The effect of altered hadron masses is studied for its effect with regard to final-state hadronic observables. It is shown that the final phase space densities of pions and kaons, which can be inferred experimentally, are sensitive to in-medium properties of the excited matter at earlier stages of the collision, but that the sensitivity is significantly moderated by interactions that change the effective numbers of pions and kaons during the latter part of the collision.

Relativistic heavy ion collisions at the CERN SPS (160 A GeV Pb + Pb) or the Brookhaven AGS (11 A GeV Au + Au) produce a mesoscopic region where initial energy densities are in the neighborhood of a few GeV/fm$^3$, several times the energy density of a proton. As the system expands and cools normal hadronic degrees of freedom become justified, but the system might still have novel properties when energy densities are in the region of 500 MeV/fm$^3$. Most notably, as a consequence of restoring chiral symmetry, the masses of heavier hadrons might fall as much as 50% [3]. Evidence of falling masses has appeared in dilepton measurements of the $\rho$ peak in Pb + Pb collisions at $E/A = 160$ GeV, performed at the SPS. The observed lack of strength of dilepton pairs in the region of the $\rho$ meson mass, combined with the observed additional strength for invariant masses near 400 MeV, suggest either that the $\rho$ meson was altered [4], dissolved [5], or broadened beyond recognition by collisions [6].

Since dileptons largely pass through the collision volume unscathed, they provide a transparent probe for investigating hadronic properties during the most interesting stages of the collision, but only those hadrons with the quantum numbers of the photon. Final state measurements of hadrons – pions, kaons, protons and hyperons, provide a rich chemistry as nearly $10^3$ hadrons are commonly produced in a single event. However, hadrons interact several times after the system has expanded beyond the energy densities of greatest interest when temperatures are near or above 150 MeV, and before the breakup density is reached, when temperatures are approximately 110 MeV. In the high density hadronic state, equilibrium chemical abundances can easily change by factors of two if masses are adjusted by several hundred MeV as predicted by some chiral models. In this letter we investigate whether such mass changes, and the corresponding changes in hadronic chemical abundances, survive and produce a signal in the measured hadrons. By using phenomenologically motivated chemical rates, we model the chemical development of a kinetically equilibrated gas that expands under a time scale relevant for relativistic heavy ion collisions. We find that falling hadron masses, on the order of 50%, result in increased final phase space densities for both pions and kaons which can be inferred by measuring spectra and two-particle correlations. We show that if reactions that preserve the effective pion and kaon numbers are ignored, a strong signal survives the final expansion, and that if such reactions are included, the manifestations of the original novel chemistry survive, but are strongly moderated. We also find that hadronic observables are sensitive to the issue of whether both baryon and vector mesons scale, or whether just the baryon masses [7].

In Pb + Pb collisions at the SPS or in Au + Au collisions at the AGS, ≈ 7 fm/c after initial contact, matter has expanded and cooled to the point where a model based on binary interactions of hadrons is justified. For the following thermal calculations, we take the onset of binary modeling to occur at a temperature of 160 MeV. We assume that the system is both kinetically and chemically equilibrated at this point and is characterized by four numbers: a baryon chemical potential $\mu_b$, a strangeness chemical potential $\mu_s$, and a temperature $T$. The strangeness chemical potential is chosen such that the net strangeness is zero. It would be zero if the baryon density were zero. The baryon chemical potential is chosen to match the effective baryon to pion ratios, unity for the AGS example and 1/5 for the SPS example. The assumption of equilibration when $T = 160$ MeV is an ansatz, justified only by the fact that the hadrons significantly overlap at higher temperature, suggesting very rapid equilibration of the strongly interacting system. At later times and lower temperatures, kinetic equilibrium is approximately maintained [8], but some aspects of chemical equilibrium are lost. When the system expands and cools to approximately $T = 110$ MeV, kinetic equilibrium is lost.

The baryon and strangeness chemical potentials have been omitted for brevity. The integral over analytically, and given an expression for the cross section, the integral over rest frame and $q$ the quantum numbers of the initial state. This behavior is motivated by the observed behavior of the inelastic cross sections \cite{13} with

\begin{align*}
\text{ab} & \rightarrow \sum_i N_{\pi, i} R_i(1 - \exp - \Delta N_{\pi, i} \mu_\pi t), \\
R_i & = (2J_a + 1)(2J_b + 1) \int \frac{E_{\text{cm}} d^3 p}{E} e^{-\frac{E - (N_{a, \pi} + N_{b, \pi}) \mu_\pi)} / T \int d^3 q \sigma(E_{\text{cm}}) v_{\text{rel}, \text{cm}}
\end{align*}

where the sum is over all reactions $(ab \rightarrow X)$ that increase the effective pion number by $\Delta N_{\pi, i}$. The effective rate per volume, $R_i$, for a specific reaction can be found by convoluting the phase space densities of $a$ and $b$, and folding in the cross section. The energy of the pair is $E = \sqrt{P^2 + E_{\text{cm}}^2}$, where $E_{\text{cm}}$ is the energy of the pair as measured in the $ab$ rest frame and $q$ and $v_{\text{rel}, \text{cm}}$ are the relative momentum and relative velocity of $a$ and $b$ as measured in that frame. The baryon and strangeness chemical potentials have been omitted for brevity. The integral over $P$ can be performed analytically, and given an expression for the cross section, the integral over $q$ can be performed numerically.

The effective pion density,

$$n_\pi = \sum_a N_{a, \pi} (2J_a + 1) \int \frac{d^3 p}{(2\pi)^3} e^{-\mu_\pi N_{a, \pi}}$$

can also be found analytically given the effective pionic content, $N_{a, \pi}$ of the species $a$. One can expand the above expressions for small $\mu_\pi$ to find the rate at which $\mu_\pi$ returns to equilibrium,

$$\frac{d\mu_\pi}{dt} = \frac{1}{\tau} \mu_\pi$$

$$\frac{1}{\tau} = \sum_i \frac{\Delta N_{i, \pi}^2 R_i(\mu_\pi = 0)}{n_\pi(\mu_\pi = 0)}$$

Unfortunately, experimental cross sections are not available for the majority of the combinations $ab$ of the 26 mass states used in this analysis, and since the relevant energies for pion production are several hundred MeV, perturbation theory is not particularly reliable. We have therefore instituted simplified expressions for the cross sections.

$$\sigma(E_{\text{cm}}) = \sigma_0(\theta(E_{\text{cm}} - E_{\text{th}} - N_{\pi, X} 350 \text{ MeV})$$

where $N_{\pi, X}$ is the number of pions in the final state, and the threshold $E_{\text{th}}$ is the minimum energy of a state with the quantum numbers of the initial state. This behavior is motivated by the observed behavior of the inelastic $pp$ and $p\pi$ cross sections \cite{14} with $\sigma_0$ being 25 mb if both incoming particles are baryons, 20 mb if one is a baryon and 15 mb if neither is a baryon. When the production of more pions becomes available, all the cross section is then devoted to that number of pions. For the case where no baryons are present in the initial state, only even numbers of pions
are allowed in the final state as required by conservation of g-parity. For the production of strangeness, only pairs of strange-anti strange are allowed and the steps are in units of 1.2 GeV if no baryons are present in the initial state and 800 MeV if baryons are present.

\[
\sigma(E_{cm}) = \sigma_0 \theta(E_{cm} - E_{th} - N_{K,X}(800 \text{ or } 1200 \text{ MeV})) ,
\]

The reduced stepsize of 800 MeV is to account for Λ production which only requires a few hundred MeV energy. The cross section \(\sigma_0\) for strangeness production is taken as one fourth that of the pion production cross section. These values were motivated by measurements of Λ production \([14,15]\), with the value of \(\sigma_0\) being multiplied by 2.5 to account for the production of other hyperons. Although the prescription for determining cross sections is phenomenologically motivated, given the large number of experimentally unknown information, the cross sections must not be taken seriously beyond the 50\% level, especially for the case of strangeness producing rates.

Characteristic chemical equilibration times are displayed in Figure 1. Characteristic expansion times are \(\approx 5 \text{ fm/c}\) when \(T = 160 \text{ MeV}\) and \(\approx 20 \text{ fm/c}\) when the system is near breakup at \(T \approx 110 \text{ MeV}\). From viewing Figure 1 one expects pionic chemical equilibration to be lost when the temperature approaches 150 MeV while strangeness equilibration can be hardly justified even at \(T = 160 \text{ MeV}\). We should point out that if masses fall due to restoration of chiral symmetry, hadron densities rise accordingly and characteristic times are considerably shorter. The role of the baryons in maintaining chemical equilibration is crucial. Even when baryons comprise only a fifth of the produced hadrons, reactions involving baryons contribute the majority of the rate. This comes from the fact that reactions involving baryons do not need to conserve g-parity and pions need not be produced pairwise.

We now proceed to calculate generated chemical potentials for systems which cool from an equilibrated state at \(T = 160 \text{ MeV}\) to an unequilibrated state at \(T = 110 \text{ MeV}\) with chemical potentials \(\mu_\pi\) and \(\mu_K\). If number-changing rates are neglected the four final chemical potentials, \(\mu_\pi\), \(\mu_K\), \(\mu_\pi\), and \(\mu_\rho\) can be found by the four constraints: (1) The net strangeness is zero. (2) The baryon to pion ratio is fixed. (3) The entropy per pion is fixed. (4) The net number of strange quarks per pion is fixed. If rates that change the pion number and strange quark number are included, the latter three constraints must be modified by integrating the time development of the system.

\[
\frac{d}{dt} \frac{n_b}{n_\pi} = -\frac{n_b}{n_\pi^2} \frac{d}{dt} n_\pi
\]

\[
\frac{d}{dt} \frac{n_S}{n_\pi} = -\frac{n_S}{n_\pi^2} \frac{d}{dt} n_\pi - \frac{\mu_\pi}{n_\pi} \frac{d}{dt} n_\pi - \frac{\mu_K}{n_\pi} \frac{d}{dt} n_K
\]

\[
\frac{d}{dt} \frac{n_K}{n_\pi} = -\frac{n_K}{n_\pi^2} \frac{d}{dt} n_\pi + \frac{1}{n_\pi} \frac{d}{dt} n_K,
\]

where \(n_S\) is the entropy density. Thus if one knows the temperature as a function of time, one can integrate these equations forward in time, using the four aforementioned quantities to determine the four unknown chemical potentials at any time. For our purposes we assumed a simplified behavior of the temperature, \(T\), as a function of time, \(dT/dt = -6.5 \text{ MeV/(fm/c)}\), which was motivated by the behavior observed in cascade simulations \([3]\).

The resulting evolutions of \(\mu_\pi\) and \(\mu_K\) as a function of temperature are illustrated in Figure 2. The baryon to pion ratio was chosen to be 0.2, which is relevant for Pb + Pb collisions at the SPS. Inclusion of the rates is clearly important in determining the final chemistry.

The chemical evolutions were also calculated with the assumption that the hadronic masses varied as a function of the temperature. The hadrons, aside from the pseudoscalar mesons which are Goldstone bosons, were assumed to scale linearly with the temperature from their vacuum mass when \(T = 110 \text{ MeV}\) to a fraction, \(m/m_0\), at \(T = 160 \text{ MeV}\). The lower panels of Figure 3 show the value of \(\mu_\pi\) at breakup for four cases. The final baryon to pion ratio was chosen to be 0.2 or 1.0, roughly appropriate for SPS or AGS conditions respectively. If no number-changing rates are included, the generated chemical potential is large, approaching 100 MeV for the SPS case and 150 MeV for the AGS case, when the mass reduction factor falls below 0.5. However, inclusion of the rates reduces the resulting chemical potential to near 50 MeV. Since the falling of the \(\rho\) mass is controversial, the calculations were repeated with the assumption that only the baryon masses scaled (right panels of Figure 3), while the vector meson masses remained fixed. In this case the resulting chemical potentials were far lower for the SPS case, and in fact chemical potentials were smaller for increasingly small mass reduction factors. This owes itself to the fact that the entropy per pion due to the presence of baryons is rather high, compared to the entropy per pion in the mesonic sector.

Calculations of \(\mu_K\) as a function of the mass reduction factor are displayed in the upper panels of Figure 3. The resulting \(\mu_K\) is much larger than \(\mu_\pi\), surpassing 100 MeV, even for the case where rates were included. Since the phase space density is proportional to \(e^{\mu/T}\), the strangeness phase space density is nearly doubled compared to the \(\mu_K = 0\) case if masses don’t scale, and more than doubled when mass-scaling occurs. The number-changing rates that most strongly affected \(\mu_K\) were not those that changed the effective kaon number but those that affected the net
pion number. The kaon-number-changing rates are sufficiently small that they had a relatively small effect toward the final outcome.

Chemical potentials can be inferred from hadronic measurements via correlation measurements \[16\]. Combining two-particle correlations measurements, which are sensitive to the breakup volume, and spectra one can infer phase space densities, which should be \( \approx e^{\mu/T} \), at low momentum. Combined with careful modeling of the breakup stage of the reaction, one can thus infer chemical potentials to the accuracy of \( \pm 30 \) MeV.

Perhaps the observable that is most directly sensitive to \( \mu_K \) is the abundance of anti-hyperons. For instance, \( \bar{\Omega} \) consists of three anti-quarks, and would feel an enhancement of \( \exp(3\mu_K/T) \). Figure 4 displays the ratio \( \Lambda/\bar{p} \) as a function of the mass reduction factor. The baryon-to-pion ratio was set to 0.2 or 1.0 to be relevant for the SPS and AGS experiments respectively. Calculations where number changing rates are included or not included are both shown, and it is evident that number-changing rates have a profound influence on the population of anti-hyperons. When rates are included, there is little sensitivity to the mass reduction factor, whereas when number changing rates are ignored, calculations yield very large ratios. Preliminary measurements of the \( \Lambda/\bar{p} \) by E864 \[17\] have yielded values above unity, approximately double or triple the calculations presented here. If one argued that the cross sections for number changing rates used here, particularly those that changed the effective number of strange quarks, were overestimated by a factor of two, one could then explain the experimental findings. Before one can make firm conclusions with regard to this measurement, a better understanding of number-changing cross sections, especially those involving the annihilation of strange hyperons, must be reached.

Several conclusions can be made from this investigation. First, the chemical properties of the hottest stages of relativistic heavy ion collisions do indeed manifest themselves in the final hadronic measurements. In particular, chiral restoration can affect the final phase space densities of both the pions and kaons. However, chemical processes, which drive the system towards equilibrium, significantly mitigate such signals. Altering the chiral properties of the hottest stages results in a difference of the final chemical potentials of the order of 50 MeV or less, while the ability of an experiment to determine the chemical potentials, is probably in the 30 MeV range at best. Thus, measuring hadrons can be expected to provide information or evidence regarding the chiral transition, but would probably not supply a “smoking gun” signal, unless the chemical rates employed in this paper are overestimated.

It should be stressed that this analysis has relevance beyond the issue of dropping hadron masses. Effective chemical potentials and phase space densities are of crucial importance in understanding the entropy of the reaction, which can signal the presence of the deconfinement transition. Secondly, the conditions of the final state provide boundary conditions necessary for modeling the earlier stages of the collision. For instance, dilepton production from \( \pi\pi \) annihilation would scale as \( \exp(2\mu_\pi/T) \). Finally, the sensitivity of the observables to the inclusion of pion-number-changing and kaon-number-changing chemical processes demonstrates the importance of including such reactions, along with the corresponding time-reversed processes, in any modeling of the final state expansion.

FIG. 1. Characteristic times for chemical potentials returning to zero are shown for \( \mu_\pi \) (circles) and \( \mu_K \) (squares). The decay time corresponding to \( \mu_\pi \) becomes larger than characteristic expansion times when \( T \approx 150 \text{ MeV} \), while equilibration times for \( \mu_K \) are longer than characteristic expansion times even for \( T = 160 \text{ MeV} \).

FIG. 2. The evolution of \( \mu_\pi \) (solid line) and \( \mu_K \) (dashed line) are shown for an expanding hadron gas that began at a 160 MeV temperature. This calculation has incorporated pion and kaon number changing rates.
FIG. 3. Final chemical potentials are shown as a function of the mass reduction factor at the initial temperature of 160 MeV. Calculations are shown for the cases where number-changing processes are neglected (solid lines) or included (dashed lines), and for when vector mesons scale with the baryon masses (left panel) or remain fixed (right panel). Calculations are performed for two choices of the baryon-to-pion ratio, 1.0 which is relevant for AGS measurements (squares) and 0.2 which is relevant for measurements at SPS (circles). One sees that number-changing rates significantly damp the effect of altering hadron masses, and if vector meson masses are unchanged that the chemistry is less affected.

FIG. 4. The $\bar{\Lambda}/\bar{p}$ ratio is plotted as a function of the mass reduction factor. Calculations are shown for the cases where number-changing processes are neglected (solid lines) or included (dashed lines). Calculations are performed for the two choices of the baryon-to-pion ratio, 1.0 which is relevant for AGS measurements (squares) and 0.2 which is relevant for measurements at CERN (circles). Calculations are sensitive to both the inclusion of number-changing rates and alterations of hadronic masses.
