Abstract

The scalar, vector, and tensor components of the (generalized) deuteron electric polarizability are calculated, as well as their logarithmic modifications. Several of these quantities arise in the treatment of the nuclear corrections to the deuterium Lamb shift and the deuterium hyperfine structure. A variety of second-generation potential models are used and a (subjective) error is assigned to the calculations. The zero-range approximation is used to analyze a subset of the results, and a simple relativistic version of this approximation is developed.
1 Introduction

The spectra of hydrogenic atoms and ions have been measured to such high precision that nuclear properties play a significant role\[1\]. This is especially true of the deuterium atom, which has large nuclear contributions to both the Lamb shift[2, 3] and the S-state hyperfine structure[4]. These large nuclear contributions result from the weak binding of the deuteron and from the concomitant large size of this simplest of all nuclei.

The Lamb shift can be defined as the difference between calculated energy level values and those from predefined reference values, which is typically a Dirac spectrum modified by reduced-mass effects. This shift results after removing hyperfine splittings, which is equivalent to having a spinless nucleus. Hyperfine structure results from the electron’s interaction with the nuclear spin, and can be linear in that spin (the usual type) or quadratic (quadrupole hyperfine structure). This typically means that the effective nuclear interaction with the electron can be a scalar, a vector, or a tensor in character.

The dominant electron-nucleus interactions (beyond the point-nucleus Coulomb potential) occur in first-Born approximation in their electromagnetic coupling. Examples are the scalar (or L=0) nuclear finite-size modification of the Coulomb potential, which dominates nuclear effects in the Lamb shift, and the tensor (or L=2) modification that dominates the quadrupole hyperfine structure. The leading-order (vector) hyperfine structure results from the electron’s interaction with the nuclear magnetic moment.

Sub-leading nuclear effects are generated by two-photon processes, which necessarily involve a loop integral over a virtual photon momentum. The Lamb shift integral has a weaker dependence on that momentum (i.e., the process is “softer”) than the corresponding hyperfine process (which is therefore “harder”). Because the most important parts of the two-photon nuclear amplitudes involve sequential electron-nucleus electromagnetic interactions, numerically important contributions arise from inelastic intermediate nuclear states, and thus are non-static or polarization phenomena. These mechanisms can also be scalar, vector, or tensor in type.

The leading-order nuclear contribution to the Lamb shift is proportional to the mean-square nuclear charge radius, while the subleading order is proportional to the nuclear electric polarizability and its logarithmic modification. The polarizability is defined in terms of the nuclear electric-dipole operator, $\vec{D}$, and the fine-structure...
constant, $\alpha$, as
\[
\alpha_E = \frac{2\alpha}{3} \sum_{N \neq 0} \frac{|\langle N| \vec{D}|0 \rangle|^2}{E_N - E_0},
\]
and its logarithmic mean-excitation energy\[2\], $\bar{E}$, by
\[
\log(2\bar{E}/m_e) \alpha_E = \frac{2\alpha}{3} \sum_{N \neq 0} \frac{|\langle N| \vec{D}|0 \rangle|^2}{E_N - E_0} \log \left[ \frac{2(E_N - E_0)}{m_e} \right].
\]
Both are purely non-static, and involve the (virtual) excitation of negative-parity intermediate states with energy, $E_N$, from the deuteron ground state with energy, $E_0$. The precise form of the argument of the logarithm has been dictated by conventional atomic physics usage.

The dominant part of the sub-leading-order nuclear (vector) hyperfine structure is determined by “Low” moments\[4\], while smaller subleading-order contributions involve ordinary dipole excitations of a different type. Adopting a uniform convention for constant factors that will be apparent later we define
\[
\vec{\sigma} = -i \frac{2\alpha}{3} \sum_{N \neq 0} \langle 0| \vec{D}|N \rangle \times \langle N| \vec{D}|0 \rangle \equiv -i \frac{2\alpha}{3} \langle 0| \vec{D} \times \vec{D}|0 \rangle,
\]
and
\[
\log(2\bar{E}/m_e) \vec{\sigma} = -i \frac{2\alpha}{3} \sum_{N \neq 0} \langle 0| \vec{D}|N \rangle \times \langle N| \vec{D}|0 \rangle \log \left[ \frac{2(E_N - E_0)}{m_e} \right].
\]
The factor of $i$ is necessary to make the appropriate part of $\vec{\sigma}$ real. We also note that in non-relativistic approximation $\vec{D} \times \vec{D}$ vanishes because all components of $\vec{D}$ commute with each other. This is not true when relativity is incorporated in the calculation (see Eqn. (34) of \[5\], which demonstrates that $\vec{D} \times \vec{D}$ is imaginary). In that event the commutator contributes an essential part of the derivation of the Drell-Hearn-Gerasimov sum rule\[6\] and the Low-Energy Theorem\[7\]. The quantity $\vec{\sigma}$ is more appropriately described as a sum rule, rather than as a polarizability.

The leading-order contribution to the quadrupole hyperfine structure is driven by the quadrupole part of the ordinary Coulomb interaction, whose scale is set by the nuclear quadrupole moment, $Q$. A sub-leading contribution is determined by the tensor ($L=2$) component of the nuclear electric polarizability tensor
\[
\alpha_E^{\beta\alpha} = \frac{2\alpha}{3} \sum_{N \neq 0} \frac{\langle 0| D^{\beta}|N \rangle \langle N| D^{\alpha}|0 \rangle}{E_N - E_0},
\]
which has been calculated only once long ago using separable potentials and the RSC potential model\[8\]. Those calculations were used in a purely nuclear (as opposed to
molecular) determination[9] of the deuteron’s quadrupole moment. No estimate of the polarizability effect on the determination of the deuteron’s quadrupole moment from the HD molecular hyperfine structure has ever been made. There will also be a logarithmic modification of this tensor polarizability, which is obtained by inserting $\log [2(E_N - E_0)/m_e]$ in the sum over intermediate states.

A system with spin 1 can in general have scalar, vector, and tensor polarizabilities, and these can be of the ordinary type defined in Eqn. (5a), or of a type without the factor of $(E_N - E_0)$ in the denominator, determined by

$$D^{\beta\alpha} = \frac{2\alpha}{3} \langle 0| D^\beta D^\alpha|0 \rangle,$$

(5b)

which was illustrated by Eqn. (3) (and more accurately called a sum rule). Each of these 6 types can have a logarithmic modification. Because the deuteron is an important nucleus and deuterium an important atom, we will calculate all twelve of these polarizabilities (or sum rules) using modern second-generation potentials. Only three of the polarizabilities have been calculated before, and only two with modern potentials. None of the logarithmic modifications of the sum rule above have been previously calculated. Our approach will be non-relativistic in keeping with the potential models we use. Our calculations will be based upon Podolsky’s method[10] for computing second-order perturbation-theory matrix elements, and on several integration tricks, one of which has been used in the past.

2 Tensor Polarizabilities

The electric polarizability is most easily calculated using second-order perturbation theory and the coupling of the nuclear electric-dipole-moment operator to a uniform electric field, which leads immediately to Eqn. (5a). This equation is fully equivalent to

$$\alpha^{\beta\alpha}_E = \frac{2\alpha}{3} \langle 0| D^\beta |\Delta\Psi^\alpha \rangle,$$

(6a)

where[10]

$$(H - E_0) |\Delta\Psi^\alpha \rangle = D^\alpha |0 \rangle$$

(6b)

is solved subject to finite boundary conditions. Note that $\vec{D}$ does not connect the ground state (the only bound state) of the deuteron to itself. Resolution of Eqns. (6) into partial waves is necessary in order to perform a numerical calculation.

Because we wish to compute all tensor components of the electric polarizability tensor we present a very brief derivation of the partial-wave decomposition that up-
dates older work[11, 2]. We begin with Eqns. (5a) and (6) and convert them to a scalar by contracting the Cartesian index $\alpha$ with a constant vector $E^\alpha$ and the index $\beta$ with a constant vector $E'^\beta$. The deuteron initial state $\Psi_d = |SM\rangle$ (and analogously for the final state) depends on the azimuthal quantum number $M$ and we formally remove it from the problem by defining[12] a (vector) projection operator (appropriate for $S = 1$):

$$ e^*_1 \lambda (M) \equiv \delta_{\lambda,M} . $$

Performing the sum $\sum_{\lambda} e^*_1 \lambda (M) |S\lambda\rangle$ results formally in a scalar quantity independent of spin projections and amenable to manipulation. A similar projector $\sum_{\lambda'} e^*_1 \lambda' (M') \langle S\lambda'|$ is used for the final (i.e., leftmost) deuteron state.

We define general orthonormal spin-angular wave functions for the deuteron system

$$ \phi^\ell_{JM} = (Y_\ell (\hat{r}) \otimes \chi_1)_{JM}, \quad (7) $$

which couples the usual angular wave function that depends on the direction $\hat{r}$ of the internucleon vector $\vec{r}$ to the (unit-) spin wave function, $\chi$. The deuteron’s full wave function is then given by

$$ \psi_d = \sum_{\ell=0,2} a_\ell (r) \phi^\ell_1 (\hat{r}), \quad (8) $$

where $a_0 (r) = u (r) / r$ and $a_2 (r) = w (r) / r$ expresses $a_\ell$ in terms of the conventional radial wave function components of the deuteron. We have suppressed for now the azimuthal quantum number, $M$.

We ignore the tiny effect of the n-p mass difference on the deuteron center-of-mass (CM), and find $\vec{D} = \frac{1}{4} (\tau_1^z - \tau_2^z) \vec{r}$ expressed in terms of the isospin operators $\tau_i$ of nucleon $i$. The dipole isospin operator generates $T = 1$ states when acting on the deuteron, together with a residual numerical factor of $\frac{1}{2}$ that we will ignore until later. If the right-hand-side (RHS) of Eqn. (6b) (contracted with $E^\alpha$ and $e^*_1 \lambda (M)$) is expanded in terms of $\phi^\ell_j$ functions, one finds

$$ \text{RHS} = \sum_{L=1,3} \sum_{J=0,1,2} \phi^L_J \cdot (E_1 \otimes \hat{e}_1)_J (-1)^J \frac{g^J_L (r)}{\sqrt{3}}, \quad (9) $$

where

$$ g^1_0 = u - \sqrt{2} w \quad (10a) $$
$$ g^1_1 = u + w / \sqrt{2} \quad (10b) $$
$$ g^2_0 = u - \sqrt{2} w / 10 \quad (10c) $$
$$ g^3_2 = 3 \sqrt{3} w / 5 \quad (10d) $$

are the relevant radial functions. We manipulate the left-hand-side of Eqn. (6b)
(similarly contracted) into the same form as Eqn. (9)

\[ |\Delta \Psi^\alpha \rangle E^\alpha = \frac{-2\mu r}{r} \sum_{L=1,3}^{J=0,1,2} \phi^J_L \cdot (E_1 \otimes \hat{e}_1)_J (-1)^J \frac{f^J_L(r)}{\sqrt{3}}, \]

where \( \mu \) is the n-p reduced mass and the functions \( f^J_L(r) \) satisfy

\[ (H_{LJ} - E_d) \frac{-2\mu r}{3} f^J_L(r) = g^J_L. \]

We note that for total angular momentum \( J = 2 \) the \( L = 1 \) and \( L = 3 \) orbital components are coupled by the tensor force. We do treat that coupling properly, although it is not reflected in the simplified notation employed in Eqn. (12).

The matrix element in Eqn. (6a) (including its factor of \( (2\alpha/3) \), a factor of \( \frac{1}{2} \) from each of the two dipole operators, the factors of \( (-2\mu) \) and \( 1/\sqrt{3} \) from Eqn. (11), and the \( 1/\sqrt{3} \) from Eqn. (9)) then becomes

\[ a_E^{\beta\alpha} \rightarrow \sum_J \langle E'_1 \otimes \hat{e}'_1 \rangle_J \cdot \langle E_1 \otimes \hat{e}_1 \rangle_J (-1)^J \sum_L a^L_J, \]

where

\[ a^L_J = \frac{-\mu \alpha}{9} \int_0^\infty dr r^2 f^J_L(r) g^J_L(r) \]

now expresses the entire content of the electric polarizability tensor in terms of projection operators and matrix elements. Equation (13a) is not a convenient form, and we recouple it so that the projectors of the same type are coupled together. We also note that only the \( J = 2 \) part of the \( a^J_L \) terms has two non-vanishing components. We therefore define

\[ A_J = a^1_J + \delta_{J,2} a^3_J, \]

and

\[ \lambda_\kappa = (E'_1 \otimes E_1)_\kappa \cdot (\hat{e}'_1 \otimes \hat{e}_1)_\kappa \]

which yields

\[ a_E^{\beta\alpha} \rightarrow \sum_{\kappa=0,1,2} \lambda_\kappa b_\kappa, \]

where the (real) quantities

\[ b_0 = \frac{1}{3} (A_0 + 3A_1 + 5A_2) \]

\[ b_1 = \frac{1}{6} (-2A_0 - 3A_1 + 5A_2) \]

\[ b_2 = \frac{1}{6} (2A_0 - 3A_1 + A_2) \]
determine the tensor properties of the nuclear physics.

The structure of the \( \lambda_\kappa \) operators corresponds to tensors of order \( \kappa \) in both the Cartesian indexes \( \alpha \) and \( \beta \), and in the effective (azimuthal) spin dependence. The dependence on the two spin-projection operators \( \hat{e}_1 \) and \( \hat{e}_1^* \) is indeed equivalent to using the Wigner-Eckart Theorem\[12\] on the nuclear matrix elements. This allows us to rewrite the spin factors \( \lambda_\kappa \) as effective operators in the nucleus total-angular-momentum Hilbert space, determined by powers of the angular-momentum operator, \( \vec{S} \) of the nucleus:

\[
\alpha_E^{\beta\alpha} = \alpha_E \frac{\delta^{\alpha\beta}}{3} + i\sigma e^{\beta\alpha\gamma} S_\gamma^\gamma + \tau \left( \frac{S_\alpha S_\beta + S_\beta S_\alpha}{2} - \frac{2\delta^{\alpha\beta}}{3} \right).
\] (18)

The three coefficients \( \alpha_E, \sigma, \) and \( \tau \) are, respectively, the scalar, vector, and tensor components of the polarizability. Equation (1) (a trace) defines \( \alpha_E \), while \( \sigma, \) and \( \tau \) are defined by

\[
\sigma = -\frac{2\alpha}{3} \epsilon^{\lambda\mu\nu} \sum_{N \neq 0} \frac{\langle SS|D^\lambda|N\rangle\langle N|D^\mu|SS\rangle}{E_N - E_0},
\] (19a)

and

\[
\tau = 3\alpha_3 - \alpha_E,
\] (19b)

where the deuteron should be in the state \( M' = M = S = 1 \). Finally the relationships

\[
\alpha_E = b_0 \tag{20a}
\]
\[
\sigma = -b_1 \tag{20b}
\]
\[
\tau = -b_2 \tag{20c}
\]

determine the various polarizabilities in terms of the partial waves. Note that \( \sigma \) is real, since the Cartesian vector cross product differs from the spherical one by a factor of \(-i\sqrt{2}\) and the Wigner-Eckart Theorem guarantees that the spherical result is overall real.

The sum-rule quantity \( D^{\beta\alpha} \) is decomposed in strict analogy to Eqn. (18), with coefficients, \( s, v, \) and \( t \) replacing \( \alpha_E, \sigma, \) and \( \tau \). In the non-relativistic approximation that we employ (or, equivalently in the deuteron, the impulse approximation) the former quantities are related to conventional deuteron moments by

\[
s = \frac{2\alpha}{3}<r^2>_{ch},
\]
\[
v = 0,
\]
\[
t = \frac{2\alpha}{3}Q,
\]

where \( <r^2>_{ch} \) is the mean-square charge radius and \( Q \) is the quadrupole moment. Note that in the representation of Eqn. (18) the quantity \( \bar{\sigma} \) in Eqn. (3) becomes \( \bar{\sigma} = v \vec{S} \).
3 Logarithmic Sum Rules

Calculations of the logarithmic modification of the basic polarizabilities or sum rules use the trick of adding an arbitrary energy $\xi f$ to the energy denominator in Eqn. (5a), where $f$ has the dimensions of energy and $\xi$ is dimensionless. This defines

$$\alpha_E^{\beta\alpha}(\xi) = \frac{2\alpha}{3} \sum_{N \neq 0} \frac{\langle 0 | D^\beta | N \rangle \langle N | D^\alpha | 0 \rangle}{\xi f + E_N - E_0}.$$  \hfill (21)

We first integrate $\alpha_E^{\beta\alpha}(\xi)$ with respect to $\xi$ from 0 to $\Lambda$, where $\Lambda$ is very large compared to any relevant energies $(E_N - E_0)$. This produces

$$f \int_0^\Lambda d\xi \alpha_E^{\beta\alpha}(\xi) = \frac{2\alpha}{3} \sum_{N \neq 0} \langle 0 | D^\beta | N \rangle \langle N | D^\alpha | 0 \rangle \log \left[ \frac{\Lambda f}{(E_N - E_0)} \right].$$  \hfill (22)

We split the integration region from $[0, \Lambda]$ into $[0, 1]$ plus $[1, \Lambda]$. In the second region we change variables from $\xi$ to $1/\xi$. We also note that $\int_1^{1/\Lambda} d\xi/\xi = \log \Lambda$. Putting everything together we find that $\Lambda$ can be taken to infinity if we use

$$\frac{2\alpha}{3} \sum_{N \neq 0} \langle 0 | D^\beta | N \rangle \langle N | D^\alpha | 0 \rangle \log \left[ \frac{2(E_N - E_0)}{m_e} \right] = D^{\beta\alpha} \log \left( \frac{2\bar{E}}{m_e} \right) =$$

$$- \int_0^1 d\xi f \alpha_E^{\beta\alpha}(\xi) - \int_0^1 \frac{d\xi}{\xi} \left[ \frac{f}{\xi} \alpha_E^{\beta\alpha}(1/\xi) - D^{\beta\alpha} \right] + D^{\beta\alpha} \log \left( \frac{2f}{m_e} \right),$$  \hfill (23)

where $D^{\beta\alpha}$ is defined in Eqn. (5b).

A similar set of manipulations was developed previously in which the integral

$$\int^\infty_{\epsilon} \frac{d\xi}{\xi} \alpha_E^{\beta\alpha}(\xi) = \frac{2\alpha}{3} \sum_{N \neq 0} \frac{\langle 0 | D^\beta | N \rangle \langle N | D^\alpha | 0 \rangle}{E_N - E_0} \log \left[ \frac{(E_N - E_0)}{\epsilon f} \right]$$  \hfill (24)

was split into the regions $[\epsilon, 1]$ plus $[1, \infty]$, and the integration variable for the second region was also changed to $1/\xi$. This led to a special case of

$$\alpha_E^{\beta\alpha}(0) \log \left( \frac{2\bar{E}}{m_e} \right) = \int_0^1 \frac{d\xi}{\xi} \left[ \alpha_E^{\beta\alpha}(\xi) - \alpha_E^{\beta\alpha}(0) + \alpha_E^{\beta\alpha}(1/\xi) \right] - \alpha_E^{\beta\alpha}(0) \log \left( \frac{m_e}{2f} \right).$$  \hfill (25)

Equations (23) and (25) provide a tractable scheme for calculating logarithmic modifications of our basic polarizability, $\alpha_E^{\beta\alpha}(0)$, and of the sum-rule quantity $D^{\beta\alpha}$. The results are independent of the scale parameter, $f$. Note also that since the various polarizabilities are particular linear combinations of partial waves, the logarithmic modifications are also the same linear combinations involving those partial waves,
and this is a convenient way to perform the calculations. We will also see in the next section that the zero-range approximation provides an excellent starting point for understanding the scalar polarizabilities (the vector and tensor ones are significantly smaller and vanish in this approximation). In the Appendix we develop the zero-range form of Eqn. (5a), which allows the analytic calculation of the logarithmic modifications to $\alpha_E$ and $D^{\alpha \alpha}$. We also develop a zero-range model based on the Relativistic Schrödinger Equation (RSE).

4 Results and Conclusions

We have calculated the scalar, vector, and tensor components of both $\alpha_E^{\beta \alpha}$ and $D^{\alpha \alpha}$, together with their logarithmic modifications. These calculations were performed with seven different second-generation potential models, including the Argonne V$_{18}$ (AV18) [13], the Reid Soft Core 1993 (RSC93), and 5 Nijmegen models[14, 15], including the full model (no partial-wave expansion) as well as the local and non-local Reid-like models. The last two types had been fitted to both relativistic and non-relativistic forms of the deuteron binding energy.

It has been known for a long time that the deuteron mean-square radius and the electric polarizability are rather accurately predicted by the zero-range approximation (see the Appendix). That approximation over-predicts the polarizability by approximately 1% and $D^{\alpha \alpha}$ by less than 2%, and is therefore an excellent starting point for investigating the uncertainties in the four scalar quantities. The largest uncertainty in the zero-range results is due to $A_S$, the asymptotic S-wave normalization constant, whose value was determined in phase-shift analyses[16] to be $A_S = 0.8845(8)$ fm$^{-1/2}$. This leads via Eqn. (A6) to the zero-range result, $\alpha_E^{zr} = 0.6378(12)$ fm$^3$, and via Eqn. (A2) to $D^{zr \alpha} = 0.01916(4)$ fm$^2$, where we use the relativistic form of the deuteron binding energy for both quantities.

The second-generation potentials are sufficiently accurate that they can be regarded as alternative phase-shift analyses. We therefore expect that the values of the electric polarizability and $D^{\alpha \alpha}$ will scatter around a central value with the variance of 2 parts/thousand associated with $A_S^2$. In order to check whether the potential-model variation of the remaining 1% of $\alpha_E$ and roughly 2% of $D^{\alpha \alpha}$ is small, we have scaled each calculated quantity by $(A_S^{exp}/A_S^{model})^2$, and have examined the remaining variations. The scaled values are listed in Table I. This procedure verifies that the dominant uncertainty in the scalar quantities is the error in $A_S$.

The tensor quantities should be expected to scale like $\eta$, the asymptotic $D/S$
Table I

Table 1: Scalar, vector, and tensor components of $D^{\beta \alpha}$ (viz., $s$, $v$, $t$) and $\alpha_E^{\beta \alpha}$ (viz., $\alpha_E$, $\sigma$, $\tau$), followed by the product with the appropriate logarithmic factor, $\log (2E/m_e)$, for each case. Results were calculated using a number of different potential models as discussed in the text, and the “error bar” results from combining a subjective estimate of the spread in the results after scaling to the experimental values of $A_2^S$ and $\eta$, as discussed in the text, with the variances of those two quantities. All calculations used the impulse approximation for the dipole operator and assumed equal-mass nucleons. Note that the first two rows have been multiplied by a factor of 10 to make the entries more uniform in size.

| type | Scalar | Vector | Tensor |
|------|--------|--------|--------|
| $D^{\beta \alpha}$ $\times$ 10 | 0.1882(4) | 0.00000 | 0.01322(10) $\text{fm}^2$ |
| $D^{\beta \alpha} \log (2E/m_e)$ $\times$ 10 | 0.6327(12) | 0.0003(1) | 0.0503(4) $\text{fm}^2$ |
| $\alpha_E^{\beta \alpha}$ | 0.6330(13) | $-0.00092(5)$ | 0.0317(3) $\text{fm}^3$ |
| $\alpha_E^{\beta \alpha} \log (2E/m_e)$ | 1.8750(36) | $-0.0023(2)$ | 0.1014(8) $\text{fm}^3$ |

(ampplitude) ratio of the deuteron. Those quantities in Table I have therefore also been scaled by $\eta^{\text{exp}}/\eta^{\text{model}}$, where the experimental value of $\eta$ was determined from phase-shift analyses\[16\] to be $\eta^{\text{exp}} = 0.0253(2)$. This scaling considerably reduces the scatter in the calculated tensor results. The small size of $\eta$ also roughly accounts for the size of the tensor quantities relative to the scalar ones. The result in Table I is nearly 10% smaller than the one in Ref. \[8\], reflecting a smaller modern value of $\eta$ [16].

The vector quantities are very suppressed and are sensitive to details of the nuclear force that vary from model to model. They are sensitive to the forces in the $^3P_J$ states, and in the absence of those forces can be shown to be determined by the square of the D-state wave function. The quoted uncertainties are inferred solely from the model variations. Note that the vector part of $D^{\beta \alpha}$ vanishes identically in non-relativistic approximation, and this accounts for the very small sizes of the vector quantities.

In summary, we have calculated a variety of polarizabilities and sum rules for the deuteron that are generated by (unretarded) electric dipole interactions. These quantities have been divided into scalar, vector, and tensor components, and include logarithmic modifications of each. Our numerical techniques allow us to generate all such components at no extra cost. The scalar polarizabilities were previously calculated\[2\], and have not changed significantly. The vector components of the sum rule play a role in the ordinary deuterium hyperfine structure\[4\] and are very small. The tensor components determine part of the deuterium quadrupole hyperfine
structure[1], although calculations of this effect have not yet been performed. The sizes and uncertainties of the various quantities were analyzed using the zero-range approximation and various scales appropriate to the deuteron.

5 Appendix

The zero-range approximation is motivated by the asymptotic dominance of radial matrix elements that contain (positive) powers of the distance between the nucleons. The mean-square radius is an obvious example, as is the electric polarizability, since each is weighted by two powers of the inter-nucleon separation. The usual version of this approximation is to assume that in intermediate states the nucleons lie outside the range of the nuclear force (i.e., we set that force to zero) and in the initial and final deuteron states we ignore the D-wave and use the asymptotic form of the S-wave function. The zero-range deuteron wave functions are therefore given by

\[ u_{zr}(r) = A_S \exp(-\kappa r), \tag{A1a} \]
\[ w_{zr}(r) = 0, \tag{A1b} \]

where \( A_S \) is the asymptotic S-wave normalization constant, \( \kappa = \sqrt{2\mu E_b} \), \( \mu \) is the n-p reduced mass, and \( E_b \) is the (positive) deuteron binding energy. Ignoring the tiny difference in the proton and neutron masses (the neutron lies slightly closer to the CM than the proton) one finds that the mean-square charge radius and \( \langle \vec{D}^2 \rangle \) are proportional in impulse approximation (which we have assumed as a consequence of the non-relativistic approximation), but not otherwise. Recalling the factor of \( (2\alpha/3) \) from Eqn. (5b) and two factors of \( 1/2 \) from the two dipole operators, the zero-range value of \( D^{\alpha\alpha} \) is given by

\[ D^{\alpha\alpha}_{sr} = \frac{\alpha A_S^2}{24 \kappa^3} \rightarrow 0.01916(4) \text{ fm}^2, \tag{A2} \]

where the numerical result uses the experimental value of \( A_S \) and the relativistic value of \( \kappa \) defined below. The calculation of the remaining quantities requires an analytic expression for the scalar electric polarizability with the \( \xi f \) insertion. It is convenient to choose \( f \) to be the deuteron binding energy (i.e., \( E_b = -E_0 \)), so that in momentum space we have

\[ \xi E_b + E_N - E_0 \rightarrow \frac{(1 + \xi) \kappa^2 + \vec{p}^2}{2\mu}, \tag{A3} \]

and the required Green’s function is therefore a simple modification of the usual zero-range Green’s function for the deuteron:

\[ G_0(\xi) = \frac{2\mu}{4\pi r} \exp(-\bar{\kappa} r), \tag{A4a} \]
\[ \bar{\kappa} = \sqrt{1 + \xi \kappa}. \]  
(A4b)

Performing the integrals in Eqn. (5a) using Eqn. (A1) for the wave function and Eqn. (A4) for the Green’s function leads to the zero-range result

\[
\alpha_{zr}^{st}(\xi) = \frac{\alpha_{zr}^{st}(0)}{12 \kappa^3} \frac{(\kappa^2 + \bar{\kappa}^2 + 4 \kappa \bar{\kappa})}{(\kappa + \bar{\kappa})^4}. 
\]  
(A5)

This gives the well-known result

\[
\alpha_{zr}^{st}(0) = \frac{\alpha_{zr}^{st}(0)}{32 \kappa^5} \rightarrow 0.6378(12) \text{ fm}^3, 
\]  
(A6)

where the numerical result uses the experimental value of \( A_S \) and the relativistic value of \( \kappa \) defined below. Equations (22) and (24) can now be used to calculate the logarithmic modifications of \( \alpha_{zr}^{st} \) and \( \langle \vec{D}^2 \rangle_{zr} \). The logarithmic modification of \( \alpha_{zr}^{st} \) is determined by

\[
\log \left( \frac{\bar{E}}{E_b} \right) = \log 4 - \frac{7}{12}, \quad \tag{A7a}
\]

or \( \frac{\bar{E}}{E_b} = 2.23214 \cdots \), while the modification of \( \langle \vec{D}^2 \rangle_{zr} \) is determined by

\[
\log \left( \frac{\bar{E}}{E_b} \right) = \log 4 - \frac{1}{6}, \quad \tag{A7b}
\]

or \( \frac{\bar{E}}{E_b} = 3.38592 \cdots \). Both results are very simple and quite accurate.

Our final task is to estimate the size of one class of relativistic corrections to \( \alpha_{zr}^{st} \). We begin with the so-called Relativistic Schrödinger Equation, which we construct for two non-interacting nucleons with identical masses, \( M \), by summing the kinetic energies of each:

\[
\left[ E - \left( M^2 + \vec{p}_1^2 \right)^{1/2} - \left( M^2 + \vec{p}_2^2 \right)^{1/2} \right] \psi = 0. \quad \tag{A8}
\]

A potential could also be added to the kinetic energy. In the center-of-mass frame of the two particles (with momenta \( \vec{p} \) and \( -\vec{p} \), respectively)

\[
\left[ E_{cm} - 2 \left( M^2 + \vec{p}^2 \right)^{1/2} \right] \psi = 0, \quad \tag{A9a}
\]

indicating that the energy of a bound deuteron would be given by

\[ E_d = 2 \left( M^2 - \kappa_\tau^2 \right)^{1/2} \equiv 2M - E_b. \quad \tag{A9b} \]

Since the rightmost (experimental) result holds in all cases, it clearly makes a difference if the non-relativistic approximation \( 2M - \kappa_{nr}^2 / M \) is substituted for the
square root in Eqn. (A9b). For this reason we have labelled the relativistic value of $\kappa$ as $\kappa_r$ and the non-relativistic approximation as $\kappa_{nr}$. They are related by $\kappa_r \equiv \kappa_{nr}(1 - \kappa_{nr}^2/8M^2)$.

Equation (A9a) also holds if we multiply it by $E_{cm} + E_{cm}'$, where $E_{cm}' = 2\left( M^2 + \vec{p}^2 \right)^{1/2}$. This reduces the equation to non-relativistic form, but with $\kappa_r$ replacing $\kappa_{nr}$. Equations (A1) therefore still hold mutatis mutandis. This does not apply to the Green’s function, however. If we invert Eqn. (A9a) and multiply top and bottom by the identical factor $E_{cm} + E_{cm}'$, the denominator has the desired form $-4(\kappa_r^2 + \vec{p}^2)$, but the numerator now contains the factor $(E_{cm} + E_{cm}')$, which we rewrite as $2E_{cm} + (E_{cm}' - E_{cm})$ and note that the second part of this expression cancels a similar factor in the denominator. The remainder is very short ranged (range $\sim 1/M$) when Fourier transformed, and in keeping with the zero-range approximation we ignore this term. Thus the appropriate zero-range Green’s function for the RSE is simply $(1 - \kappa_r^2/M^2)^{1/2} G_0$, where the form in Eqn. (A4a) holds if we replace $2\mu$ by $M$ and $\kappa$ by $\kappa_r$. Thus previous results for $\alpha_E$ hold is we use $\kappa_r$ everywhere for $\kappa$ and multiply by the factor of $(1 - \kappa_r^2/M^2)^{1/2}$. This produces a correction (compared to 1) $\sim -\kappa_r^2/2M^2 \sim -0.0012$, which reflects the expected size of relativistic effects for the deuteron. For a full treatment, see Ref.[17].

Although nuclear physicists almost universally denote the total nuclear angular momentum by $\vec{J}$, we have chosen to use $\vec{S}$ instead. This more closely conforms to conventional usage in atomic physics. Nuclear physicists should be careful not to confuse our $\vec{S}$ with the simple sum of individual nucleon spins.
