( ||u||_2 \), respectively. Matrices are denoted by uppercase letters, such as \( X \), its transpose is \( X' \) and their \( i, j \)-th
entry is $A_{i,j}$, $M_{m \times n}$ denotes the space of real $m$-by-$n$ matrices, $(X, Y) = \sum_{i,j} X_{i,j} Y_{i,j}$ denotes the Hilbert-Schmidt inner product, and $\|X\|_F$ denotes the corresponding Frobenius norm on $M_{m \times n}$. For simplicity we only consider $m \leq n$. We denote matrix denoisers, or estimators, by $\hat{X} : M_{m \times n} \rightarrow M_{m \times n}$. The symbols $\overset{a.s.}{\rightarrow}$ and $\overset{a.s.}{=}$ denote almost sure convergence and equality of a.s. limits, respectively.

A. Scaling Considerations in Singular Value Thresholding

With the exception of TSVD, when $\sigma$ is known, all the denoisers we discuss operate by shrinkage of data singular values, namely are of the form

$$\hat{X} : \sum_{i=1}^{m} y_i u_i v_i' \mapsto \sum_{i=1}^{m} \eta(y_i; \lambda) u_i v_i'$$

where $Y$ is given by (1) and $\eta : [0, \infty) \rightarrow [0, \infty)$ is some univariate shrinkage rule. As we will see, in the general model $Y = X + \sigma Z$, the noise level in the singular values of $Y$ is $\sqrt{\sigma}$. Instead of specifying a different shrinkage rule that depends on the matrix size $n$, we calibrate our shrinkage rules to the “natural” model $Y = X + Z/\sqrt{n}$. In this convention, shrinkage rules stay the same for every value of $n$, and we conveniently abuse notation by writing $\hat{X}$ as in (6) for any $\hat{X} : M_{m \times n} \rightarrow M_{m \times n}$, keeping $m$ and $n$ implicit. To apply any denoiser $\hat{X}$ below to data from the general model $Y = X + \sigma Z$, use the denoiser

$$\hat{X}^{(n, \sigma)}(Y) = \sqrt{\sigma} \cdot \hat{X}(Y/\sqrt{\sigma})$$.

For example, to apply the SVHT

$$\hat{X}_\lambda : \sum_{i=1}^{m} y_i u_i v_i' \mapsto \sum_{i=1}^{m} \eta_H(y_i; \lambda) u_i v_i'$$

to data sampled from the model $Y = X + \sigma Z$, use $\hat{X}_\tau$, with

$$\tau = \lambda \cdot \sqrt{\sigma}$$.

Throughout the text, we use $\hat{X}_\lambda$ to denote SVHT calibrated for noise level $1/\sqrt{n}$ and $\hat{X}_\tau$ to denote SVHT calibrated for a specific general model $Y = X + \sigma Z$.

To translate the AMSE of any denoiser $\hat{X}$, calibrated for noise level $1/\sqrt{n}$, to an approximate MSE of the corresponding denoiser $\hat{X}^{(n,\sigma)}$, calibrated for a model $Y = X + \sigma Z$, we use the identity

$$\left\| \hat{X}^{(n,\sigma)}(Y) - X \right\|_F^2 = n \cdot \sigma^2 \cdot \left\| \hat{X}(X/(\sqrt{\sigma})) + Z/\sqrt{n} - X/(\sqrt{\sigma}) \right\|_F^2$$.

Below, we spell out this translation of AMSE where appropriate.

B. Asymptotic Framework and Problem Statement

In this paper, we consider a sequence of increasingly larger denoising problems $Y_n = X_n + Z_n/\sqrt{n}$, with $X_n, Z_n \in M_{m_n \times n}$, satisfying the following assumptions:

1) Invariant White Noise: The entries of $Z_n$ are i.i.d samples from a distribution with zero mean, unit variance and finite fourth moment. To simplify the formal statement of our results, we assume that this distribution is orthogonally invariant in the sense that the corresponding Frobenius norm on $M_{m \times n}$. For simplicity we only consider $m \leq n$. We denote matrix denoisers, or estimators, by $\hat{X} : M_{m \times n} \rightarrow M_{m \times n}$. The symbols $\overset{a.s.}{\rightarrow}$ and $\overset{a.s.}{=}$ denote almost sure convergence and equality of a.s. limits, respectively.

2) Fixed Signal Column Span $(x_1, \ldots, x_r)$: Let the rank $r > 0$ be fixed and choose a vector $x \in \mathbb{R}^r$ with coordinates $x = (x_1, \ldots, x_r)$ such that $x_1 \geq \cdots \geq x_r > 0$. Assume that for all $n$,

$$X_n = U_n \text{diag}(x_1, x_2, 0, \ldots, 0) V_n'$$

is an arbitrary\(^1\) singular value decomposition of $X_n$, where $U_n \in M_{m_n \times m_n}$ and $V_n \in M_{n \times n}$.

3) Asymptotic Aspect Ratio $\beta$: The sequence $m_n$ is such that $m_n/n \rightarrow \beta$. To simplify our formulas, we assume that $0 < \beta \leq 1$.

Let $\hat{X}$ be any singular value shrinkage denoiser calibrated, as discussed above, for noise level $1/\sqrt{n}$. Define the Asymptotic MSE (AMSE) of an $\hat{X}$ at a signal $x$ by the (almost sure) limit\(^2\)

$$\mathbf{M}(\hat{X}, x) \overset{a.s.}{\rightarrow} \lim_{n \rightarrow \infty} \left\| \hat{X}(Y_n) - X_n \right\|_F^2.$$

Adopting the asymptotic framework above, we seek singular value thresholding rules $\hat{X}_\lambda$ that minimize the AMSE $\mathbf{M}(\hat{X}_\lambda, x)$. As we will see, in this framework there are simple, satisfying answers to the questions posed in the introduction.

III. RESULTS

Define the optimal hard threshold for singular values for $n$-by-$n$ square matrices by

$$\lambda_* = \frac{4}{\sqrt{3}}.$$\(^{10}\)

More generally, define the optimal threshold for $m$-by-$n$ matrices with $m/n = \beta$ by

$$\lambda_*(\beta) \overset{\text{def}}{=} \sqrt{2(\beta + 1) + \frac{8\beta}{(\beta + 1)^2 + 14\beta + 1}}.$$\(^{11}\)

Some values of $\lambda_*(\beta)$ are provided in Table I.

A. Optimally Tuned SVHT Asymptotically Dominates TSVD and Any SVHT

Our primary result is simply that $\hat{X}_{\lambda_*}$ always has equal or better AMSE compared to SVHT with any other choice of threshold, and compared to TSVD. In other words, from the ideal perspective of our asymptotic framework, the decision-theoretic picture is very straightforward: TSVD is asymptotically inadmissible, and so is any SVHT with $\lambda \neq \lambda_*$. We note

\(^{10}\)While the signal rank $r$ and nonzero signal singular values $x_1, \ldots, x_r$ are shared by all matrices $X_n$, the signal left and right singular vectors $U_n$ and $V_n$ are unknown and arbitrary.

\(^{11}\)Our results imply that the AMSE is well-defined as a function of the signal singular values $x$.
that since AMSE of SVHT with $\lambda < 1 + \sqrt{\beta}$ in our framework turns out to be infinite, here and below we need only consider SVHT with $\lambda > 1 + \sqrt{\beta}$. As discussed in Section VIII, AMSE calculation in the case where the threshold $\lambda$ is placed exactly at the bulk edge $1 + \sqrt{\beta}$ is a little more subtle and lies beyond our current scope.

**Theorem 1 (Threshold $\lambda_*$ Is Asymptotically Optimal for SVHT):** Let $0 < \beta \leq 1$. For any $\lambda > 1 + \sqrt{\beta}$, any $r \in \mathbb{N}$ and any $x \in \mathbb{R}^r$, the AMSE (9) of the SVHT denoiser $\hat{X}_\lambda$ is well defined and

$$M(\hat{X}_\lambda, x) \leq M(\hat{X}_\beta, x),$$

where $\lambda_* = \lambda_*(\beta)$ is the optimal threshold (11). Moreover, if $\lambda \neq \lambda_*(\beta)$, strict inequality holds at least at one point $x_*(\lambda) \in \mathbb{R}^r$.

We can therefore say that $\lambda_*(\beta)$ is asymptotically unique admissible for SVHT. In particular, the popular practice of hard thresholding close to the bulk edge is asymptotically inadmissible. The popular Truncated SVD $\hat{X}_r$ is asymptotically inadmissible, too:

**Theorem 2 (Asymptotic Inadmissibility of TSVD):** Let $0 < \beta \leq 1$. For any $r \in \mathbb{N}$ and any $x \in \mathbb{R}^r$, the AMSE of the TSVD estimator $\hat{X}_r$ is well defined, and

$$M(\hat{X}_r, x) \leq M(\hat{X}_\beta, x).$$

Moreover, strict inequality holds at least at one point $x_*(\lambda) \in \mathbb{R}^r$.

Figure 2 shows the uniform ordering of the AMSE curves, stated in Theorems 1 and 2, for a few values of $\beta$.

To apply the optimal hard threshold to $m$-by-$n$ matrices sampled from the general model $Y = X + \sigma Z$, by translating $\hat{X}_\lambda$ using Eq. (7), we find the optimal threshold

$$\tau_* = \lambda_* \cdot \sqrt{n} \sigma.$$

Note that Theorem 1 obviously does not imply that for any finite matrix $X$ and $\tau \neq \tau_*$ we have $||\hat{X}_{\tau_0}(X) - X||_{F} \leq ||\hat{X}_{\tau}(X) - X||_{F}$. However, empirical evidence discussed in Section VII suggests that even for relatively small matrices, e.g. $n \sim 20$, the performance gain from using $\hat{X}_{\tau_*}$ is noticeable, and becomes substantial in low SNR.

### B. Minimaxity Over Matrices of Bounded Rank

Theorem 1 implies that $\hat{X}_{\lambda_*}$ is asymptotically minimax among SVHT denoisers, over the class of matrices of a given low rank. Our next result explicitly characterizes the least favorable signal and the asymptotic minimax MSE.

**Theorem 3:** In the asymptotic square case $\beta = 1$, the following holds.

1) **Asymptotically Least Favorable Signal for SVHT:** Let $\lambda > 2$. Then

$$\arg\max_{x \in \mathbb{R}^r} M(\hat{X}_\lambda, x) = x_*(\lambda) \cdot (1, \ldots, 1) \in \mathbb{R}^r,$$

where

$$x_*(\lambda) = \frac{\lambda + \sqrt{\lambda^2 - 4}}{2}.$$

2) **Minimax AMSE of SVHT:** For the AMSE of the SVHT denoiser (2) we have

$$\min_{\lambda > 2} \max_{x \in \mathbb{R}^r} M(\hat{X}_\lambda, x) = 3r.$$

3) **Asymptotically Minimax Tuning of SVHT Threshold:** For the AMSE of the SVHT denoiser (2) we have

$$\arg\min_{\lambda > 2} \max_{x \in \mathbb{R}^r} M(\hat{X}_\lambda, x) = \frac{4}{\sqrt{\beta}}.$$

In words, in our asymptotic framework, the least favorable signal for SVHT is fully degenerate. We will see in Lemma 2 below that the least favorable location for signal singular values, $x_*(\lambda)$, is such that the top $r$ observed data singular values fall exactly on the chosen threshold $\lambda$.

**Theorem 4:** For a general asymptotic aspect ratio $0 < \beta \leq 1$, the following holds. Let $\lambda > 1 + \sqrt{\beta}$, then

$$\arg\max_{x \in \mathbb{R}^r} M(\hat{X}_\lambda, x) = x_*(\lambda) \cdot (1, \ldots, 1) \in \mathbb{R}^r,$$

where

$$x_*(\lambda) = \sqrt{\frac{\lambda^2 - \beta - 1 + \sqrt{(\lambda^2 - \beta - 1)^2 - 4\beta}}{2}}.$$

Moreover,

$$\min_{\lambda > 1 + \sqrt{\beta}} \max_{x \in \mathbb{R}^r} M(\hat{X}_\lambda, x) = \frac{r}{2} \left[ \beta + 1 + \sqrt{\beta^2 + 14\beta + 1} \right].$$
and

\[
\operatorname{argmin}_{\lambda > 1 + \sqrt{\beta}} \max_{x \in \mathbb{R}^r} M(\hat{x}_s, x) = \sqrt{2(\beta + 1) + \frac{8\beta}{(\beta + 1) + \sqrt{\beta^2 + 14\beta + 1}}}.
\]  

(20)

C. Comparison of Worst-Case AMSE

By Theorem 1, the AMSE of optimally tuned SVHT \( \hat{X}_s \) is always lower than the AMSE of other choices for the hard threshold location. One way to measure how much worse the other choices are, and to compare \( \hat{X}_s \) with other popular matrix denoisers, is to evaluate their worst-case AMSE.

Table II compares the guarantees provided on AMSE by shrinkage rules mentioned, for the square matrix case \( m = n \) in the model \( Y = X + Z/\sqrt{n} \). For the general noise \( Y = X + \sigma Z \) multiply each guarantee by \( n/\sigma^2 \).

1) TSVD: The AMSE of the TSVD \( \hat{X}_s \) is calculated in Lemma 5 below. A simple calculation shows that, in the square matrix case (\( \beta = 1 \))

\[
\max_{x \in \mathbb{R}^r} M(\hat{x}_s, x) = 5r.
\]

This is \( 5/3 \) times the corresponding worst-case AMSE of \( \hat{X}_s \).

2) Hard Thresholding Near the Bulk Edge: Lemma 4 provides the AMSE of the SVHT denoiser \( \hat{X}_s \), for any \( \lambda > 1 + \sqrt{\beta} \). A simple calculation shows that

\[
\max_{x \in \mathbb{R}^r} M(\hat{x}_{2.02}, x) = 4.26r,
\]

providing the worst-case AMSE of the Universal Singular Value Threshold (USVT) of [17]. When thresholding near the bulk edge, the change in worst-case AMSE for just a small increase in the threshold \( \lambda \) is drastic (see Figure 2). The reason for this phenomenon is discussed in section IV.

3) Soft Thresholding: Many authors have considered matrix denoising by applying the soft thresholding nonlinearity \( \eta_s(y; s) = (|y| - s)_+ \cdot \text{sign}(y) \), instead of hard thresholding, to the data singular values. The denoiser

\[
\hat{X}_s = \sum_{i=1}^{n} \eta_s(y_i; s) u_i v_i^	op
\]

is known as Singular Value Soft Thresholding (SVST) or SVT; See [29]–[31] and references therein. In our asymptotic framework, following reasoning similar to the proof of Theorem 1, one finds that the AMSE of SVST is well defined, and that the optimal (namely, asymptotically unique admissible) tuning \( s \) for the soft threshold is exactly at the bulk edge \( 1 + \sqrt{\beta} \). In the square case, the AMSE guarantee of optimally-tuned SVST \( \hat{X}_s \) turns out to be 6r. This is twice as large as that for the optimally tuned SVHT \( \hat{X}_s \). It is interesting to now that both optimal tuning for the soft threshold \( \lambda \) and the corresponding best-possible AMSE guarantee agree with calculations done in an altogether different asymptotic model, in which one first takes \( n \to \infty \) with rank \( r/n \to \rho \), and only then takes \( \rho \to 0 \) [31, Sec. 8]. We also note that the worst-case AMSE of SVST is obtained in the limit of very high SNR, where SVH does very well in comparison. When both are optimally tuned, SVHT does not dominate SVST across all matrices; In fact, soft thresholding does better than hard thresholding in low SNR (Figure 3). For example, in the square case, when the signal is near \( \sqrt{3} \) (the least favorable location for \( \hat{X}_s \)), the AMSE of \( \hat{X}_s \) is \( (7 - 8/\sqrt{3})r \approx 2.38r \), compared to 3r, the worse-case AMSE of \( \hat{X}_s \).

4) Optimal Singular Value Shrinker: Our focus in this paper is denoising by singular value hard thresholding (SVHT), where \( \hat{X}_s \) acts applying a hard thresholding nonlinearity to each of the data singular values. As mentioned in the introduction, one may ask how SVHT compares to other singular value shrinkage denoisers, which use a different nonlinearity that may be more suitable to the problem at hand. In a special case of our asymptotic framework, Shabalin and Nobel [22] and Perry [13] have derived an optimal singular value shrinker \( \hat{X}_{opt} \). Proceeding along this line, in [28] we explore optimal shrinkage of singular values under various loss functions and develop a simple expression for the optimal shrinkers. Calibrated for the model \( X + Z/\sqrt{n} \), in the square setting \( m = n \), this shrinker takes the form

\[
\hat{X}_{opt} : \sum_{i=1}^{n} y_i u_i v_i' \mapsto \sum_{i=1}^{n} \eta_{opt}(y_i) u_i v_i',
\]

where

\[
\eta_{opt}(x) = \sqrt{(x^2 - 4)^+}.
\]

In our asymptotic framework, this rule dominates in AMSE essentially any other estimator based on singular value shrinkage, at any configuration of the non-zero signal singular values \( x \). The AMSE of the optimal shrinker (in the square matrix case) at \( x \in \mathbb{R}^r \) is [28]

\[
M(\hat{X}_{opt}, x) = \sum_{i=1}^{r} \left( 2 - \frac{1}{\sqrt{\lambda_i}} \right) x_i \geq 1
\]

(21)

\[
0 \leq x_i \leq 1.
\]
is at most $\xi$ this is the class of all matrices for which the nuclear norm matrices, namely nuclear norm balls. For a given constant $r$ matrices of at most rank $D$. Minimaxity Over Matrices of Bounded Nuclear Norm 

(See Figure 2.) It follows that the worst-case AMSE of $\hat{X}_{opt}$ is

$$\max_{x \in \mathbb{R}^n} M(\hat{X}_{opt}, x) = 2r$$

in the square case. We conclude that, for square matrices, in worst-case AMSE, singular value hard thresholding at the optimal location is $50\%$ worse than the best possible singular value shrinker, Truncated SVD or SVHT just above the bulk-edge (which roughly equals the widely used Scree-plot elbow truncation) is $250\%$ worse, and singular value soft thresholding edge (which roughly equals the widely used Scree-plot elbow) is $300\%$ worse.

D. Minimality Over Matrices of Bounded Nuclear Norm

So far we have considered minimaxity over the class of matrices of at most rank $r$, where $r$ is given. In [17], the author considered minimax estimation over a different class of matrices, namely nuclear norm balls. For a given constant $\varepsilon$, this is the class of all matrices for which the nuclear norm is at most $\varepsilon$. Recall that the nuclear norm of a matrix $X \in M_{m \times n}$, whose vector of singular values is $x \in \mathbb{R}^m$, is given by $\|x\|_1$. Our next result shows that $\hat{X}_{\lambda}$ is minimax optimal over this class as well. Specifically, it is the minimax estimator, in AMSE, among all SVHT rules, over a given Nuclear Norm ball. We note that unlike Theorems 3 and 4, this result does not follow directly from Theorem 1. We restrict our discussion to square matrices ($\beta = 1$); the general nonsquare case is handled similarly.

Theorem 5: Let $\lambda > 2$ and let $\varepsilon = r \cdot (\lambda + \sqrt{\lambda^2 - 4})/2$ for some $r \in \mathbb{N}$.

1) The least favorable singular value configuration obeys

$$\arg\max_{\|x\|_1 \leq \varepsilon} M(\hat{X}_{\lambda}, x) = x_0(\lambda) \cdot (1, \ldots, 1) \in \mathbb{R}^r,$$

where

$$x_0(\lambda) = \frac{\lambda + \sqrt{\lambda^2 - 4}}{2}.$$

2) The best achievable inequality between norm $\varepsilon$ and AMSE of a hard threshold rule is:

$$\min_{\lambda > 2} \max_{\|x\|_1 \leq \varepsilon} M(\hat{X}_{\lambda}, x) = \sqrt{3} \cdot \varepsilon.$$ (23)

3) The threshold achieving this inequality is

$$\arg\min_{\lambda > 2} \max_{\|x\|_1 \leq \varepsilon} M(\hat{X}_{\lambda}, x) = \frac{4}{\sqrt{3}}.$$ (24)

As an alternative to comparing denoisers by comparing their guarantees on AMSE over a prescribed rank $r$, one can compare denoisers based on the best available constant $C$ in the inequality

$$\min_{\lambda > 2} \max_{\|x\|_1 \leq \varepsilon} M(\hat{X}_{\lambda}, x) = C \cdot \varepsilon.$$ (25)

The results in the square matrix case are summarized in Table III. Each constant is derived from the AMSE formula for the respective denoiser, as cited above. To understand why the best available constant for optimally tuned SVST is smaller than than of optimally tuned SVHT, consider Figure 3.

E. When the Noise Level $\sigma$ Is Unknown

When the noise level in which $Y$ is observed is unknown, it no longer makes sense to use $\hat{X}_{\lambda}$, which is calibrated for a specific noise level. We now describe a method to estimate the optimal hard threshold from the data matrix $Y$. To emphasize that the resulting denoiser is ready for use on data from the general model $Y = X + \sigma Z$, we denote this estimated threshold by $\hat{X}_\tau$, and the SVHT denoiser by $\hat{X}_\tau$. To this end, we are required to estimate the unknown noise level $\sigma$. In the closely related Spiked Covariance Model, there are existing methods for estimation of an unknown noise level; see for example [32] and references therein.

Consider the following robust estimator for the parameter $\sigma$ in the model $Y = X + \sigma Z$:

$$\hat{\sigma}(Y) \equiv \frac{Y_{med}}{\sqrt{\pi} \cdot \beta Y}.$$

where $Y_{med}$ is a median singular value of $Y$ and $\mu Y$ is the median of the the Marčenko-Pastur distribution, namely, the unique solution in $\beta_+ \leq x \leq \beta_+$ to the equation

$$\int_{\beta_-}^{\beta_+} \frac{\sqrt{t(\beta_+ - t)(t - \beta_-)}}{2\pi t} dt = \frac{1}{2},$$

where $\beta_\pm = (1 \pm \sqrt{\beta})^2$. Define the optimal hard threshold for a data matrix $X \in M_{m \times n}$ observed in unknown noise level, with $m/n = \beta$, by defining $\hat{\sigma}(Y)$ instead of $\sigma$ in Eq. (3):

$$\hat{\tau}_\lambda(\beta, Y) \equiv \frac{\lambda_\varepsilon(\beta)}{\sqrt{\mu Y}} \cdot \hat{\sigma}(Y).$$

Writing $\omega(\beta) = \lambda_\varepsilon(\beta)/\sqrt{\mu Y}$, the threshold is

$$\hat{\tau}(\beta, Y) = \omega(\beta) \cdot \hat{\sigma}(Y).$$

The median $\mu Y$ and hence the coefficient $\omega(\beta)$ are not available analytically; in [1] we make available a Matlab script to evaluate the coefficient $\omega(\beta)$. Some values are tabulated in Table IV for convenience. A useful approximation to $\omega$ is given as a cubic polynomial in Eq. (5) above. Empirically,

$$\max_{0.001 < \beta < 3} \frac{|\omega(\beta) - (0.56\beta^3 - 0.95\beta^2 + 1.82\beta + 1.43)|}{\beta} \leq 0.02$$

which may be sufficient for some practical purposes if one does not have access to a more exact value of \omega.
TABLE IV

| \( \beta \) | \( \omega(\beta) \) | \( \beta \) | \( \omega(\beta) \) |
|---------|--------|---------|--------|
| 0.05    | 1.5194| 0.55    | 2.2365|
| 0.10    | 1.6089| 0.60    | 2.3024|
| 0.15    | 1.6896| 0.65    | 2.3679|
| 0.20    | 1.7650| 0.70    | 2.4339|
| 0.25    | 1.8371| 0.75    | 2.5011|
| 0.30    | 1.9061| 0.80    | 2.5697|
| 0.35    | 1.9751| 0.85    | 2.6399|
| 0.40    | 2.0403| 0.90    | 2.7099|
| 0.45    | 2.106 | 0.95    | 2.7832|
| 0.50    | 2.1711| 1.00    | 2.8582|

In the null case \( X = 0 \), the largest data singular value is located asymptotically exactly at the bulk edge, \( 1 + \sqrt{\beta} \). It might seem that just above the bulk edge is a natural place to set a threshold, since anything smaller could be the product of a pure noise situation. However, for \( \beta > 0.2 \), the optimal hard threshold \( \lambda^*(\beta) \) is 15-20% larger than the bulk edge; as \( \beta \to 0 \), it grows about 40% larger. Inspecting the proof of Theorem 1 and particularly the expression for AMSE of SVHT (Lemma 4), one finds the reason: one component of the AMSE is due to the angle between the signal singular vectors and the data singular vectors. This angle converges to a nonzero value as \( n \to \infty \) (given explicitly in Lemma 3) which grows as SNR decreases. When some data singular value \( \gamma_i \) is too close to the bulk, its corresponding singular vectors are too badly rotated, and the rank-one matrix \( \gamma_i \mathbf{u}_i \mathbf{v}_i' \) it contributes to the denoiser hurts the AMSE more than it helps. For example, for square matrices \( \beta = 1 \), this situation is most acute when the signal singular value is just barely larger than \( x_1 = 1 \), causing the corresponding data singular value \( \gamma_i \) to be just barely larger than the bulk edge, which for square matrices is located at 2. A SVHT denoiser thresholding just above the bulk edge would include the component \( \gamma_i \mathbf{u}_i \mathbf{v}_i' \), incurring an AMSE about 5 times larger than the AMSE incurred by excluding \( \gamma_i \) from the reconstruction. The optimal threshold \( \lambda_*(\beta) \) keeps such singular values out of the picture; this is why it is necessarily larger than the bulk edge. The precise value of \( \lambda_*(\beta) \) is the precise point at which it becomes advantageous to include the rank-one contribution of a singular value \( \gamma_i \) in the reconstruction.

B. The Optimal Threshold \( \lambda_*(\beta) \) Relative to the USVT \( \hat{X}_{2.02} \)

As mentioned in the introduction, S. Chatterjee has recently discussed SVHT in a broad class of situations [17]. Translating his much broader discussion to the confines of the present context, he observed that any \( \lambda > 2 \) can serve as a universal hard threshold for singular values (USVT), offering fairly good performance regardless of the matrix shape \( m/n \) and the underlying signal matrix \( X \). The author makes the specific recommendation \( \lambda = 2.02 \) and writes:

“The algorithm manages to cut off the singular values at the ‘correct’ level, depending on the structure of the unknown parameter matrix. The adaptiveness of the USVT threshold is somewhat similar in spirit to that of the SureShrink algorithm of Donoho and Johnstone.”

Keeping in mind that the scope of [17] is much broader than the one considered here, we would like to evaluate this proposal, in the setting of low rank matrix in white noise, and specifically in our asymptotic framework. Figure 4 includes the value 2.02: indeed, this threshold is larger than the bulk edge, for any \( 0 < \beta \leq 1 \), so Chatterjee’s \( \hat{X}_{2.02} \) rule asymptotically set to zero all singular values which could arise due to an underlying noise-only situation. When \( \lambda_*(\beta) < 2.02 \), the \( \hat{X}_{2.02} \) rule sometimes “kills” singular values that the optimal threshold deems good enough for keeping, and when \( \lambda_*(\beta) > 2.02 \), the \( \hat{X}_{2.02} \) rule sometimes “keeps” singular values.
values that did in fact arise from signal, but are so close to the bulk that the optimal threshold declares them unusable.

For $\beta = 1$, the guarantee on worst-case AMSE obtained by using $\lambda = 2.02$ over matrices of rank $r$ is about $4.26\sqrt{r}$, roughly 140% larger than the guarantee obtained by using the minimax threshold $\lambda = 4/\sqrt{3}$ (see Figure 2). For square matrices, the regret for preferring USVT to optimally-tuned SVHT can be substantial: in low SNR ($\chi \approx 1$), using the threshold $\lambda = 2.02$ incurs roughly twice the AMSE of the minimax threshold $4/\sqrt{3}$.

We note that unlike the optimally tuned SVHT $\hat{X}_{\lambda^*}$, the USVT $\hat{X}_{2.02}$ does not take into account the shape factor $\beta$, namely the ratio of number of rows to number of columns of the matrix in question. A comparison of worst-case AMSE between the fixed threshold choice $\lambda = 2.02$ and the optimal hard threshold $\lambda = \lambda_4(\beta)$ is shown in Figure 5. The two curves intersect at $\lambda \approx 0.55$, where the optimal threshold (11) is approximately 2.02.

One might argue that [17] proposed 2.02 based on its MSE performance over classes of matrices bounded in nuclear norm. But also for that purpose, 2.02 is noticeably outperformed by $\lambda^4(\beta)$. Arguing as in Theorem 5 we obtain, in the square case:

$$\max_{\|x\|_1 \leq \xi} M(\hat{X}_{2.02}, x) \approx 3.70 \cdot \xi. \quad (27)$$

The coefficient 3.70 is about 110% larger than the best coefficient achievable by SVHT, namely $C = \sqrt{3}$ in (25).

One should keep in mind that USVT is applicable for a wide range of noise models, e.g. in stochastic block models. [17] is the first, to the best of our knowledge, to suggest that a matrix denoising procedure as simple as SVHT could have universal optimality properties. In our asymptotic framework of low-rank matrices in white noise, the 2.02 threshold performs fairly well in AMSE, except for very small values of $\beta$ (Figure 2); but one often gets a substantial AMSE improvement by switching to the rule we recommend. Since our recommendation dominates in AMSE, there is no downside to making this switch – i.e. there is no configuration of signal singular values $x$ which could make one regret this switch.

V. PROOFS

Setting additional notation required in the proofs, let

$$X_n = \sum_{i=1}^{r} x_i a_{n,i} b_{n,i}^*$$

be a sequence of signal matrices in our asymptotic framework, so that $a_{n,i} \in \mathbb{R}^{m_n}$ (resp. $b_{n,i} \in \mathbb{R}^n$) is the left (resp. right) singular vector corresponding to the singular value $x_i$, namely, $i$-th column of $U_n$ (resp. $V_n$) in (39). Similarly, let $Y_n$ be a corresponding sequence of observed matrices in our framework, and write

$$Y_n = \sum_{i=1}^{m_n} y_{n,i} u_{n,i} v_{n,i}^*$$

so that $u_{n,i} \in \mathbb{R}^m$ (resp. $v_{n,i} \in \mathbb{R}^n$) is the left (resp. right) singular vector corresponding to the singular value $y_{n,i}$. (Note that $\{a_{n,i}\}$ and $\{b_{n,i}\}$ are unknown, arbitrary, non-random vectors.)

Our main results depend on Lemma 4, a formula for the AMSE of SVHT. This formula in turn depends on Lemma 2 and Lemma 3. Both follow from recent key results due to [25].

Lemma 2 (Asymptotic Data Singular Values): For $1 \leq i \leq r$,

$$\lim_{n \to \infty} y_{n,i} \left. \begin{array}{ll} \frac{1}{\sqrt{m_n}} \frac{1}{\sqrt{d_n}} \bigg\{ x_i + \sqrt{d_n} \bigg\} \bigg\{ x_i + \frac{\beta}{\sqrt{d_n}} \bigg\} & \quad x_i > \beta^{1/4} \\frac{1}{\sqrt{m_n}} \frac{1}{\sqrt{d_n}} \bigg\{ x_i - \sqrt{d_n} \bigg\} \bigg\{ x_i - \frac{\beta}{\sqrt{d_n}} \bigg\} & \quad x_i \leq \beta^{1/4} \end{array} \right. \right.$$\quad (28)

Lemma 3 (Asymptotic Angle Between Signal and Data Singular Vectors): Let $1 \leq i \neq j \leq r$ and assume that $x_i$ has degeneracy $d$, namely, there are exactly $d$ entries of $x$ equal to $x_i$. If $x_i > \beta^{1/4}$, we have

$$d \cdot \lim_{n \to \infty} \left| \langle a_{n,i} , u_{n,j} \rangle \right|^2 \overset{a.s.}{=} \left\{ \begin{array}{ll} \frac{x_i^2 - \beta}{x_i^2 + \beta^2} & \quad x_i = x_j \\ 0 & \quad x_i \neq x_j \end{array} \right. \quad (29)$$

and, a slightly different formula,

$$d \cdot \lim_{n \to \infty} \left| \langle b_{n,i} , v_{n,j} \rangle \right|^2 \overset{a.s.}{=} \left\{ \begin{array}{ll} \frac{x_i^2 - \beta}{x_i^2 + \beta^2} & \quad x_i = x_j \\ 0 & \quad x_i \neq x_j \end{array} \right. \quad (30)$$

If however $x_i \leq \beta^{1/4}$, then we have

$$\lim_{n \to \infty} \left| \langle a_{n,i} , u_{n,j} \rangle \right|^2 \overset{a.s.}{=} \lim_{n \to \infty} \left| \langle b_{n,i} , v_{n,j} \rangle \right|^2 \overset{a.s.}{=} 0.$$\quad (31)

To appeal to these results, we need to show that our asymptotic framework satisfies the assumptions of [25]. By [21] the limiting law of the singular values of $Z_n/\sqrt{m}$ is the quarter-circle density

$$f(x) = \frac{\pi \beta}{x \beta^2} \{1 - \sqrt{1 - \beta^2} \}^{1/2} \left| 1 - \sqrt{1 - \beta^2} \right| \quad (31)$$

by [26], $y_{n,1} \overset{a.s.}{\to} 1 + \sqrt{\beta}$; by [27], $y_{n,m_n} \overset{a.s.}{\to} 1 - \sqrt{\beta}$. This satisfies assumptions 2.1, 2.2 and 2.3 of [25], respectively. Formulas (28), (29) and (30), as seen in [25, Example 3.1], depend only on the shape of the limiting distribution (31) and not on any Gaussian assumptions.

Using Lemma 2 and Lemma 3, we can calculate the AMSE (9) of the hard thresholding estimator $\hat{X}_{\beta}$, for given
threshold \( \lambda \), at a matrix of specific aspect ratio \( \beta \) and signal singular values \( x \):

**Lemma 4 (AMSE of Singular Value Hard Thresholding):** Fix \( r > 0 \) and \( x \in \mathbb{R}^r \). Let \( (X_n(x))_{n=1}^{\infty} \) and \((Z_n)_{n=1}^{\infty}\) be matrix sequences in our asymptotic framework, and let \( \lambda \geq 1 + \sqrt{\beta} \). Then

\[
\mathbf{M}(\hat{X}_r, x) = \sum_{i=1}^{r} \mathbf{M}(\hat{X}_r, x_i)
\]

where

\[
\mathbf{M}(\hat{X}_r, x) = \left\{ \left( x + \frac{1}{x} \right) (x + \frac{\beta}{x^2}) - (x^2 - \frac{2\beta}{x^2}) \right\} \quad x \geq x_s(\lambda) \quad x < x_s(\lambda)
\]

and \( x_s(\lambda) \) is given by Eq. (18).

Figure 2 shows the AMSE of Lemma 4, in square case \( \beta = 1 \) and nonsquare cases \( \beta = 0.1, \beta = 0.3 \) and \( \beta = 0.7 \).

**Proof:** By definition,

\[
\hat{X}_r(Y_n) = \sum_{i=1}^{m_n} \eta_H(y_n,i; \lambda) u_n,i v_{n,i}^t,
\]

where \( \eta_H(y, \tau) = y 1_{\{\tau \geq 1\}} \). Observe that

\[
\|\hat{X}_r(Y_n) - X_n\|_F^2 = (\hat{X}_r(Y_n) - X_n, \hat{X}_r(Y_n) - X_n) = (\hat{X}_r(Y_n), \hat{X}_r(Y_n)) + (X_n, X_n) - 2(\hat{X}_r(Y_n), X_n) = \sum_{i=1}^{m_n} \eta_H(y_n,i; \lambda)^2
\]

\[
+ \sum_{i=1}^{r} x_i^2 - 2 \sum_{i,j=1}^{r} x_i \eta_H(y_n,i; \lambda) (a_i b_j^t, u_n,j v_{n,j}^t)
\]

\[
= \sum_{i=r+1}^{m_n} \eta_H(y_n,i; \lambda)^2 + \sum_{i=1}^{r} \eta_H(y_n,i; \lambda)^2 + x_i^2
\]

\[
- 2x_i \sum_{j=1}^{r} \eta_H(y_n,j; \lambda) (a_i b_j^t, u_n,j v_{n,j}^t)
\]

where we have used Lemma 2 again. Collecting the terms, we find for the limiting value of (34) that

\[
\lim_{n \to \infty} \mathbf{M}(\hat{X}_r, x) = \sum_{i=1}^{r} \mathbf{M}(\hat{X}_r, x_i),
\]

where \( M(\hat{X}_r, x) \) is given by (33) as required.

For the TSVD, the same argument gives:

**Lemma 5 (AMSE of TSVD):** Fix \( r > 0 \) and \( x \in \mathbb{R}^r \). Let \( (X_n(x))_{n=1}^{\infty} \) and \((Z_n)_{n=1}^{\infty}\) be matrix sequences in our asymptotic framework, and let \( \lambda \geq 1 + \sqrt{\beta} \). Then

\[
\mathbf{M}(\hat{X}_r, x) = \sum_{i=1}^{r} \mathbf{M}(\hat{X}_r, x_i),
\]

where

\[
M(\hat{X}_r, x) = \left\{ \left( x + \frac{1}{x} \right) (x + \frac{\beta}{x^2}) - (x^2 - \frac{2\beta}{x^2}) \right\} \quad x \geq \beta^{1/4} \quad \beta \leq \beta^{1/4} \cdot \left(1 + \sqrt{\beta}\right)^2 + x^2
\]

We now to turn to prove our main results.

**Proof of Theorem 1:** Let \( x_s = x_s(\lambda_\ast(\beta)) \) where \( \lambda_\ast(\beta) \) is defined in (11) and \( x_s(\lambda) \) is defined in (18).

Then

\[
x_s^2 = \left( x_s + \frac{1}{x_s} \right)^2 \left( x_s + \frac{\beta}{x_s} \right) - \left( x_s^2 - \frac{2\beta}{x_s^2} \right)
\]

It follows that for all \( x > 0 \) and \( \lambda \geq 1 + \sqrt{\beta} \),

\[
M(\hat{X}_{x_s}, x) \leq M(\hat{X}_r, x)
\]

and the theorem follows from Eq. (32).
Figure 6 provides a visual explanation of this proof for the square ($\beta = 1$) case.

Proof of Theorem 2: For $x < \beta^{1/4}$, by Lemma 4 and Lemma 5 we have

$$M(\hat{X}_{\lambda}, x) = x^2 \leq x^2 + (1 + \sqrt{\beta})^2 = M(\hat{X}, x).$$

For $x \geq \beta^{1/4}$, by Lemma 5 and Theorem 1 we have

$$M(\hat{X}_{\lambda}, x) \leq M(\hat{X}, x).$$

Proof of Theorems 3 and 4: Theorem 3 is a special case of Theorem 4. By (32), it is enough to consider the univariate function $x \mapsto M(\hat{X}, x)$ defined in (33). The theorem follows from Lemma 4 using the following simple observation.

Let $0 < \beta \leq 1$ and $\lambda > 1 + \sqrt{n}$. Denote by $x_\lambda(\lambda)$ the unique positive solution to the equation $(x + 1/x)(x + \beta/x) = \lambda^2$. Let $\lambda_\ast$ be the unique solution to the equation in $\lambda$

$$x_\lambda^2(\lambda) - (\beta + 1)x_\lambda^2 - 3\beta = 0.$$

Then for the function $M(\hat{X}, x)$ defined in (33), we have

$$\text{argmax}_{x > 0} M(\hat{X}, x) = x_\lambda(\lambda),$$

$$\text{argmin}_{x > 1+\sqrt{n}} \max_{x > 0} M(\hat{X}, x) = \lambda_\ast,$$

$$\min_{x > 1+\sqrt{n}} \max_{x > 0} M(\hat{X}, x) = x_\ast(\lambda_\ast)^2.$$

Note that the least favorable situation occurs when $x_1 = \ldots = x_r = x_\lambda(\lambda)$, and that $x_\lambda(\lambda)$ is precisely the value of $x$ for which the corresponding limiting data singular value satisfies $y_{n,i} \overset{a.s.}{\longrightarrow} \lambda$. In other words, the least favorable situation occurs when the data singular values all coincide with each other and with the chosen hard threshold.

Proof of Lemma 1: Let $F_n$ denote the empirical cumulative distribution function (CDF) of the squared singular values of $Y_n$. Write $\hat{y}_{\text{med}, n} = \text{Median}(F_n)$, where $\text{Median}(\cdot)$ is a functional which takes as argument the CDF and delivers the median of that CDF. Under our asymptotic framework, almost surely, $F_n$ converges weakly to a limiting distribution, $F_{MP}$, the CDF of the Marčenko-Pastur distribution with shape parameter $\beta$ [21]. This distribution has a positive density throughout its support, in particular at its median. The median functional is continuous for weak convergence at $F_0$, and hence, almost surely,

$$\hat{y}_{\text{med}, n} = \text{Median}(F_n) \overset{a.s.}{\longrightarrow} \text{Median}(F_0) = \mu_\beta, \quad n \to \infty.$$

It follows that,

$$\lim_{n \to \infty} \frac{\hat{\sigma}(Y_n)}{1/\sqrt{n}} \overset{a.s.}{=} \lim_{n \to \infty} \frac{\hat{\sigma}_{\text{med}, n}}{\sqrt{n}} \overset{a.s.}{=} 1.$$

VI. GENERAL WHITE NOISE

Our results were formally stated for a sequence of models of the form $Y = X + Z$, where $X$ is a non-random matrix to be estimated, and the entries of $Z$ are i.i.d samples from a distribution that is orthogonally invariant (in the sense that the matrix $Z$ satisfies the same distribution as $AZB$, for any orthogonal $A \in M_{m,m}$ and $B \in M_{n,n}$). While Gaussian noise is orthogonally invariant, many common distributions, which one could consider to model white observation noise, are not.

One attractive feature of the discussion on optimal choice of singular value hard threshold, presented above, is that the AMSE $M(\hat{X}, x)$ only depends on the signal matrix $X$ through its rank, or more specifically, through its nonzero singular values $x$. If the distribution of $Z$ is not orthogonally invariant, MSE (or AMSE) losses this property and depends on properties of $X$ other than its rank. This point is discussed extensively in [22].

In general white noise, which is not necessarily orthogonally invariant, one can still allow MSE to depend on $X$ only through its singular values by placing a prior distribution on $X$ and shifting to a model where it is a random, instead of a fixed, matrix. Specifically, consider an alternative asymptotic framework to the one in Section II-B, in which the sequence denoising problems $Y_n = X_n + Z_n/\sqrt{n}$ satisfies the following assumptions:

1) General White Noise: The entries of $Z_n$ are i.i.d samples from a distribution with zero mean, unit variance and finite fourth moment.

2) Fixed Signal Column Span and Uniformly Distributed Signal Singular Vectors: Let the rank $r > 0$ be fixed and choose a vector $x \in \mathbb{R}^r$ with coordinates $x = (x_1, \ldots, x_r)$. Assume that for all $n$,

$$X_n = U_n \text{diag}(x_1, \ldots, x_r, 0, \ldots, 0) V_n'$$

is a singular value decomposition of $X_n$, where $U_n$ and $V_n$ are uniformly distributed random orthogonal matrices. Formally, $U_n$ and $V_n$ are sampled from the Haar distribution on the $m$-by-$m$ and $n$-by-$n$ orthogonal group, respectively.
Fig. 7. The AMSE (solid line) and empirical MSE (circles) of TSVD $\hat{X}_r$ and optimal SVHT $\hat{X}_\lambda^\ast$ for $\beta = 1$ and signal singular value $x \geq 1$ which correspond to leading data singular values that fall beyond the bulk edge. In a given panel, for a given value of $x$, the blue and the red dots were generated by first generating a signal matrix $X$, and then averaging each of the losses $\|\hat{X}(X + Z/\sqrt{n}) - X\|_F^2$ over the same 50 Monte Carlo draws of the noise matrix $Z$. Each column of panels represents a different noise with zero mean and unit variance: Gaussian, Bernoulli on $\pm 1$, uniform on $[-0.5, 0.5]$ and Student’s $t$-distribution with 6 degrees of freedom; Panel titles indicate $(m, n, r)$ and the noise distribution. Top rows: $r = 1$, different values of $m = n$; Bottom rows: $m = n = 50$, different values of $r$ (for $r > 1$, signal singular values are all equal). Reproducibility advisory: script to generate figure, and to perform similar experiments, is included in code supplement [1] (color online).

3) Asymptotic Aspect Ratio $\beta$: The sequence $m_n$ is such that $m_n/n \to \beta$.

The second assumption above implies that $X_n$ a “generic” choice of matrix with nonzero singular values $x$, or equivalently, a generic choice of coordinate systems in which the linear operator corresponding to $X$ is expressed.

The results of [25], which we have used, hold in this case as well. It follows that Lemma 4 and Lemma 5, and consequently
all our main results, hold under this alternative framework. In short, in general white noise, all our results hold if one is willing to only specify the signal singular values, rather than the signal matrix, and consider a “generic” signal matrix with these singular values.

VII. EMPIRICAL COMPARISON OF MSE WITH AMSE

We have calculated the exact optimal threshold \( \tau_n \) in a certain asymptotic framework. The practical significance of our results hinges on the validity of the AMSE as an approximation to MSE, for values of \((m, n, r)\) and error distributions encountered in practice. This in turn depends on the simultaneous convergence of three terms:

- Convergence of the top data singular values \( y_{n,i} (1 \leq i \leq r) \) to the limit in Lemma 2,
- Convergence of the angle between the top data singular vectors \( u_{n,i}, v_{n,i} \) and their respective signal singular vectors to the limit in Lemma 3, and
- Convergence of the rest of the data singular values \( y_{n,i} \) \((r+1 \leq i \leq m)\) to the interval \([0, 1 + \sqrt{r}]\).

Analysis of each of these terms for specific error distributions is beyond our current scope. Figure 7 contains a few sample comparisons of AMSE and empirical MSE we have performed. The matrix sizes and number of Monte Carlo draws are small enough to demonstrate that AMSE is a reasonable approximation even for relatively small low-rank matrices. As convergence of the empirical spectrum to its limit is known to depend on moments of the underlying distributions, we include results for different error distributions. AMSE is found to be a useful proxy to MSE even in small matrix sizes. AMSE of SVHT was found to be inaccurate when: (i) the rank fraction is nontrivial (e.g., \( n = 50, r = 4 \)) shown at the bottom of Figure 7; (ii) the threshold \( \lambda \) is very close to the approximate bulk edge \( 1 + \sqrt{m/n} \). In case (i), interaction effects between singular values, which are ignored in our asymptotic framework, start to have non-negligible effect. In case (ii), where the discontinuity of the SVHT nonlinearity is placed close to the bulk edge, the distribution of the largest “non-signal” singular value \( y_{n,r+1} \), which is known in some cases to be asymptotically a Tracy-Widom distribution [23], becomes important. Indeed, some data singular values from the bulk manage to pass the threshold \( \lambda \) and cause their singular vectors to be included in the estimator \( \hat{X}_2 \). Our derivation of AMSE assumed however that no such singular vectors are included in \( \hat{X}_1 \), since \( y_{n,r+1} \to \lambda \). Note however that the main recommendation of this paper is that one should not threshold at or near the bulk edge, as explained in detail above. Therefore, from a practical perspective, the inaccuracy of AMSE for SVHT with \( \lambda \) near the bulk edge is slightly irrelevant.

VIII. CONCLUSION

The asymptotic framework considered here is perhaps the simplest nontrivial model for matrix denoising. It allows one to calculate, in AMSE, basically any quantity of interest, for any denoiser of interest. The fundamental elements of matrix denoising in white noise, which underly more complicated models, are present yet understandable and quantifiable. For example, the AMSE of any denoiser based on singular value shrinkage contains a component due to noise contamination in the data singular vectors, and this component determines a fundamental lower bound on AMSE.

We conjecture that results calculated in this model, which are not attached to a specific assumption on rank (e.g., the constants in Table III, which determine the minimax AMSE over nuclear norm balls) remain essentially correct in more complicated models.

The decision-theoretic landscape as it appears through the naive prism of our asymptotic framework is extremely simple: there is a unique admissible hard thresholding rule, and moreover a unique admissible shrinkage rule, for singular values. This is of course quite different from the situation encountered, for example, in estimating normal means. The reason is the extreme simplicity of our model. For example, we have replaced the data singular values, which are random for finite matrix size, with their almost sure limits, and in effect neglected their random fluctuations around these limits. These fluctuations are now well understood (see [33], [34]). We have ignored this structure. However, including these second-order terms in the asymptotic distributions is only likely to achieve second-order improvements in MSE over our suggested optimal truncation threshold.

REPRODUCIBLE RESEARCH

In the code supplement [1] we offer a Matlab software library that includes:

1) A function that calculates the optimal shrinkage coefficient in known or unknown noise level.
2) Scripts that generate each of the figures in this paper.
3) A script that generates figures similar to Figure 7, which compare AMSE to MSE in various situations.

ACKNOWLEDGMENT

The authors would like to thank Andrea Montanari for pointing to the work of Shabalin and Nobel, Drew Nobel and Sourav Chatterjee for helpful discussions, Art Owen for pointing to Perry’s work, and the anonymous referees for their useful suggestions.
