Schizophrenia is a psychiatric disorder that affects over 20 million people globally. Notably, schizophrenia is associated with decreased density of dendritic spines and decreased levels of $\delta$-serine, a co-agonist required for opening of the N-methyl-$\delta$-aspartate receptor (NMDAR). We hypothesized that lowered $\delta$-serine levels associated with schizophrenia would enhance ion flux-independent signaling by the NMDAR, driving destabilization and loss of dendritic spines. We tested our hypothesis using the serine racemase knockout (SRKO) mouse model, which lacks the enzyme for $\delta$-serine production. We show that activity-dependent spine growth is impaired in SRKO mice, but can be acutely rescued by exogenous $\delta$-serine. Moreover, we find a significant bias of synaptic plasticity toward spine shrinkage in the SRKO mice as compared to wild-type littermates. Notably, we demonstrate that enhanced ion flux-independent signaling through the NMDAR contributes to this bias toward spine destabilization, which is exacerbated by an increase in synaptic NMDARs in hippocampal synapses of SRKO mice. Our results support a model in which lowered $\delta$-serine levels associated with schizophrenia enhance ion flux-independent NMDAR signaling and bias toward spine shrinkage and destabilization.

1. Introduction

Experience-dependent growth and long-term stabilization of dendritic spines are critical for learning and memory (Hayashi-Takagi et al., 2015). Long-term changes in spine structure and stability are tightly associated with long-term potentiation (LTP) (Hill and Zito, 2013; Matsuizki et al., 2004) and long-term depression (LTD) (Oh et al., 2013; Zhou et al., 2004) of synaptic strength and are mediated through activation of N-methyl-$\delta$-aspartate receptors (NMDARs). NMDARs can signal through flux of positive ions, including Ca$^{2+}$, in response to binding of both glutamate and co-agonist, glycine or $\delta$-serine. In addition, NMDARs can signal in an ion flux-independent manner upon the binding of agonist or co-agonist alone (Park et al., 2022; Valbuena and Lerma, 2016). Notably, recent studies have demonstrated that glutamate binding to NMDARs in the absence of co-agonist drives LTD and spine shrinkage (Nabavi et al., 2013; Stein et al., 2015).

Dysfunctional NMDAR signaling is thought to contribute to the etiology of schizophrenia, a psychiatric disorder that affects up to 1% of the global population and is characterized by a variety of symptoms such as hallucinations and cognitive deficits (Coyle et al., 2020; Dalmau et al., 2019). These debilitating symptoms may be linked to synaptic and neuroanatomical changes in the brain, such as decreased spine and synapse densities (Konopaske et al., 2014; Onwordi et al., 2020; Radhakrishnan et al., 2021; Rosoklija et al., 2000; Sweet et al., 2009). As NMDARs mediate bidirectional structural plasticity and stabilization of spines (Hill and Zito, 2013; Oh et al., 2013; Stein et al., 2021), alterations in NMDAR function influence spine densities and impact the ability to learn and form memories (Alvarez et al., 2007; Brigman et al., 2010; Kannangara et al., 2015; Ultanir et al., 2007). Notably, individuals with schizophrenia have decreased levels of $\delta$-serine (Bendikov et al., 2007; Hashimoto et al., 2003a) and elevated levels of kynurenic acid (Plitman et al., 2017), an endogenous antagonist of the NMDAR co-agonist binding site. In addition, single nucleotide polymorphisms (SNPs) in the serine racemase enzyme for $\delta$-serine production and reduced serine racemase mRNA expression in post-mortem human brain have been reported as associated with increased risk for schizophrenia.

Neurobiology of Disease 170 (2022) 105772

Furthermore, there is evidence of increased \( \alpha \)-amino acid oxidase expression in schizophrenia (Madeira et al., 2008), which similarly would contribute to lower \( \alpha \)-serine and subsequent NMDAR hypofunction. Importantly, animal studies that mimic NMDAR hypofunction by reducing ion flux or co-agonist binding show cognitive deficits and decreased spine density (Barnes et al., 2014; Basu et al., 2009; Latysheva and Raevskii, 2003; Schobel et al., 2013; Wu et al., 2016).

We hypothesized that the decreased \( \alpha \)-serine level associated with schizophrenia promotes ion flux-independent NMDAR signaling (Nabavi et al., 2013; Stein et al., 2015), creating a bias for spine shrinkage that ultimately leads to decreased spine density. To test our hypothesis, we used a serine racemase knockout (SRKO) (Basu et al., 2009) mouse model, which lacks the enzyme required for \( \alpha \)-serine production and exhibits decreased levels of \( \alpha \)-serine, decreased spine densities, and cognitive deficits (Balu et al., 2013; Basu et al., 2009). We found that SRKO mice exhibit impaired activity-dependent spine growth, and that activity-dependent spine structural plasticity in SRKO animals is biased toward spine shrinkage and destabilization. Furthermore, we observed increased numbers of synaptic NMDARs and reduced CaMKII activation at synapses of SRKO animals. Finally, we demonstrate that non-ionotropic NMDAR signaling is increased at hippocampal synapses of SRKO animals.

2. Materials and methods

2.1. Animals

SRKO (Basu et al., 2009) and GFP-M (Feng et al., 2000) mice in a C57BL/6J background were crossed to generate serine racemase knockout and wild-type littersmates with GFP expressed in a subset of hippocampal pyramidal neurons. All experimental protocols were approved by the University of California Davis Institutional Animal Care and Use Committee.

2.2. Two-photon imaging and image analysis

Acute hippocampal slices were prepared from P14-21 WT and SRKO littersmates of both sexes as described (Stein et al., 2021). GFP-expressing CA1 pyramidal neurons at depths of 10–50 \( \mu \)m were imaged using a custom two-photon microscope (Woods et al., 2011). For each neuron, image stacks (512 \( \times \) 512 pixels; 0.02 \( \mu \)m per pixel\(^1\)-1-\( \mu \)m z-steps) were collected from one segment of secondary or tertiary dendrite at 5 min intervals between 27–30 °C in recirculating artificial cerebral spinal fluid (ACSF; in mM: 127 NaCl, 25 NaHCO\(_3\), 1.2 NaH\(_2\)PO\(_4\), 2.5 KCl, 25 \( \alpha \)-glucose, aerated with 95% O\(_2\) / 5% CO\(_2\); ~310 mOsm, pH 7.2) with 1 \( \mu \)M TTX, 0.1 mM Mg\(^{2+}\), and 2 mM Ca\(^{2+}\), unless otherwise stated. Cells were pre-incubated for at least 10 min with 10 \( \mu \)M \( \alpha \)-serine or for at least 30 min with 10 \( \mu \)M L-689,560 L-689,10 \( \mu \)M Bay-K and 50 \( \mu \)M NBQX (all from Tocris), which were included as indicated. Images are maximum projections of three-dimensional image stacks after applying a median filter (\( \times \)3 \( \times \)3) to raw image data. Estimated spine volume was measured from background-subtracted green fluorescence using the integrated pixel intensity of a boxed region surrounding the spine head, as described (Woods et al., 2011).

2.3. Glutamate uncaging

High-frequency uncaging (HFU) consisted of 60 pulses (720 nm; 2 ms duration, 7–11 mW at the sample) at 2 Hz delivered in ACSF containing (in mM: 2 Ca\(^{2+}\), 0.1 Mg\(^{2+}\), 2.5 MNI-glutamate, and 0.001 TTX. For experiments using HFU+ stimulation, healthy and stimulus responsive cells were selected as described (Stein et al., 2021).

2.4. Electrophysiology

Modified transverse 300 \( \mu \)m slices of dorsal hippocampus were prepared from P15–P19 mice anesthetized with isoflurane (Bischofberger et al., 2006), and mounted cut side down on a Leica VT1200 vibratome in ice-cold sucrose cutting buffer containing (in mM): 210 sucrose, 25 NaHCO\(_3\), 2.5 KCl, 1.25 NaH\(_2\)PO\(_4\), 7 glucose, 7 MgCl\(_2\), and 0.5 CaCl\(_2\). Slices were recovered for 1 h in 32 °C ACSF solution containing (in mM): 119 NaCl, 26.2 NaHCO\(_3\), 11 glucose, 2.5 KCl, 1 NaH\(_2\)PO\(_4\), 2.5 CaCl\(_2\), and 1.3 MgSO\(_4\). Slices were perfused in ACSF at RT containing picrotoxin (0.1 mM) and TTX (0.5 \( \mu \)M) and saturated with 95% O\(_2\) / 5% CO\(_2\). mEPSCs were recorded from CA1 pyramidal neurons patched with 3–5 \( \mu \)M borosilicate pipettes filled with intracellular solution containing (in mM): 135 cesium methanesulfonate, 8 NaCl, 10 HEPES, 0.3 Na-GTP, 4 Mg-ATP, 0.3 EGTA, and 5 QX-314 (290 mOsm, pH 7.3). Cells were discarded if series resistance varied by more than 25%.

Recordings were obtained with a MultiClamp 700B amplifier (Molecular Devices), filtered at 2 kHz, digitized at 10 Hz. Miniature synaptic events were analyzed using Mini Analysis software (Synaptosoft) using a threshold amplitude of 5 pA for peak detection. To generate cumulative probability plots for amplitude and inter-event time intervals, events from each CA1 pyramidal neuron (>100 per cell) were pooled. The Kolmogorov-Smirnov two-sample test (KS test) was used to compare the distribution of events between WT and SRKO. Statistical comparisons were made using Graphpad Prism 8.0.

2.5. Biochemistry

Hippocampi of P20 mice of either sex were homogenized with 1% deoxycholate. For immunoprecipitation, 50 \( \mu \)L of Protein G Dynabeads (Invitrogen) were pre-incubated with 2.4 \( \mu \)g of either CaMKIIa (Leonard et al., 1998; Leonard et al., 1999; Lu et al., 2007) or mouse IgG antibody (sc-2025, Santa Cruz Biotechnology) at RT for 10 min, washed with 0.05% TBS-tween, incubated with 1000–1500 \( \mu \)g of protein lystate for 30 min at RT, washed four times with 0.01% TBS-triton, and then eluted. For PSD isolation, lysates were fractionated by centrifugation and sucrose gradient, and extracted with Triton X-100, as described (Dosemeci et al., 2006). Protein samples were run on a SDS-PAGE gel at 30 mA and transferred to 0.45 um PVDF membrane for 210 min at 50 V. Blots were stained for total protein with Revert 700 Total Protein Stain Kit (LICOR). Membranes were blocked with TBS Odyssey Blocking Buffer (LICOR) and incubated overnight at 4 °C with primary antibodies for GluN2B, GluN2A, GluN1, CaMKIIa (Leonard et al., 1998; Leonard et al., 1999; Lu et al., 2007), pT286 CaMKIIa (sc-12886R, Santa Cruz), synaptophysin (Sigma S5768), Cav1.2 (FP1) (Buonarati et al., 2017), or serine racemase (sc-365,271, Santa Cruz). Secondary antibody (IRDye; LICOR) incubation was for 1 h at RT and the blots scanned and analyzed using Odyssey CLx and Image Studio.

2.6. Experimental design and statistical analysis

Cells for each condition were obtained from at least 3 independent hippocampal acute slices preparations of both sexes. Data analysis was done blind to the experimental condition. All statistics were calculated across cells and performed in GraphPad Prism 8.0. Student’s unpaired \( t \)-test, ordinary one-way ANOVA, or two-way ANOVA with Bonferroni’s multiple comparisons were used, as indicated. Details on ‘n’ are included in the figure legends. All data are represented as mean ± standard error of the mean (SEM). Statistical significance was set at \( p < 0.05 \).
3. Results

3.1. Activity-induced growth of dendritic spines is impaired in SRKO mice

NMDAR-dependent long-term potentiation (LTP) of synaptic strength and associated spine growth, mediated by simultaneous binding of glutamate and co-agonist, \(\alpha\)-serine or glycine, is an important cellular process for memory formation and maintenance of spine density. Based on the requirement for robust calcium influx during NMDAR-dependent spine growth and stabilization, we hypothesized that reduced bioavailability of \(\alpha\)-serine observed in individuals with schizophrenia (Bendikov et al., 2007; Hashimoto et al., 2003a) would inhibit LTP-associated spine growth. Furthermore, we predicted that the reduction in \(\alpha\)-serine levels would increase ion flux-independent NMDAR signaling, resulting in further spine destabilization that could contribute to the reduced spine density associated with the disorder (Rosoklija et al., 2000; Sweet et al., 2009).

To begin testing our hypothesis, we first examined whether spine structural plasticity is altered in a serine racemase knockout (SRKO) mouse line, which lacks the enzyme required for \(\alpha\)-serine production and serves as an important model for studying the consequences of reduced \(\alpha\)-serine levels, which have been associated with schizophrenia (Basu et al., 2009). To visualize spines and dendrites for monitoring activity-dependent long-term spine growth, we crossed the SRKO mouse line with the GFP-M (Feng et al., 2000) mouse line to obtain \(\alpha\)-serine-deficient mice that have sparse neuronal GFP expression in the hippocampus. Using high-frequency uncaging (HFU) of glutamate to induce long-term spine growth at single dendritic spines on basal dendrites of CA1 neurons in acute hippocampal slices, we observed a complete inhibition of long-term spine growth in SRKO mice relative to WT littermates (Fig. 1A–C; WT: 168 ± 17%; KO: 103 ± 7%). Altered long-term spine growth in the SRKO was not due to a difference in the initial volumes of target spines in the mutant animals, as baseline size of target spines did not differ between WT and SRKO (Supplemental Fig. 1A).

Notably, the lack of long-term spine growth in SRKO was rescued with acute treatment of 10 \(\mu\)M \(\alpha\)-serine (Fig. 1D–F; WT: 201 ± 23%; KO: 169 ± 16%), demonstrating that the deficit in long-term spine growth is not due to chronic alterations in synaptic function in SRKO animals or a role for serine racemase independent of \(\alpha\)-serine synthesis. Thus, aligned with the previously reported LTP deficit in these mice (Basu et al., 2009), we conclude that activity-induced spine growth is impaired in SRKO mice.

3.2. Shift toward spine destabilization in SRKO mice

Because we observed a complete block of activity-dependent spine growth in the SRKO mice, we further wondered whether the reduced \(\alpha\)-serine levels generated abnormal conditions, beyond just reducing ion flow through NMDARs, that disrupted downstream signaling and completely inhibited all forms of spine structural plasticity. We therefore tested whether increasing or decreasing the influx of Ca\(^{2+}\) through the NMDAR would be sufficient to drive downstream signaling and spine structural plasticity in the SRKO.

We first tested whether increasing the amount of Ca\(^{2+}\) influx would overcome the impairment of activity-dependent spine growth in the SRKO. We increased the extracellular Ca\(^{2+}\) concentration to 3 mM in order to strengthen the influx of Ca\(^{2+}\) in response to HFU stimulation, while maintaining a set amount of glutamate binding to the NMDAR. We found that HFU in 3 mM Ca\(^{2+}\) induced long-term spine growth in both WT and SRKO mice (Fig. 2A, B; WT: 187 ± 25%; KO: 193 ± 35%),

Fig. 1. LTP-associated growth of dendritic spines is impaired in SRKO mice. A, D) Images of basal dendrites of CA1 pyramidal neurons in acute hippocampal slices from WT and SRKO mice (P14–21). Individual spines (yellow arrowhead) were stimulated with high frequency glutamate uncaging (HFU, yellow crosshair) during vehicle condition or in the presence of \(\alpha\)-serine (10 \(\mu\)M). B, C) HFU leads to long-term spine growth in WT (black filled circles/bar; \(n = 7\) cells/7 mice) but not in SRKO (red filled circles/bar; \(n = 9\) cells/8 mice; \(p > 0.99\)) relative to baseline. E, F) Addition of \(\alpha\)-serine rescues HFU-induced long-term spine growth (red filled circles/bar; \(n = 8\) cells/7 mice) to levels comparable to those in WT (black filled circles/bar; \(n = 6\) cells/5 mice; \(p = 0.55\)). Data are represented as mean +/- SEM. Two-way ANOVA with Bonferroni post hoc multiple comparison test. *\(p < 0.05\); **\(p < 0.01\); ***\(p < 0.001\). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
demonstrating that the signaling mechanisms downstream of Ca\textsuperscript{2+} influx that support long-term spine growth are intact in SRKO mice.

We next tested whether decreasing the amount of Ca\textsuperscript{2+} influx would result in activity-dependent spine shrinkage in the SRKO. We decreased the extracellular Ca\textsuperscript{2+} concentration to 0.3 mM in order to weaken the influx of Ca\textsuperscript{2+} in response to HFU stimulation, while maintaining a set amount of glutamate binding to the NMDAR. We found that HFU in 0.3 mM Ca\textsuperscript{2+} induced long-term spine shrinkage in both WT and SRKO mice (Fig. 2C, D; WT: 69 ± 7%; KO: 82 ± 3%), demonstrating that the signaling mechanisms that support long-term spine shrinkage are intact in SRKO mice.

Because we found bidirectional spine structural plasticity intact in SRKO mice, we hypothesized that the disruption of activity-dependent long-term spine growth in SRKO mice that we observed in Fig. 1 was due to a bias in spine structural plasticity toward shrinkage relative to that of WT mice. We therefore predicted that a Ca\textsuperscript{2+} concentration that resulted in no spine structural plasticity (at the threshold between spine shrinkage and growth) in WT mice would drive spine shrinkage in the SRKO mice. Indeed, we found that HFU in 1.5 mM Ca\textsuperscript{2+}, which did not lead to spine structural plasticity in WT mice, resulted in spine shrinkage
in SRKO mice (Fig. 2E, F; WT: 109 ± 5%; KO: 76 ± 5%). Altered long-term spine shrinkage in the SRKO was not due to a difference in initial volumes of target spines in the mutant animals, as baseline size of target spines did not differ between WT and SRKO (Supplemental Fig. 1B). Plotting all of our data together, we observed that both genotypes have similar S-shaped plasticity curves, but the SRKO plasticity curve is significantly shifted to the right (Fig. 2G), demonstrating that a wider range of $\text{Ca}^{2+}$ levels elicit spine shrinkage in the SRKO, thus biasing spine structural plasticity toward shrinkage.

### 3.3. Increased synaptic NMDARs and decreased CaMKII activation in SRKO

Recent studies have established that glutamate binding to the NMDAR in the absence of co-agonist binding is sufficient to drive destabilization and shrinkage of dendritic spines (Stein et al., 2015; Stein et al., 2020; Thomazeau et al., 2020). We predicted that binding of glutamate to NMDAR in the absence of co-agonist would drive ion flux-independent NMDAR signaling and contribute to spine destabilization and shrinkage in SRKO mice. Furthermore, because adult SRKO mice exhibit elevated NMDAR expression (Balu and Coyle, 2011; Mustafa et al., 2010), we wondered if NMDARs were also elevated in hippocampus in young mice and, in combination with the reduction in $\text{D}-\text{serine}$ levels, would contribute to even further increase in non-ionotropic NMDAR signaling. Thus, we hypothesized that the combination of reduced $\text{D}-\text{serine}$ levels and increased expression of NMDARs available for non-ionotropic NMDAR signaling led to the observed bias for spine shrinkage in SRKO.

To investigate whether SRKO mice also have increased synaptic NMDAR expression levels at dendritic spines within the hippocampus, we isolated postsynaptic density (PSD) fractions from the hippocampi of P20 SRKO mice. We found increased levels of the obligatory NMDAR subunit GluN1 in SRKO animals relative to WT littermates, suggesting greater number of synaptic NMDARs (Fig. 3A, B; KO: 141 ± 11%). Interestingly, we also observed increased synaptic enrichment (Fig. 3A, B; KO: 237 ± 15%) and total expression (Fig. 3C, D; KO: 122 ± 3%) of GluN2B in SRKO relative to WT. Despite the greater number of NMDARs, we expected disrupted calcium-dependent NMDAR signaling due to reduced ion flux through the NMDAR. Indeed, when we probed CaMKII-GluN2B interaction by immunoprecipitation or phosphorylation of CaMKII at the T286 autophosphorylation site, both induced by strong calcium influx and integral for LTP (Halt et al., 2012; Lee et al., 2009), we found that basal levels of CaMKII-GluN2B interaction and pT286 are both decreased in SRKO compared to WT (Fig. 3E, F; KO CaMKII-GluN2B: 68 ± 6%; KO pT286: 89 ± 1%), despite no change in CaMKII expression or enrichment levels (Fig. 3A, B; KO CaMKII expression: 112 ± 4%; KO synaptic enrichment: 114 ± 15%). In sum, our results confirm increased NMDAR content and decreased calcium-dependent NMDAR signaling due to reduced ion flux through the NMDAR. Indeed, when we probed CaMKII-GluN2B interaction by immunoprecipitation or phosphorylation of CaMKII at the T286 autophosphorylation site, both induced by strong calcium influx and integral for LTP (Halt et al., 2012; Lee et al., 2009), we found that basal levels of CaMKII-GluN2B interaction and pT286 are both decreased in SRKO compared to WT (Fig. 3E, F; KO CaMKII-GluN2B: 68 ± 6%; KO pT286: 89 ± 1%), despite no change in CaMKII expression or enrichment levels (Fig. 3A, B; KO CaMKII expression: 112 ± 4%; KO synaptic enrichment: 114 ± 15%). In sum, our results confirm increased NMDAR content and decreased calcium-dependent NMDAR signaling due to reduced ion flux through the NMDAR. Indeed, when we probed CaMKII-GluN2B interaction by immunoprecipitation or phosphorylation of CaMKII at the T286 autophosphorylation site, both induced by strong calcium influx and integral for LTP (Halt et al., 2012; Lee et al., 2009), we found that basal levels of CaMKII-GluN2B interaction and pT286 are both decreased in SRKO compared to WT (Fig. 3E, F; KO CaMKII-GluN2B: 68 ± 6%; KO pT286: 89 ± 1%), despite no change in CaMKII expression or enrichment levels (Fig. 3A, B; KO CaMKII expression: 112 ± 4%; KO synaptic enrichment: 114 ± 15%). In sum, our results confirm increased NMDAR content and decreased calcium-dependent NMDAR signaling due to reduced ion flux through the NMDAR. Indeed, when we probed CaMKII-GluN2B interaction by immunoprecipitation or phosphorylation of CaMKII at the T286 autophosphorylation site, both induced by strong calcium influx and integral for LTP (Halt et al., 2012; Lee et al., 2009), we found that basal levels of CaMKII-GluN2B interaction and pT286 are both decreased in SRKO compared to WT (Fig. 3E, F; KO CaMKII-GluN2B: 68 ± 6%; KO pT286: 89 ± 1%), despite no change in CaMKII expression or enrichment levels (Fig. 3A, B; KO CaMKII expression: 112 ± 4%; KO synaptic enrichment: 114 ± 15%). In sum, our results confirm increased NMDAR content and decreased calcium-dependent NMDAR signaling due to reduced ion flux through the NMDAR.
dependent NMDAR downstream signaling in hippocampal synapses of SRKO mice.

3.4. Enhanced non-ionotopic NMDAR signaling in SRKO mice

Our observations of increased number of synaptic NMDARs in mice with reduced n-serine levels support that altered structural plasticity in SRKO could be due to increased non-ionotopic NMDAR signaling driven by glutamate binding to the increased number of NMDARs in the absence of co-agonist binding. Because there is no direct means of measuring the relative amount of non-ionotopic signaling, we first set out to probe the relative contribution of non-ionotropic NMDAR signaling to spine structural plasticity between the SRKO and WT using an assay that assesses non-ionotropic NMDAR signaling levels by monitoring spine growth that is driven with calcium influx through voltage-gated calcium channels (VGCCs) ([Stein et al., 2021]) (Fig. 4A). These experiments are designed based on our finding that non-ionoprotic NMDAR signaling is essential not only for LTD-induced spine shrinkage, but also contributes to LTP-induced spine growth ([Stein et al., 2021]). We hypothesized that, under conditions of robust calcium influx through VGCCs, we would observe enhanced spine growth in the SRKO due to the enhanced synaptic NMDARs driving more...
non-ionotropic NMDAR signaling.

To isolate non-ionotropic NMDAR signaling in SRKO mice, we used the NMDAR co-agonist site inhibitor L-689,560 (L-689) to mimic the absence of co-agonist and thus block NMDAR-mediated Ca\(^{2+}\) influx following glutamate binding. We combined this with the L-type Ca\(^{2+}\) channel agonist Bay K 8644 (Bay K) to promote Ca\(^{2+}\) influx through VGCCs. A modified HFU paradigm (HFU\(^+\)) was used to induce a weak, non-saturated long-term increase in spine size in WT mice (Fig. 4B-D). Remarkably, the same HFU\(^+\) stimulation drove a robust increase in spine growth in SRKO mice (Fig. 4B-D; WT: 122 ± 4%; KO: 171 ± 11%). Altered long-term spine growth in the SRKO was not due to a difference in the initial volumes of target spines in the mutant animals, as baseline size of target spines did not differ between WT and SRKO (Supplemental Fig. 1C). The enhancement in spine growth cannot be attributed to increased AMPAR function in SRKO mice, as the amplitude of miniature excitatory postsynaptic currents (mEPSCs) was not different between WT and SRKO (Fig. 4E; WT: 10 ± 0.6 pA; KO: 9.3 ± 0.3 pA), nor can it be attributed to increased expression of synaptic voltage-gated calcium channels or AMPARs, as synaptosomal preparations showed no change in Cav1.2 or GluA1 in SRKO compared to WT, despite the increased GluN2B levels (Fig. 4F, G; KO Cav1.2: 94 ± 4%; KO GluA1: 104 ± 5%; KO GluN2B: 124 ± 6%). We therefore interpret the greater amount of spine growth in SRKO to be indicative of a higher level of non-ionotropic NMDAR signaling.

To confirm using a different approach that increased non-ionotropic NMDAR signaling in SRKO causes a shift of spine plasticity toward shrinkage, we next used L-689 to block co-agonist binding during a weak glutamate-uncaging stimulation. We reasoned that if SRKO mice have more synaptic NMDARs and thus undergo more non-ionotropic NMDAR signaling relative to WT, a weak glutamate uncaging stimulation that fails to induce spine shrinkage in WT should be sufficient to drive shrinkage in SRKO. Indeed, while our weaker HFU stimulus (reduced pulse width of 1 ms) in the presence of L-689 and NBQX failed to induce shrinkage of dendritic spines in WT animals (Fig. 5A-C; WT 1 ms: 99 ± 2%), despite robust shrinkage observed with the control HFU 2 ms stimulus (Fig. 5A-C; WT 2 ms: 66 ± 5%), it was sufficient to drive

![Fig. 5. Shift of plasticity toward spine shrinkage in SRKO mice.](image-url)

A) Images of basal dendrites of CA1 pyramidal neurons from P14-21 WT and SRKO mice. Individual spines (yellow arrowhead) were stimulated with HFU (yellow crosshair) in the presence of L-689 (10 μM) and NBQX (50 μM) for 1 or 2 ms. B, C) HFU in L-689 with 2 ms pulse duration (black filled circles/bar; n = 7 cells/5 mice) leads to shrinkage of WT target spines, but not HFU in L-689 with 1 ms pulse duration (blue filled circles/bar; n = 7 cells/5 mice; p > 0.99) relative to baseline. In contrast, HFU in L-689 with 1 ms pulse duration (red filled circles/bar; n = 7 cells/6 mice) is sufficient to drive spine shrinkage in SRKO mice relative to baseline. Neighboring spines were unchanged in all conditions (open circles/bars). Data are represented as mean ±/− SEM. Two-way ANOVA with Bonferroni post hoc multiple comparisons test. *p < 0.05; **p < 0.01; ***p < 0.001 D) Proposed model. Binding of glutamate and D-serine leads to both non-ionotropic NMDAR signaling and calcium influx required for activity-induced long-term spine growth. In contrast, increased NMDAR levels and reduced levels of D-serine in the SRKO mouse model for studying schizophrenia results in glutamate binding alone to more NMDARs in the absence of D-serine that results in strong non-ionotropic NMDAR activation with small calcium influx, promotes spine shrinkage and destabilization. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
shrinkage of dendritic spines in SRKO mice (Fig. 5A–C; SRKO 1 ms: 72 ± 4%). Altered long-term spine shrinkage in the SRKO was not due to a difference in the initial volumes of target spines in the mutant animals, as baseline size of target spines did not differ between WT and SRKO (Supplemental Fig. 1D). These combined results support our model (Fig. 5D) in which conditions of reduced α-serine levels in SRKO lead to increased synaptic NMDARs, which drive enhanced non-ionotropic NMDAR signaling, and thus create a bias toward spine shrinkage and loss.

4. Discussion

4.1. Lowered α-serine levels create a bias toward spine shrinkage

It has been widely reported that schizophrenia is associated with a reduction in dendritic spine density that is thought to contribute to cognitive deficits. As changes in spine density and gray matter volume mirror each other (Bennett, 2011), and longitudinal MRI studies of high risk individuals report normal increase in gray matter during childhood that then declines in adolescence (Job et al., 2005; Pamela et al., 2005; Thompson et al., 2001), a time when spine pruning increases (Penzes et al., 2011), it has been suggested that excessive spine elimination, rather than a deficit in new spine outgrowth, is the potential cause of decreased spine density in schizophrenia (Glausier and Lewis, 2013).

Here, we show a disruption of long-term spine growth and a bias toward activity-induced spine shrinkage in a SRKO mouse model for studying schizophrenia, which is reported to have decreased spine density at older ages (Balu et al., 2013). Although we focus our studies on basal dendrites, we expect to observe similar results in apical dendrites, as prior studies have established that serine racemase is present in apical dendrites of CA1 pyramidal neurons (Wong et al., 2020). Our observations that deficits in long-term spine growth in the SRKO are rescued by exogenous α-serine, combined with those of others demonstrating that decreased spine density can be rescued in these mice with α-serine treatment (Balu and Coyle, 2014), support that deficits in spine plasticity and density in the SRKO are attributable to lowered α-serine levels instead of to developmental deficits or other functions of serine racemase. Indeed, although we found deficits in spine structural plasticity in the SRKO mice, it was possible to induce both spine shrinkage and growth by manipulating the strength of our stimulation, supporting that serine racemase, the enzyme that produces α-serine and observed to interact with various synaptic structural proteins such as PSD-95 (Lin et al., 2016; Ma et al., 2014), is itself not required for structural plasticity of spines.

As glutamate binding in the absence of co-agonist to the NMDAR drives shrinkage of dendritic spines in an ion flux-independent manner (Stein et al., 2015), we proposed that reduced levels of α-serine in the SRKO mice would drive enhanced non-ionotropic NMDAR signaling, and thus would bias spine structural plasticity toward spine shrinkage, ultimately contributing to spine loss associated with schizophrenia. Notably, α-serine has been shown to promote spine stability (Lin et al., 2016). Indeed, we saw a shift in spine structural plasticity toward spine shrinkage in the SRKO mice. However, although decreased spine densities are observed in these mice at older ages (Balu et al., 2013), we did not observe decreased spine densities in the SRKO animals relative to their WT siblings at the ages used in our studies (P14-21; Supplemental Fig. 2). This result is perhaps not surprising because the age range of mice used in our study is prior to the age (P20) when serine racemase reaches maximal expression (Polorusso et al., 2005; Miya et al., 2008). Furthermore, our studies are focused before the end of the developmental period in which glycine is replaced by α-serine as the primary synaptic NMDAR co-agonist (Le Bail et al., 2015; Papouin et al., 2012); thus, we expect that we are measuring only the initial stages of disruption of spine structural plasticity, prior to detectable consequences on spine densities.

4.2. Enhanced levels and altered composition of synaptic NMDARs in SRKO mice

Our observation of increased synaptic enrichment of NMDARs relative to WT within the hippocampus of young mice is consistent with previous studies on SRKO mice showing increased expression of GluN1 (Balu and Coyle, 2011; Mustafa et al., 2010) and GluN2B (Basu et al., 2009; Wong et al., 2020). These changes in the overall number and composition of NMDARs may be a direct consequence of reduced α-serine levels, as prior studies have demonstrated the role of co-agonist binding in priming of the NMDAR for endocytosis, with α-serine specifically acting on GluN2B subunits (Ferreira et al., 2017; Nong et al., 2003). We found that the increase in synaptic NMDAR levels was associated with an increase in the magnitude of non-ionotropic signaling in SRKO, which would be expected to drive enhanced spine destabilization and shrinkage (Stein et al., 2015; Stein et al., 2021). It is also possible that the selective enhancement of GluN2B levels conferred increased non-ionotropic NMDAR signaling; however, we consider this scenario less likely, as a recent study has shown that non-ionotropic NMDAR signaling can drive LTD without any reduction in efficacy in the absence of GluN2B (Wong and Gray, 2018).

Notably, despite the enhancement of NMDAR levels at the synapse, we observed decreased CaMII-GluN2B interaction and decreased autophosphorylation of CaMII in SRKO mice, which we attribute to the reduced NMDAR pore opening in the conditions of reduced co-agonist α-serine, and thus lack of strong Ca2+ influx required for increasing both CaMII activity and interaction with GluN2B (Goodell et al., 2017). This altered downstream CaMII signaling likely contributes to NMDAR hypofunction in schizophrenia (Banerjee et al., 2015).

4.3. Enhanced non-ionotropic NMDAR signaling in SRKO mice

We made several observations that together support our hypothesis that there is increased ion flux-independent NMDAR signaling driving spine destabilization in the SRKO mice. First, we observed that patterns of glutamatergic activation which normally induce spine growth in WT mice instead drive spine shrinkage in SRKO. Second, we found increased NMDARs at hippocampal synapses in the SRKO mice, which, in combination with the reduced α-serine levels, is expected to bias NMDARs toward ion flux-independent signaling. Third, we showed increased ion flux-independent NMDAR signaling in SRKO animals. Finally, we observed that weak activation of non-ionotropic NMDAR signaling that fails to induce spine shrinkage in WT can drive spine shrinkage in SRKO mice, further supporting that enhanced non-ionotropic NMDAR signaling in SRKO mice drives spine destabilization and shrinkage, and would be expected to drive eventual spine elimination.

The molecular mechanisms through which ion flux-independent NMDAR signaling leads to dendritic spine shrinkage and destabilization are beginning to be elucidated. p38 mitogen-activation protein kinase (p38 MAPK), which was shown to attain its active phosphorylated state during LTD induction even in the presence of the NMDAR pore blocker MK-801 (Nabaví et al., 2013), was the first molecule confirmed to be required for spine shrinkage initiated by non-ionotropic NMDAR signaling (Stein et al., 2015). A recent study has identified several signaling components on the pathway, including neuronal nitric oxide synthase (nNOS), the interaction between nNOS and the adaptor protein NOS1AP, the kinases MK2 and CaMKII, and the actin-depolymerizing factor cofilin (Stein et al., 2020). Another study implicated mammalian target of rapamycin complex 1 (mTORC1), which is important for protein synthesis, in spine shrinkage induced by non-ionotropic NMDAR signaling (Thomazeau et al., 2020). Furthermore, studies using FRET to monitor movements of the C terminus of the NMDAR, have shown that agonist (glutamate or NMDA) binding drives the GluN1 C-tails to move away from each other, independent of NMDAR ion flux (Aow et al., 2015; Dore et al., 2015; Ferreira et al., 2017). Intriguingly, overexpression of PSD-95 is sufficient to block both agonist-induced NMDAR...
conformational changes and non-ionotropic NMDAR-LTD, leading to a proposal that PSD-95 plays an important role linking NMDAR conformational changes to ion flux-independent downstream signaling (Dore and Malinow, 2020).

Studies in which NMDAR channel blockers produce schizophrenia-like symptoms in healthy individuals and exacerbate them in individuals with schizophrenia helped give rise to the NMDAR hypothesis (Javitt and Zukin, 1991; Krystal et al., 1994; Lahti et al., 2001; Newcomer et al., 1999). Due to high sensitivity of inhibitory GABAergic neurons to NMDAR blockers (Grunze et al., 1996; Homayoun et al., 2001; Newcomer et al., 1999), decreased expression of both interneurons and GABAergic neurons to NMDAR blockers (Grune et al., 1996; Homayoun et al., 2001; Newcomer et al., 1999). Due to high sensitivity of inhibitory function hypothesis (Javitt and Zukin, 1991; Krystal et al., 1994; Lahti et al., 2001; Newcomer et al., 1999), decreased expression of both interneurons and GABAergic neurons to NMDAR blockers (Grune et al., 1996; Homayoun et al., 2001; Newcomer et al., 1999). Due to high sensitivity of inhibitory function hypothesis (Javitt and Zukin, 1991; Krystal et al., 1994; Lahti et al., 2001; Newcomer et al., 1999), decreased expression of both interneurons and GABAergic neurons to NMDAR blockers (Grune et al., 1996; Homayoun et al., 2001; Newcomer et al., 1999).

Here we show that a SRKO mouse model for studying schizophrenia displays altered dendritic structural plasticity biased toward spine shrinkage and destabilization. We further report an increased number of synaptic NMDARs in the hippocampus of SRKO mice and increased ion flux-independent NMDAR signaling at hippocampal spines. Taken together, our findings support a model in which NMDAR hypofunction brought on by lack of &-serine, promotes excessive non-ionotropic NMDAR signaling that drives a bias toward spine shrinkage and likely contributes to decreased spine density associated with schizophrenia.

Author contributions
D.K.P., I.S.S., and K.Z. designed the study and wrote the initial draft of the manuscript. D.K.P., S.P., and M.A. performed imaging and biochemistry experiments and analysis. D.K.P., J.A.G., and E.V.B. designed and E.V.B. performed electrophysiology experiments and analysis. All authors edited the manuscript.
