ABSTRACT
We present a sample of 131 quasars from the Sloan Digital Sky Survey at redshifts 0.8 < z < 1.6 with double peaks in either of the high-ionization narrow emission lines [Ne v] λ3426 or [Ne iii] λ3869. These sources were selected with the intention of identifying high-redshift analogs of the z < 0.8 active galactic nuclei (AGNs) with double-peaked [O iii] λ5007 lines, which might represent AGN outflows or dual AGNs. Lines of high ionization potential are believed to originate in the inner, highly photoionized portion of the narrow line region, and we exploit this assumption to investigate the possible kinematic origins of the double-peaked lines. For comparison, we measure the [Ne v] λ3426 and [Ne iii] λ3869 double peaks in low-redshift (z < 0.8) [O iii]-selected sources. We find that [Ne v] λ3426 and [Ne iii] λ3869 show a correlation between line splitting and line width similar to that of [O iii] λ5007 in other studies, and the velocity splittings are correlated with the quasar Eddington ratio. These results suggest an outflow origin for at least a subset of the double peaks, allowing us to study the high-ionization gas kinematics around quasars. However, we find that a non-negligible fraction of our sample show no evidence for an ionization stratification. For these sources, the outflow scenario is less compelling, leaving the dual AGN scenario as a viable possibility. Finally, we find that our sample shows an anti-correlation between the velocity-offset ratio and luminosity ratio of the components, which is a potential dynamical argument for the presence of dual AGNs. Therefore, this study serves as a first attempt at extending the selection of candidate dual AGNs to higher redshifts.

Key words: galaxies: active – galaxies: high-redshift – galaxies: jets – galaxies: nuclei – quasars: emission lines

Online-only material: color figures, machine-readable tables

1. INTRODUCTION
Mergers of gas-rich galaxies are likely to play a key role in the growth of supermassive black holes (SMBHs) through accretion, particularly in the triggering of quasar phases (Sanders et al. 1988; Treister et al. 2010). Quasars may also represent an important phase in the evolution of galaxies due to radiative feedback (Silk & Rees 1998; Kauffmann & Haehnelt 2000). This sequence of events is a potential scenario linking the evolution of galaxies and the growth of SMBHs (Di Matteo et al. 2005; Hopkins et al. 2005). Interestingly, both the merger and quasar phases can manifest themselves as active galactic nuclei (AGNs) with double-peaked narrow emission lines in their spectra. Specifically, during a galaxy merger, when the SMBHs are separated by ~1 kpc and are actively accreting as a double AGN (Comerford et al. 2009a), they will each produce Doppler-shifted emission from their narrow line regions (NLRs), resulting in a double-peaked profile in the integrated spectrum. In the feedback scenario, radiation from a single quasar can drive bi-conical outflows of the NLRs (Arribas et al. 1996; Veilleux et al. 2001; Crenshaw et al. 2010a), producing similar emission line profiles (Zheng et al. 1999; Fischer et al. 2011).

AGNs whose spectra exhibit double-peaked narrow emission lines (i.e., they are best fit by two components) represent a subclass of the AGN population. Extended, offset, and double-peaked line profiles have been observed in the narrow emission lines of AGNs since the earliest studies of AGN NLRs (Heckman et al. 1981). These complex narrow line profiles are observed in both Type 1 and Type 2 AGNs (Crenshaw et al. 2010b), and they are generally most pronounced in forbidden transition lines of high ionization potentials (I.P.s). In particular, such observations have often focused on the 5007 Å transition line of [O iii] (I.P. = 35.15 eV) since it is a relatively intense emission line produced by the ionizing continuum of AGNs and is accessible in optical spectra (see Veilleux 1991 and Whittle 1992 for examples). However, there is even variation among the high-ionization lines, with those of the highest I.P.s, such as [Ne iii] (I.P. = 41.07 eV), and [Ne v] (I.P. = 97.16 eV), displaying the largest velocity offsets (De Robertis & Osterbrock 1984; Sturm et al. 2002; Spoon & Holt 2009).

In the dual AGN scenario, the two emission line peaks are produced by the orbital motion of two AGNs within a single-merger remnant galaxy. This interpretation is intriguing since SMBHs reside in the bulges of galaxies, and dual SMBHs (kpc-scale separations) are a stage of galaxy mergers before the SMBHs coalesce. The existence of dual AGNs has been confirmed observationally in several serendipitous cases, most notably in ultraluminous infrared galaxies as pairs of X-ray point sources (Komossa et al. 2003; Guainazzi et al. 2005; Hudson et al. 2006; Bianchi et al. 2008; Piconcelli et al. 2010; Koss et al. 2011; Mazzarella et al. 2012). Systematic searches for dual AGNs in large spectroscopic databases, such as the Sloan Digital Sky Survey (SDSS; Abazajian et al. 2009) and DEEP2 (Newman et al. 2012), have involved identifying AGNs with double emission line systems (Comerford et al. 2009a; Wang et al. 2009; Liu et al. 2010b; Smith et al. 2010; Ge et al. 2012). Promising results are being obtained through follow-up observations in the form of high-resolution optical imaging (Comerford et al. 2009b), near-infrared (NIR) adaptive optics imaging (Liu et al. 2010a; Fu et al. 2011a; Rosario
et al. 2011; Shen et al. 2011a; Barrows et al. 2012), spatially resolved spectroscopy (McGurk et al. 2011; Fu et al. 2012), hard X-ray observations (Comerford et al. 2011; Civano et al. 2012; Liu et al. 2013), radio observations (Fu et al. 2011b), and diagnostics deduced statistically from longslit spectroscopy (Comerford et al. 2012). A sample of dual AGNs will be useful in studying the connection between galaxy interactions/mergers and AGN activity (Green et al. 2010; Liu et al. 2011, 2012), and for refining the galaxy merger rate (Conselice et al. 2003; Berrier et al. 2006; Lotz et al. 2011; Berrier & Cooke 2012).

In the outflow scenario, offset or double-peaked narrow emission lines are often attributed to radially flowing NLR gas driven by energy from the AGN. Furthermore, this effect is also thought to produce a stratification of the NLR since the incident ionizing flux and electron density should diminish with increasing distance from the nuclear source. This will result in the production of different lines in varying proportions as a function of radius from the AGN (Veilleux 1991). Observationally, luminous quasars are known to have extended NLRs driven by energy from the AGN coupled to the interstellar medium gas (Bennert et al. 2002), and powerful radio galaxies often show complex, spatially extended NLRs with multiple components aligned along the radio axis. Models for this alignment include reflection of the AGN emission (Tadhunter et al. 1988) or material entrained in a radio jet (Holt et al. 2003, 2008; Komossa et al. 2008). In AGNs with sufficiently high Eddington ratios, radiation pressure acting on gas and dust (Everett 2007) or a hot wind that entrains the NLR clouds (Everett & Murray 2007) are possible mechanisms capable of driving the line splitting. Whichever mechanism is the dominant driver of outflows in an individual source, they may represent cases of AGN feedback, which might be important in quenching star formation in galaxies following a merger and in establishing the observed correlations between SMBH masses and host galaxy properties (Ferrarese & Merritt 2000; Marconi & Hunt 2003).

Whether AGNs with double-peaked emission lines represent dual AGNs or powerful AGN outflows, they have proven useful for investigating several aspects of AGN evolution, including AGN triggering and feedback. Systematic searches for double-peaked AGNs have primarily utilized the [O \text{ iii}] λ5007 emission line and have therefore been limited to below redshifts of \( z \approx 0.8 \) since [O \text{ iii}] λ5007 is not accessible in optical spectra at higher redshifts. However, there is evidence that at high redshifts galaxy mergers were more prevalent, and AGN outflows might have played an important role in the evolution of galaxies at \( z \geq 1 \), including massive radio galaxies (Nesvadba et al. 2008). Furthermore, there is significant controversy over the role that galaxy mergers play in AGN activity and SMBH growth at high redshifts (Cisternas et al. 2011; Treister et al. 2012; Kocevski et al. 2012). Therefore, a sample of high-redshift double-peaked narrow line AGNs will be important for investigating these questions. So far only one such candidate dual AGN has been identified above \( z \sim 0.8 \) as a serendipitous discovery at \( z = 1.175 \) through double-peaked UV and optical emission lines, particularly evident in [Ne \text{ v}] λ3426 and [Ne \text{ iii}] λ3869 (Barrows et al. 2012). Motivated by this discovery, we have conducted a systematic search for additional AGNs at high redshift \( (z > 0.8) \) with double-peaked [Ne \text{ v}] λ3426 and [Ne \text{ iii}] λ3869 emission lines. These emission lines have relatively high L.P.s and trace the gas photoionized by the AGN continuum. Furthermore, they are likely to originate in the inner (more highly ionized) portion of the NLR, allowing for the identification of AGN-driven outflows at \( 0.8 < z < 1.6 \). This study will also serve as a first attempt at extending the identification of candidate dual AGNs to higher redshifts.

In Section 2, we describe our parent sample and how we selected our final sample and low-redshift comparison sample. In Section 3, we describe the systemic redshifts we will use throughout the paper. In Section 4, we describe the general properties of our sample and our estimates of selection completeness. In Section 5, we investigate several correlations among the emission line properties that aid in illuminating the origin of the double-peaked line profiles. In Section 6, we describe the radio properties of our sample and compare them to our parent sample. In Section 7, we discuss the most likely physical mechanisms driving the line splitting, particularly focusing on the scenarios of AGN outflows and dual AGNs. In Section 8, we summarize our main conclusions. Throughout the paper we adopt the cosmological parameters \( \Omega_m = 0.278, \Omega_b = 0.0455, \Omega_m h^2 = 0.1347, \) and \( H_0 = 70.4 \text{ km s}^{-1} \text{ Mpc}^{-1} \). This corresponds to the maximum likelihood cosmology from the combined WMAP+BAO+H0 results from the WMAP7 data release of Komatsu et al. (2011).

2. GENERATING THE SAMPLE

2.1. Parent Sample

Our parent sample consists of archival spectra drawn from the quasar catalog of the SDSS Data Release 7 (DR7) which is described in detail in Schneider et al. (2010). The typical resolution of the SDSS spectra is \( \lambda / \Delta \lambda \sim 2000 \). In short, inclusion in the catalog requires luminosities brighter than \( M_i = -22.0 \), at least one emission line with FWHM > 1000 \text{ km s}^{-1} or complex absorption features, apparent magnitudes fainter than \( i > 15.0 \), and having highly reliable redshifts (see Section 3 for a discussion of the redshifts). We restricted the lower redshift limit of the sample to \( z \geq 0.80 \) to only include sources not in the parent samples of [O \text{ iii}]-selected double-peaked emitters from the SDSS (Wang et al. 2009; Liu et al. 2010b; Smith et al. 2010; Ge et al. 2012) since our intention is to select sources which are not identifiable by their methods. Additionally, we required that at least [Ne \text{ v}] λ3426 be accessible in the SDSS wavelength range (3800–9200 Å), which imposes an upper limit of \( z \sim 1.7 \). We did not make any selection cuts based on the signal-to-noise ratios (S/N). This resulted in a parent sample of 39,876 sources.

2.2. Initial Selection

Our initial selection involved visually identifying quasars from the parent sample (Section 2.1) with detectable double emission line peaks in [Ne \text{ v}] λ3426 and/or [Ne \text{ iii}] λ3869. These two lines were used since they are accessible in the SDSS optical wavelength range at \( z > 0.80 \), are relatively strong narrow lines in quasar spectra, and are not severely blended with any other strong lines. We did not require that two explicit peaks be detectable in both of those emission lines for two reasons: (1) the ionizing continuum may be such that [Ne \text{ v}] λ3426 is too weak to be detected, whereas [Ne \text{ iii}] λ3869 is detectable; and (2) a difference in line ratios and/or velocity splittings between the two lines may result in one pair being more blended than the other. Therefore, since the purpose of this analysis is to investigate the origin of the double-peaked emission lines, we did not want to exclude those sources which show variations among the line properties. While [O \text{ ii}] λ3727 is another strong emission line accessible in most of our parent sample, we did not select sources based on this line since [O \text{ ii}] λ3727 is a doublet (λ3726, 3729 Å) with \( \sim 200 \text{ km s}^{-1} \) separation between
the transition wavelengths and is difficult to discern from true peaks, particularly with the limited spectral resolution of the SDSS (see Smith et al. 2010 for a similar discussion). In sources where the double-peak detections are ambiguous in each line, corresponding peaks in both [Ne v] λ3426 and [Ne iii] λ3869 are needed for confirmation. Out of the parent sample, our visual selection process resulted in 181 preliminary sources.

2.3. Modeling the Spectra and Selection of the Final Sample

To generate the final sample to be used in our subsequent analyses, we modeled each spectrum yielded by the initial selection stage (Section 2.2) in order to determine if a two-Gaussian model significantly improves the line profile fit over a single-Gaussian model. This modeling proceeded in two stages: (1) continuum modeling and (2) emission line modeling.

2.3.1. Continuum Modeling

The continuum was modeled by masking all detectable emission lines and simultaneously fitting a power-law function ($F_\lambda \sim \lambda^{-\alpha}$) for the underlying AGN continuum radiation plus a pseudo-continuum of broadened Fe ii emission lines from the empirical templates of Tsuzuki et al. (2006, $\lambda_{\text{obs}} < 3500$ Å) and Véron-Cetty et al. (2004, $\lambda_{\text{obs}} > 3500$ Å) which were developed from the spectrum of the narrow-line Seyfert 1 galaxy I Zw 1. Due to the use of two separate Fe ii templates, the power-law function was allowed to have a break at 3500 Å, and the Fe ii normalization allowed to vary independently below and above the break wavelength. The Fe ii pseudo-continuum is composed of many blended Fe ii transitions which are generally believed to originate in or near the classical broad line region (BLR), and as such the redshift and broadening of the Fe ii emission should be comparable to that of the broad emission lines. Therefore, in our modeling the Fe ii emission was fixed at the redshift of the quasar being modeled (see Section 3 for a detailed discussion of the redshifts); we broadened the Fe ii template by convolving with a Gaussian of FWHM$_{\text{conv}}$, where FWHM$_{\text{Fe ii}}$ = FWHM$_{\text{conv}}^2$ + FWHM$_{\text{Zw1}}^2$ and FWHM$_{\text{Zw1}} = 900$ km s$^{-1}$. Use of this template necessarily limits the minimum FWHM$_{\text{Fe ii}}$ best-fit to 900 km s$^{-1}$, though this was not a problem since these sources were in the quasar catalog based on the presence of broad lines with FWHM > 1000 km s$^{-1}$. The lower rest-wavelength end of the continuum+Fe ii fitting window was 2750 Å and the upper rest-wavelength end was 3950 Å (just redward of [Ne iii] λ3869) if accessible, or otherwise the equivalent red end of the spectral coverage. This fitting window allowed proper detection of the Fe ii emission since it has a relatively large equivalent width (EW) near Mg ii λ2800. We allowed FWHM$_{\text{Fe ii}}$ to vary in steps of 100 km s$^{-1}$, and in general, the solutions are in the range 2000–9000 km s$^{-1}$, though in most cases the quality of the fits were not strongly dependent on the broadening.

2.3.2. Narrow Emission Line Modeling

We fit each emission line ([Ne v] λ3426 and [Ne iii] λ3869) with both a single and a double Gaussian model, and required that sources in our final sample have fits to at least one of these two lines significantly improved by the double Gaussian model ($\Delta \chi^2 \gg \Delta \chi_{\text{DOF}}^2$). In seven individual line models, an additional broad component of line width FWHM $\approx$ 700–1500 km s$^{-1}$ was required for a satisfactory fit. Three of the [Ne v] λ3426 fits required such a component, where in two of those cases the broad component is consistent with the blue narrow peak (J074242.18+374402.0: FWHM = 1470 km s$^{-1}$; and J105035.57+190544.2: FWHM = 1220 km s$^{-1}$), and in the third case it is consistent with the red narrow peak (J150243.93+281739.9: FWHM = 1320 km s$^{-1}$). Four of the [Ne iii] λ3869 fits required a broad component, where in three of those cases it is consistent with the blue narrow peak (J105035.57+190544.2: FWHM = 1520 km s$^{-1}$; J105634.56+121023.5: FWHM = 820 km s$^{-1}$; and J145659.27+503805.4: FWHM = 700 km s$^{-1}$) and in one of those cases it is located between the blue and red peaks (J085205.91+183922.2: FWHM = 1020 km s$^{-1}$). We note that in only one of these sources (J105035.57+190544.2) is a broad component seen in both [Ne v] λ3426 and [Ne iii] λ3869, and it is consistent with the blue peak.

Properly accounting for the contribution of flux from Fe ii emission is often important in determining the profiles of the emission lines of interest in this wavelength range. In particular, there is a local peak in the broadened Fe ii emission just blueward of [Ne v] λ3426, between 3390 Å and 3410 Å, which has the potential to complicate the isolation of the blue [Ne v] λ3426 component. Therefore, careful attention was paid to the modeling in this region, and any sources for which the model was ambiguous were not admitted into the final sample. However, there is no significant Fe ii emission near [Ne iii] λ3869, and only a small local peak redward of [O ii] λ3727 but with which it is not blended.

From our spectral modeling, there are 38 sources in our sample for which we have measured robust double peaks in both [Ne v] λ3426 and [Ne iii] λ3869, 42 sources for which we have only robust [Ne v] λ3426 measurements, and 51 sources for which we have only robust [Ne iii] λ3869 measurements. Thus, there are a total of 131 double-peaked sources in our sample, making the fraction of double-peaked AGNs detected in this manner ~0.3% of the parent sample. See Figure 1 for examples of the spectra in our final sample showing the best-fit models over the rest-wavelength range containing [Ne v] λ3426 and [Ne iii] λ3869. Additionally, Figure 2 compares the individual [Ne v] λ3426 and [Ne iii] λ3869 line profiles in velocity space. The best-fit parameters of the emission line modeling are listed in Table 1 ([Ne v] λ3426) and Table 2 ([Ne iii] λ3869). All errors correspond to 1σ uncertainties and have been propagated throughout any further calculations. The reduced $\chi^2$ values for each double Gaussian model are listed in Tables 1 and 2 and shown as a distribution in Figure 3. The emission line modeling was performed with SPECFIT (Kriss 1994). Our best-fitting Fe ii FWHMs are listed in Table 3, along with other relevant quasar properties (redshifts, Mg ii λ2800 FWHMs, and Eddington ratios) which will be described in subsequent sections.

Throughout the rest of the paper, the velocity offsets of the individual blue and red components will refer to the offsets from the systemic velocity. For [Ne v] λ3426, these blue and red velocity offsets will be defined as $\Delta V_{\text{[Ne v], blue}}$ and $\Delta V_{\text{[Ne v], red}}$ respectively. For [Ne iii] λ3869, the blue and red velocity offsets will be defined as $\Delta V_{\text{[Ne iii], blue}}$ and $\Delta V_{\text{[Ne iii], red}}$ respectively. Blueshifts will correspond to positive velocities. The velocity splittings will then be the velocity difference between the lines, i.e., $\Delta V_{\text{Ne v}} \equiv \Delta V_{\text{[Ne v], blue}} - \Delta V_{\text{[Ne v], red}}$ and $\Delta V_{\text{Ne ii}} \equiv \Delta V_{\text{[Ne iii], blue}} - \Delta V_{\text{[Ne iii], red}}$. The redshifts corresponding to the systemic velocity of each source are described in Section 3.

2.4. Comparison Sample

To generate a $z < 0.8$ comparison sample to be used in our analyses, we examined the 89 [O iii]-selected Type 1 sources in...
Figure 1. Four examples of quasar spectra yielded by our selection process shown in the quasar rest-frame ($z_{\text{SDSS}}$) wavelength range of 3360–3950 Å. The spectra have been smoothed by convolving with a Gaussian of $\sigma = 1$ Å. The flux densities, $F_{\lambda}$, are in units of $10^{-17}$ erg s$^{-1}$ cm$^{-2}$ Å$^{-1}$. In each of the four panels the power-law continuum has been subtracted from the spectrum, and the Fe ii template (gray, solid line), best-fit Gaussians (black, dotted lines), and the best-fit model sum (red, solid line) are shown. See Section 2.3 for details on fitting the models. These are examples for which double components are measurable in $\text{[Ne v]}_{\lambda3426}$ and $\text{[Ne iii]}_{\lambda3869}$. In all four cases we can only place upper limits in the presence of a second $\text{[O ii]}_{\lambda3727}$ component (vertical dashed line). In each panel, we have labeled the expected position of H$\zeta$ based on its rest-wavelength; however, it is not always detected, and in no cases can we resolve double peaks in H$\zeta$.

(A color version of this figure is available in the online journal.)

Smith et al. (2010) and measured the line properties of double-peaked $\text{[Ne v]}_{\lambda3426}$ and $\text{[Ne iii]}_{\lambda3869}$ in cases for which two peaks are detectable in those lines. We chose this sample because, as opposed to other double-peaked $\text{[O iii]}_{\lambda5007}$ samples, it includes Type 1 AGNs which were selected from the SDSS quasar catalog. Therefore, it provides a $z < 0.8$ sample which can be used for direct comparison. For the measurements on the $\text{[O iii]}$-selected sample, we selected those with robust $\text{[Ne v]}_{\lambda3426}$ and $\text{[Ne iii]}_{\lambda3869}$ double peaks in the same way as for our high-redshift sample, and likewise modeled the spectra as described above. This resulted in 18 sources in the $\text{[O iii]}$-selected comparison sample for which we have measured robust double peaks in both $\text{[Ne v]}_{\lambda3426}$ and $\text{[Ne iii]}_{\lambda3869}$, four sources for which we have only have robust $\text{[Ne v]}_{\lambda3426}$ measurements, and
Barrows et al.

Figure 2. Examples of two spectra from Figure 1 zoomed-in on [Ne v] λ3426 (top) and [Ne iii] λ3869 (bottom). The spectra have been smoothed by convolving with a Gaussian of σ = 2 Å. In each panel the peak flux of the double Gaussian model has been normalized to unity, and the spectra are plotted in velocity space with zero velocity at the quasar redshift. The power-law continuum has been subtracted from the spectrum, and the model components are the same as described in Figure 1. (A color version of this figure is available in the online journal.)

Table 1

| SDSS Name          | Fλ a | ΔV b  | FWHM c | Reduced χ² (dof) |

Notes. All errors correspond to 1σ uncertainties. * denotes that a broad component was necessary.

a Flux densities, Fλ, are in units of 10⁻¹⁷ erg s⁻¹ Å⁻¹.
b ΔV is velocity offset from the quasar redshift in km s⁻¹.
c FWHM are the observed line widths in units of km s⁻¹.

(This table is available in its entirety in a machine-readable form in the online journal. A portion is shown here for guidance regarding its form and content.)

20 sources for which we have only have robust [Ne iii] λ3869 measurements. Thus, there are a total of 42 double-peaked sources in our comparison sample.

3. REDSHIFTS

Some sections of our analysis require a knowledge of the individual quasar redshifts. For the sources in our sample, we have redshifts available from several different measurement techniques. In this section, we describe those redshift estimates which are useful for our scientific interests.

3.1. SDSS Redshifts

Redshifts for spectroscopically detected sources in the SDSS are determined by the “spectro1d” code described in Stoughton.
Table 2
Emission Line Properties for Double-peaked [Ne\textsc{iii}] λ3869

| SDSS Name          | $F_\lambda$ | $\Delta\lambda$ | FWHM$^c$ | $F_\lambda$ | $\Delta\lambda$ | FWHM$^c$ | Reduced $\chi^2$ (dof) |

Figure 3. Distribution of reduced $\chi^2$ values for the best double-Gaussian fits for [Ne\textsc{v}] λ3426 (black, solid line) and [Ne\textsc{iii}] λ3869 (gray, dashed line).
3.2. Redshifts from Mg \( \lambda 2800 \)

In principle, individual emission lines can provide independent redshift estimates corresponding to the physical regions where those lines originated, e.g., the broad emission lines provide redshifts for the BLR. For our purposes, it is useful to know the redshift of the central SMBH (under the assumption of a single, active SMBH in the host galaxy) which can potentially be traced by the BLR if the gas is virialized. Fortuitously, given the redshift range of our sample, for all of our sources we have spectral access to the broad Mg \( \lambda 2800 \) emission line, which has been shown to be virialized in the potential of the central SMBH (McLure & Jarvis 2002). Therefore, we have used the Mg \( \lambda 2800 \) emission line models from the catalog of SDSS DR7 quasar properties (Shen et al. 2011b) to obtain estimates of the BLR redshifts \( z_{\text{Mg} \Pi} \).

However, we would like to note several potential technical difficulties involved in measuring the Mg \( \lambda 2800 \) line centroid which limit its application to our work. These difficulties include blending with Fe \( \Pi \) emission, UV absorption features, and the often ambiguous presence of a narrow emission line component (which is actually the doublet Mg \( \lambda \lambda 2797, 2802 \)). We also note that the Mg \( \lambda 2800 \) line centroids may be complicated if the low-ionization broad emission lines have the characteristic double-peaked profile of disk emitters (Eracleous & Halpern 2003; Strateva et al. 2003). Furthermore, since we are considering the scenario of two AGNs within the same host galaxy, we must consider the possibility that the broad Mg \( \lambda 2800 \) line is a blending of two BLRs from two Type 1 AGNs. Though the components of a dual AGN would not be close enough for the line splitting to exceed the FWHM (several thousand \( \text{km s}^{-1} \)) and produce explicit double-peaked profiles (Shen & Loeb 2010), two broad Mg \( \lambda 2800 \) components separated by several hundred \( \text{km s}^{-1} \) will still result in a relatively broadened, and possibly asymmetric, Mg \( \lambda 2800 \) profile, thereby complicating the centroid measurement. We have visually inspected the Mg \( \lambda 2800 \) line profile for each source in our sample in order to characterize their structure. There are several sources which show evidence for asymmetric structure, though it is generally difficult to discern if any of the profiles contain two broad components as would be the case if there are dual BLRs. Though many of those redshifts have rather large errors, a subset of them have robust line centroids with percent errors less than 1% (73 sources) and percent errors less than 0.1% (52 sources). The Mg \( \lambda 2800 \) redshifts are listed in Table 3.

3.3. Comparison of \( z_{\text{SDSS}} \) and \( z_{\text{Mg} \Pi} \)

Figure 4 shows the distribution of \( (z_{\text{SDSS}} - z_{\text{Mg} \Pi})/(1 + z_{\text{SDSS}}) \) where the Mg \( \lambda 2800 \) redshifts appear to be systematically larger than the cross-correlation redshifts in both our sample and the parent sample. This same effect is clearly apparent in the SDSS redshift analysis of Hewett & Wild (2010), which suggests that we are seeing the same systematic trend in our analysis. While Hewett & Wild (2010) provide redshifts which correct for this systematic offset in a statistical sense, these corrections may not be appropriate for some individual quasars. Therefore, we do not use these improved redshifts since our sample only contains 131 sources.

Based upon our comparison between \( z_{\text{SDSS}} \) and \( z_{\text{Mg} \Pi} \), for the rest of our analysis we have chosen to use the \( z_{\text{SDSS}} \) values and their associated errors. These SDSS redshifts will serve as the systemic velocities for our sources. All quoted line splittings between the two line peaks \( \Delta V_{\text{[Ne V]}} \) and \( \Delta V_{\text{[Ne III]}} \) and velocity offsets for the blue \( \Delta V_{\text{[Ne V],blue}} \) and \( \Delta V_{\text{[Ne III,blue]}} \) and red \( \Delta V_{\text{[Ne V] red}}, \Delta V_{\text{[Ne III,red]}} \) components are relative to these SDSS redshifts. The range of redshifts in our sample is \( z = 0.80 \) (low-limit cutoff discussed in Section 2.1) to \( z = 1.53 \) (highest redshift source in our sample). In Section 5.4, for which our analysis is heavily dependent upon the choice of redshift, we will also use the robust \( z_{\text{Mg} \Pi} \) measurements mentioned in Section 3.2 for comparison.

4. GENERAL PROPERTIES OF THE SAMPLE

In this section, we describe several of the general properties of our sample. We compare the distributions of these properties (redshifts, \( S/N \), and velocity offsets) to the parent sample or our low-redshift comparison sample in order to show our selection biases. Additionally, we discuss the results of our completeness estimates with respect to several of these and other properties.

4.1. Distributions

The SDSS redshifts we have adopted for our sample (Section 3) are shown and compared to the parent sample in Figure 5. The redshift distribution shows a peak near the low-redshift cutoff of the sample, with a gradual decline out to higher redshifts, in contrast to the increasing population of the parent SDSS quasar sample. This strong dependence on redshift may reflect a dependence on EW or a luminosity bias, which we discuss further below.

Figure 6 shows the distribution of the continuum \( S/N \) per pixel, where the mean values are 18.5 and 14.5 in the wavelength regions adjacent to \( \text{[Ne V] } \lambda 3426 \) and \( \text{[Ne III] } \lambda 3869 \), respectively. Compared to the parent sample, our sample shows a deficit at the low \( S/N \) regime, and a stronger tail out to higher \( S/N \) values. These distributions show that our selection is biased toward spectra of good quality, which reflect the fact that detection of double-peaked structure in \( \text{[Ne V]} \lambda 3426 \) and \( \text{[Ne III]} \lambda 3869 \) is sensitive to the \( S/N \) and generally difficult at \( S/N < 5 \). Furthermore, the larger mean value of the continuum
S/N near [Ne v] $\lambda$3426 is reflective of the fact that [Ne v] $\lambda$3426 is generally a weaker line than [Ne iii] $\lambda$3869 in AGN spectra (Osterbrock & Ferland 2006) and therefore a stronger signal is required for the detection of double-peaked structure. The dependence of our selection completeness on S/N will be addressed below.

Since this study is motivated by the identification of high-redshift analogs of AGNs with double-peaked [O iii] $\lambda$5007 lines, we compare the distribution of line properties of our sample to those of the [O iii]-selected comparison sample. The SDSS spectral resolution, S/N, and the intensity of the emission lines determine whether or not we are able to reliably detect double peaks at a given separation in velocity space. [Ne v] $\lambda$3426 and [Ne iii] $\lambda$3869 are fainter than [O iii] $\lambda$5007 in AGN spectra by a factor of $\sim$4 (Ferland & Osterbrock 1986), which means that selection based on [Ne v]/[Ne iii] will be biased toward larger line splittings relative to [O iii] $\lambda$5007. For example, double-peaked samples selected through [O iii] $\lambda$5007 have sources with line splittings down to $\sim$200 km s$^{-1}$, and the mean of the [O iii] $\lambda$5007 line splittings in the Type 1 sample of Smith et al. (2010) is $\sim$420 km s$^{-1}$. On the other hand, the mean of the [Ne v] $\lambda$3426 and [Ne iii] $\lambda$3869 line splittings of our sample is $\sim$700 and $\sim$700 km s$^{-1}$, respectively.

Figure 7 shows the distribution of velocity offsets from the systemic redshift for [Ne v] $\lambda$3426 and [Ne iii] $\lambda$3869 in both our sample and the [O iii]-selected sample. While the measurements on the comparison sample were performed in the same way as for our sample (Section 2), these sources were selected from a sample of previously determined double-peaked AGNs. Therefore, we were able to more confidently identify two peaks in [Ne v] $\lambda$3426 and [Ne iii] $\lambda$3869 at relatively smaller $\Delta V$ for the [O iii]-selected sample, as shown in Figure 7. A Kolmogorov–Smirnov (K-S) test indicates that the blue components of our sample come from a distribution different from those of the [O iii] $\lambda$5007-selected sample ($D_{[Ne v]} = 0.56$, $D_{[Ne iii]} = 0.43$, and probabilities that they come from the same distribution $P_{[Ne v]} = 3 \times 10^{-5}$, $P_{[Ne iii]} = 7 \times 10^{-5}$). A K-S test also reveals a (less significant) difference in the red components ($D_{[Ne v]} = 0.43$, $D_{[Ne iii]} = 0.33$, and probabilities of $P_{[Ne v]} = 2.3 \times 10^{-3}$, $P_{[Ne iii]} = 5.6 \times 10^{-3}$). This indicates that we are finding similar double-peaked narrow line sources to those selected through [O iii] $\lambda$5007 but that we are preferentially missing a portion of those with relatively small $\Delta V$.

4.2. Selection Completeness

To estimate what fraction of sources with double-peaked [Ne v] $\lambda$3426 and/or [Ne iii] $\lambda$3869 we are missing due to the potential selection biases discussed above, we have estimated our selection completeness through simulations. Specifically, we generated artificial spectra designed to mimic SDSS spectra in the [Ne v]/[Ne iii] wavelength ranges (a similar test was performed by Liu et al. 2010b for their [O iii]-selected sample). Using the SDSS spectral dispersion, we modeled the continuum as a power law and the emission lines as Gaussians with randomly assigned values for the parameters of EW, FWHM, continuum S/N per pixel, and line offsets from the systemic velocity. The ranges of allowed values for those parameters were made uniform and at least slightly larger than the distributions of our final sample in order to ensure that we sampled the relevant parameter space for the analysis. While the EW distribution of our sample only extended to $\sim$35 Å for the blue and red components, we allowed our simulations to have EWs of up to 50 Å for the individual lines (100 Å total EW). The simulated FWHMs ranged from 100 to 1800 km s$^{-1}$, $\sim$200 km s$^{-1}$ larger than the largest FWHM of our sample. The simulated continuum S/N values ranged from 2 to 33, just larger than the range of our sample (see Figure 6). Finally, the simulated line offsets ranged from 0 to 2000 km s$^{-1}$, $\sim$500 km s$^{-1}$ larger than the largest line offsets of our sample. We generated a total of 10,000 spectra, with 2000 of them having double-peaked emission lines, and the other 8000 having single-peaked emission lines. Out of these simulated spectra, randomly distributed, we selected a final
sample of double-peaked emission lines in the same manner as described in Section 2.

We see a positive trend between completeness and EW, and find that we are highly incomplete over the EW range of our sample. For example, we estimate a completeness of just \(~1.2\%\) for a total EW of 10 Å and \(~4.5\%\) for a total EW of 30 Å. We see a negative trend between completeness and FWHM which can be interpreted as the result of peak blending at large line widths. We see a moderate positive trend between completeness and S/N, with a completeness of \(~42\%\) at S/N = 5 and \(~50\%\) at S/N = 30. Finally, we see a strong dependence on velocity splitting, with a completeness of \(~55\%\) at \(\Delta V = 900\text{ km s}^{-1}\) and \(~34\%\) at \(\Delta V = 500\text{ km s}^{-1}\). In contrast, Liu et al. (2010b) find a completeness of \(~75\%\) at \(\Delta V = 900\text{ km s}^{-1}\) and \(~50\%\) at \(\Delta V = 500\text{ km s}^{-1}\) for their [O III] \(\lambda 5007\) sample.

Over comparable parameter ranges, we are less complete than Liu et al. (2010b) for all of the parameters (\(~50\%–80\%\) of their completeness), with the exception of FWHM, for which we have an equivalent or slightly greater completeness at the large FWHM end of their distribution (\(~900\text{ km s}^{-1}\) ). This is likely due to the fact that we allowed for a larger range of line offsets resulting in our ability to identify broader double peaks. The smaller completeness in our selection compared to those of Liu et al. (2010b) is likely due to the relatively smaller EWs of [Ne v]/[Ne IV] allowed in our simulations which is reflective of the weaker intensities compared to [O III] \(\lambda 5007\). Of the parameters investigated, we find that our completeness is most strongly dependent on and most drastically different from Liu et al. (2010b) in the velocity offsets (Figure 7). This result is again consistent with the notion that we are preferentially missing a portion of those with relatively small \(\Delta V\).

Since false double peaks are generated by noise, false positives are most likely to occur in low S/N spectra in which random noise peaks are difficult to discern from the emission line signal. However, our conservative selection criteria effectively required that the S/N be sufficiently large, as can be seen in Figure 6, with S/N-[Ne v] \(< 5\) for only four sources (3\%) and S/N-[Ne IV] \(< 5\) for only 11 sources (8\%). This is reflected in the fact that we did not select any false positives in our completeness analysis.

5. CORRELATIONS AMONG SAMPLE PROPERTIES

In the following section, we examine several trends related to the velocity offsets of the individual blue and red components from the systemic redshift and line splittings between the blue and red components. We are interested in uncovering the prevailing mechanism(s) producing the double-peaked emission lines in our sample. In particular, we investigate the following four relationships: line splitting versus line width, line splitting versus quasar Eddington ratio, [Ne v] \(\lambda 3426\) velocity offsets versus [Ne III] \(\lambda 5007\) velocity offsets, and blue/red velocity-offset ratio versus blue/red luminosity ratio. In the following analyses, we combine the [Ne v]/[Ne III] measurements of our sample with those of the [O III]-selected sample in order to increase both the sample size and the dynamic range of velocity offsets and line splittings.

5.1. A Correlation Between Line Splittings and Line Widths

In AGNs with emission lines offset from the systemic velocity, there is often an observed positive correlation between the line peak offset (blueshifts being positive offsets) and line width. For example, in samples of so-called blue outliers (AGNs with [O III] \(\lambda 5007\) lines blueshifted by \(\sim 100\text{ km s}^{-1}\)), there is an observed positive correlation between the blueshift and line width of [O III] \(\lambda 5007\) (Komossa et al. 2008). A similar trend was also seen by Liu et al. (2010b) for their sample of Type 2 double-peaked [O III] \(\lambda 5007\) sources, with the offsets being the line splitting between the two peaks. In a similar fashion, we have plotted the line splittings against the line widths (FWHM) for

![Figure 7](https://example.com/figure7.png)

**Figure 7.** Distribution of velocity offsets for double-peaked AGNs with positive velocities indicating blueshifts. “Blue” component offsets (\(\Delta V_{\text{blue}}\) and \(\Delta V_{\text{red}}\)) are shown as horizontally hatched blue lines, and “red” component offsets (\(\Delta V_{\text{red,blue}}\) and \(\Delta V_{\text{red,red}}\)) are shown as diagonally hatched red lines. The peak value in each panel has been normalized to unity. Top: sources selected through [Ne v] \(\lambda 3426\) and [Ne III] \(\lambda 3869\) emission line profiles. Bottom: distribution of velocity offsets for the [O III]-selected Type 1 AGNs from the Smith et al. (2010, S10) sample. All distributions are shown separately for [Ne v] \(\lambda 3426\) (left) and [Ne III] \(\lambda 3869\) (right). The average velocity offsets are shown for each distribution. The black solid vertical line in each panel represents zero velocity offset. (A color version of this figure is available in the online journal.)
Since the ionizing potentials of [Ne v] $\lambda$3426 and [Ne iii] $\lambda$3869 (I.P. = 41.07 and 97.16 eV, respectively) are larger than that of [O iii] $\lambda$5007 (I.P. = 35.15 eV), we might expect the correlation between line splitting and FWHM to be stronger among these emission lines. This is also expected based on the higher critical electron densities for collisional de-excitation ($n_{\text{crit}}$) of [Ne v] $\lambda$3426 and [Ne iii] $\lambda$3869 ($n_{\text{crit}}$ = $1.3 \times 10^7$ cm$^{-3}$ and $n_{\text{crit}}$ = $9.5 \times 10^6$ cm$^{-3}$, respectively) compared to [O iii] $\lambda$5007 ($n_{\text{crit}}$ = $6.8 \times 10^5$ cm$^{-3}$) since electron densities will increase toward the nuclear region. Indeed, we find that the strengths of these correlations are generally comparable to or stronger than those for [O iii] $\lambda$5007 in the sample of Liu et al. (2010b) and in the narrow line Seyfert 1 (NLS1) sample from Komossa et al. (2008). These trends in our sample might be more reflective of the even stronger trends among the subset of “blue outliers” from Komossa et al. (2008).

5.2. A Correlation Between Velocity Splitting and Eddington Ratio

Motivated by the outflow interpretation often used for samples of double-peaked emission line AGNs, we investigate the relationship between the velocity splittings and the quasar Eddington ratios ($f_{\text{Edd}} = L_{\text{bol}}/L_{\text{Edd}}$). We calculated $L_{\text{Edd}}$ using the standard derivation of the Eddington luminosity, $L_{\text{Edd}} = 4\pi cG M_\text{BH}\mu_e/\sigma_T$, where $G$ is the gravitational constant, $\mu_e$ is the mass per unit electron, and $\sigma_T$ is the Thomson scattering cross-section (Krolik 1999). $M_\text{BH}$ was estimated for each Type 1 AGN using the SMBH mass–scaling relationships from broad emission line widths and monochromatic luminosities: FWHM$_{\text{H} \beta}$ and $L_{5100\AA}$ ($z < 0.8$) or FWHM$_{\text{Mg} \text{II}}$ and $L_{3000\AA}$ ($z > 0.8$) from McLure & Dunlop (2004). The line widths are mostly from the SDSS DR7 catalog of quasar properties (Shen et al. 2011b), though we visually inspected and re-fit several of them for which we were able to improve on the models. For each AGN with an estimate of $M_\text{BH}$, we estimated $L_{\text{bol}}$ from the monochromatic luminosities $L_{5100\AA}$ ($z < 0.8$) or $L_{2000\AA}$ ($z > 0.8$) and the bolometric corrections of Richards et al. (2006).

Figure 9 shows $f_{\text{Edd}}$ plotted against three quantities: velocity splittings, blue velocity offsets, and red velocity offsets. For both [Ne v] $\lambda$3426 and [Ne iii] $\lambda$3869, a Spearman rank test reveals statistically significant correlations between $f_{\text{Edd}}$ and each of these quantities. When comparing [Ne v] $\lambda$3426 and [Ne iii] $\lambda$3869, it is apparent that the correlations are stronger for [Ne v] $\lambda$3426 than for [Ne iii] $\lambda$3869 in all correlations tested. Additionally, for both [Ne v] $\lambda$3426 and [Ne iii] $\lambda$3869 the correlations are strongest between $f_{\text{Edd}}$ and the blue velocity offsets. We note that the low velocity offsets are dominated by the [O iii]-selected sources, which simply reflects the selection bias discussed in Section 4. If the velocity splittings represent an NLR outflow in a significant number of these sources, then this result suggests that the radiation generated by the quasar accretion rate may play a crucial role in driving the line splittings. Additionally, it appears that the blue component is more strongly dominated by outflowing material than the red component, which has implications for obscuration.

5.3. Ionization Stratification

The difference in I.P. between [Ne v] $\lambda$3426 and [Ne iii] $\lambda$3869 is ~56 eV and can be used to provide insight on the gas dynamics in different regions of the NLR. Since the line offsets have been shown to correlate with the quasar Eddington

![Figure 8](image-url)
Figure 9. Plot of Eddington ratio vs. velocity splitting (top), blue component offsets (middle) and red component offsets (bottom) for [Ne v] λ 3426 (left) and [Ne iii] λ 3869 (right). See Section 5.2 for details on calculations of $f_{\text{Edd}}$. To be consistent among each subsample while accommodating the negative velocity offsets of red components, the individual velocities for each distribution have been shifted by a constant, $a$, such that the mean of that particular distribution is equivalent to 1000 km s$^{-1}$, i.e., $a = 1000 - \Delta V$. In each panel the horizontal gray, dashed line represents $\Delta V = 0$ km s$^{-1}$ for that particular distribution. Sources at 0.8 < $z$ < 1.6 ([Ne v]/[Ne iii]-selected) are plotted as filled triangles, and sources at $z < 0.8$ ([O iii]-selected) are plotted as unfilled triangles. The Spearman rank coefficients and probabilities of the null hypothesis are given for each of the subsamples and for the combined samples. The red solid lines in each distribution are the best linear fits weighted by the X and Y errors (obtained with the “FITEXY” routine) for the combined sample. (A color version of this figure is available in the online journal.)

ratios (Section 5.2), suggesting an outflowing component, we would like to search for evidence of an ionization stratification. Figures 10(a) and (b) show $\Delta V_{\text{[Ne v]}, \text{blue}}$ versus $\Delta V_{\text{[Ne iii]}, \text{blue}}$ and $\Delta V_{\text{[Ne v]}, \text{red}}$ versus $\Delta V_{\text{[Ne iii]}, \text{red}}$ for all sources in our sample and the [O iii]-selected sample for which there are detectable double peaks in both lines.

Though the true nature of the gas kinematics in NLRs is likely to be complex, under the simplest pictures of NLR ionization stratifications, it is generally not expected that lines of lower I.P. will show blue velocity offsets larger than those of greater I.P. Indeed, from Figure 10(a) it can be seen that all of the points are consistent with having equivalent blue velocity offsets in the two lines, or otherwise with a larger blue offset in [Ne v] λ 3426. This is also apparent in Figure 10(c), with a mean $\Delta V_{\text{[Ne v]}, \text{blue}} - \Delta V_{\text{[Ne iii]}, \text{blue}}$ value of 195 km s$^{-1}$. Accounting for the $\sigma$ uncertainties, from our sample 15 sources (40%) are consistent with equivalent blue velocity offsets for both [Ne v] λ 3426 and [Ne iii] λ 3869, and 23 sources (60%) have significantly larger [Ne v] λ 3426 blue velocity offsets, consistent with the presence of an ionization stratification. Comparable fractions are seen in the [O iii]-selected sample. The sources in the small velocity-offset portion of the plot are dominated by the [O iii]-selected sample, which again reflects the selection bias discussed in Section 4. In contrast, the difference in the red offsets has a narrower distribution and a mean value more consistent with $\Delta V_{\text{[Ne v]}, \text{red}} = \Delta V_{\text{[Ne iii]}, \text{red}}$ (Figures 10(b) and (d)). This suggests that the red systems are generally less stratified and have a different origin.

Also plotted are several additional double-peaked sources for which follow-up observations have been obtained, including extended and unresolved NLRs from Fu et al. (2012), dual AGNs from Fu et al. (2012) and Comerford et al. (2011), and a candidate dual AGN from Barrows et al. (2012). Note that the extended/unresolved NLRs and the dual AGNs are [O iii]-selected, and the candidate dual AGN was selected based on [Ne v] λ 3426 and [Ne iii] λ 3869. With the exception of the dual AGN SDSS J150243.1+111557, these additional sources are all consistent with no apparent ionization stratification in either the blue or the red system by the $\sigma$ criteria we have used above.

5.4. Dynamical Relation

In this section, we examine a dynamical argument, originally proposed by Wang et al. (2009), for the presence of dual AGNs in our sample. Under the simplest picture of Keplerian orbital motion, a binary system of masses should show an inverse
correlation between the ratio of their velocities, \(V_1/V_2\), and the ratio of their masses, \(M_1/M_2\), i.e., \(V_1/V_2 = M_2/M_1\). As shown in Wang et al. (2009) for their sample of double-peaked \([\text{O} \text{iii}]\) \(\lambda5007\) AGNs, the ratio of the line offsets is equivalent to the velocity ratio, and the mass ratio can be approximated by the luminosity ratio multiplied by a factor representing the ratio of the accretion rates, \(\epsilon_{1,2}\). This yields the relation \(L_b/L_r = \epsilon_{b,r} \Delta V_b/\Delta V_r\) between the blue and red components. For our sample, we have measured the requisite observational properties to perform this same analysis, but with the emission lines \([\text{Ne} \text{v}] \lambda3426\) and \([\text{Ne} \text{iii}] \lambda3869\).

Figure 10 shows \(\Delta V_b/\Delta V_r\) plotted against \(L_b/L_r\) for both \([\text{Ne} \text{v}] \lambda3426\) and \([\text{Ne} \text{iii}] \lambda3869\). The plots include both our sample and the low-redshift comparison sample. Also overplotted are the same confirmed/strong dual AGN candidates and extended/unresolved NLR AGNs shown in Figure 10 and discussed in Section 5.3. From a Spearman rank correlation test, it is clear that there is a strong positive correlation between \(\Delta V_b/\Delta V_r\) and \(L_b/L_r\), which is in the same sense as expected based on the theoretical relation of the binary, Keplerian orbit. Specifically, a strong correlation is seen individually in our sample, the comparison sample, and in the combined sample. For both \([\text{Ne} \text{v}] \lambda3426\) and \([\text{Ne} \text{iii}] \lambda3869\), the comparison sample shows slightly stronger correlations than for our sample.

As argued in Wang et al. (2009), in a major merger one might expect that the SMBHs will be in similar environments and therefore, on average, should have similar Eddington ratios (\(\epsilon_{b,r} = 1\)). Therefore, we overplotted the theoretical relation for \(\epsilon_{r,1} = 1\), which has the following form in base-10 logarithm space: \(\log_{10}[L_b/L_r] = \log_{10}[\epsilon_{b,r}] - \log_{10}[V_b/V_r]\). For both \([\text{Ne} \text{v}] \lambda3426\) and \([\text{Ne} \text{iii}] \lambda3869\) the colored/starred sources are generally consistent with the theoretical and best-fit lines, and they span a large enough dynamic range to display the same general trend as our sample. The best-fit linear relations (weighted by the X and Y errors) are \(\log_{10}[L_b/L_r] = (0.16 \pm 0.02) - (0.75 \pm 0.09) \times \log_{10}[V_b/V_r] ([\text{Ne} \text{v}] \lambda3426)\) and \(\log_{10}[L_b/L_r] = (0.05 \pm 0.02) - (0.51 \pm 0.04) \times \log_{10}[V_b/V_r] ([\text{Ne} \text{iii}] \lambda3869)\). These relations are similar to the theoretical relation for \(\epsilon_{b,r} = 1\), though they are technically not consistent when accounting for the 1σ errors, with both fits yielding shallower slopes. The shallower slopes appear to be caused by some of the sources at the low \(L_b/L_r\) end which extend out to larger \(V_b/V_r\) ratios than the rest of the sample. In this portion of the plot, our sources are systematically shifted above the theoretical relation. Finally, we have overplotted the theoretical
Figure 11. Plot of the velocity–offset ratio ($\Delta V_b/\Delta V_r$) vs. the luminosity ratio ($L_b/L_r$) shown separately for [Ne v] $\lambda$3426 (left) and [Ne iii] $\lambda$3869 (right). The solid black line is linear best-fit weighted by the $X$ and $Y$ errors found using the “FITEXY” routine. The solid red line is the theoretical relation assuming equivalent Eddington ratios for the blue and red components ($\epsilon_{1,2} = 1$), and the dashed black line is the theoretical relation for a bi-polar outflow, both of which are discussed in Section 5.4. The colored stars represent the same extended/unresolved NLRs, confirmed dual AGNs and candidate dual AGNs as in Figure 10 and have the same symbols. In each panel, the Spearman rank correlations coefficients and probabilities of no correlation are shown for our sample, this comparison sample, and the combined (“All”) sample.

(A color version of this figure is available in the online journal.)

relation expected for a biconical outflow, $L_b/L_r = (\Delta V_b/\Delta V_r)^3$ (developed in Wang et al. 2009). This relation is in the nearly the opposite sense as for the binary relation and is far from agreeing with the best-fit relations. In Section 7.2.3, we will discuss how this correlation and the offset from the theoretical relation may be consistent with the presence of both dual AGNs and outflows in our sample.

While the version of this analysis presented in Wang et al. (2009) utilized host galaxy redshifts (obtained through fitting template galaxy spectra), we cannot obtain that information for our sample since the quasar continuum outshines the galaxy starlight. Instead, the velocity offsets used in our analysis here are relative to the SDSS redshifts ($z_{SDSS}$) discussed in Section 3. However, we have attempted to investigate the dependence of our results on the choice of redshift. Recalling our discussion in Section 3, we also have redshifts based upon Mg II $\lambda$2800 which (in the single SMBH scenario) should trace the central, active SMBH redshift. Therefore, we examined $V_b/V_r$ versus $L_b/L_r$ for the subset of our sample with robust (percent error $<0.1\%$) $z_{Mg\II}$ values. We find that this does not introduce a significant change in the best-fit coefficients for [Ne v] $\lambda$3426 or [Ne iii] $\lambda$3869.

6. RADIO LOUDNESS

Since 91% (119/131) of our sources are in the FIRST footprint (5$\sigma$ flux limit of $\sim$750 mJy), to determine their radio loudness we have adopted the commonly used definition of radio to optical luminosity ratio $R = L_{5GHz}/L_{2500A}$, with $R = 10$ being the cutoff value for the radio-loud classification (Ho 2002). From our parent sample, the fraction of radio-loud SDSS quasars in the FIRST footprint is 10%, whereas that fraction is 23% in our final double-peaked [Ne v]/[Ne iii] sample. For comparison, Smith et al. (2010) obtained 9% (parent sample at $z < 0.8$) and 27% (double-peaked [O iii] $\lambda$5007 sample), respectively. This preferential selection of radio sources over the parent quasar population in both studies suggests that the origin of the double peaks might be related to the presence of radio jets in some sources, as in the case of SDSS J151709.20+335324.7 (Rosario et al. 2010).

7. INTERPRETATION

In this section, we synthesize the results of the previous sections to highlight the most likely physical scenarios that produce the line splitting and line offsets in our sample of quasars with high-ionization, double-peaked narrow emission lines. In particular, we examine the possibilities of AGN outflows and dual AGNs.

7.1. Examining the Outflow Hypothesis

The correlation between line splitting and line width evident in the blue and red systems of both [Ne v] $\lambda$3426 and [Ne iii] $\lambda$3869 (Figure 8) indicates that the mechanisms producing both the line splittings and the line broadening are related, an observation which is consistent with the two emission line components originating near the same AGNs. In general, emission line velocity offsets from the host galaxy or quasar redshift are often interpreted as evidence for outflowing photoionized gas; powerful AGNs, including quasars, are known to be capable of driving high-velocity and/or large-scale outflows (Fischer et al. 2011). We will discuss how properties of our sample are consistent with some of the mechanisms known to produce outflows, and how they result in stratified NLRs. Furthermore, we will discuss our interpretation within the context of a proposed outflow and stratification geometry shown in Figure 12.
Two of the commonly proposed mechanisms for driving outflows in powerful AGNs are radiation pressure from the accretion disk and radio jets. Figure 9 shows that the velocity outflows in powerful AGNs are radiation pressure from the central SMBH is indicated by the gray shaded regions. Various individual portions of the ISM and NLR are indicated by solid circles. Portions where \([\text{Ne}^\text{iii}]\) has compiled includes quasars with outflowing components. (A color version of this figure is available in the online journal.)

### 7.1.1. Mechanisms Producing AGN Outflows

If outflows are a common mechanism for driving line splitting in NLRs, then this should naturally result in a stratified NLR since lines of greater I.P. and \(n_{\text{crit}}\) will be preferentially produced nearer to the AGN where they are accelerated to higher velocities relative to lines of lower I.P. and \(n_{\text{crit}}\). The relative origins and velocities of emission lines in the stratification scenario are illustrated in Figure 12, where \([\text{Ne}^\text{v}]\lambda 3426\) originates closer to the SMBH than \([\text{Ne}^\text{iii}]\lambda 3869\). We examined this scenario by looking at the relationship between the velocity offsets of \([\text{Ne}^\text{v}]\lambda 3426\) and \([\text{Ne}^\text{iii}]\lambda 3869\) in Section 5.3. In that analysis, Figure 10(a) shows that 60% of the sources have a significantly larger blue velocity offset in \([\text{Ne}^\text{v}]\lambda 3426\) compared to \([\text{Ne}^\text{iii}]\lambda 3869\), suggestive of a stratified NLR. We are only seeing the projected velocity offsets, so this percentage might represent a lower limit on the number of sources with stratified NLRs when accounting for random orientations of the outflow axes. We note that in Figure 10 the largest stratifications are seen at the largest velocities. This could also be a result of projection effects, since orientations which reduce the radial velocity components will also reduce the observed stratification. However, this trend may also be due, in part, to the physical effect of stronger outflows (larger velocities) producing larger stratifications.

For most of the sources in our sample we can only place upper limits on the fluxes and velocity offsets of blue \([\text{O}^\text{iii}]\lambda 3727\) components. This is partly due to the blending of the \(\lambda 3726, 3729\ \AA\) doublet (Section 2.2). However, if the double...
emission line components are driven by outflows and the NLR is stratified, one might expect that [O \textsc{iii}] $\lambda$3727, with a relatively small ionization potential of I.P. = 13.614 eV and critical density of $n_{\text{crit}} = 3.4 \times 10^3$ cm$^{-3}$, will be strongest in a portion of the NLR relatively farther from the central AGN. As a result, it will not be accelerated to high velocities, resulting in a small line splitting.

With the outflow axis oriented at some angle intermediate to edge-on or face-on, the redshifted NLR emission will consequently be more attenuated than the blueshifted emission, as illustrated by the “obscuring ISM” labeled in Figure 12. The portions of the NLR with the largest line-of-sight velocity components will be most obscured. Conversely, the portions with the smallest line of sight velocity components will be the least obscured. The result is that, in the presence of such attenuation, the most redshifted portion of the emission lines will be observed, moving the observed position of the red emission peak closer to the systemic, i.e., non-Doppler-shifted, redshift. In this case, the red component resembles the “classical” NLR. This is consistent with observations in which offset narrow emission lines in AGNs are usually bluer of the systemic velocity, indicating that we are able to view the outflowing component moving toward the observer, while the component moving away from the observer is obscured by a larger column of dust. For example, from Figure 7 it appears that the mean magnitude of the red component velocity offsets from the systemic redshift are generally smaller than those of the blue components, consistent with the notion that the red components are less dominated by outflows.

Note that in Figure 12, with sufficient attenuation even the NLR emission which is least Doppler-shifted will be obscured, resulting an apparent blueshifting of the red component, as is occasionally seen in some of our sources and in other studies (Spoon & Holt 2009). For example, the blue [Ne \textsc{v}] $\lambda$3426 component may be emitted from a portion of the NLR on the observer’s side which is closest to the central source and moving at the greatest velocity (e.g., white dots in Figure 12), while the red [Ne \textsc{v}] $\lambda$3426 component is from a portion which is farther from the central source (e.g., gray dots in Figure 12). We did find in Section 5.2 evidence for a mild positive correlation between the red line offsets and the quasar Eddington ratio. This suggests that, while the red system tends to represent the “classical” NLR, it is still affected by the radiation pressure since it must originate close enough to the central source where the ionizing flux is sufficient. Additionally, Figures 10(b) and (c) show that there is some evidence for stratification of the red systems (though much less significant than for the blue systems).

7.2. Implications for Dual AGNs at High Redshift

It is possible that some of the sources in our sample may host two SMBHs following a galaxy merger. In this case, the double peaks may be from two distinct NLRs that each accompanies its own active SMBH, or perhaps two NLR peaks are influenced by the orbital motion of two SMBHs (Blecha et al. 2013). So far there are only a handful of known plausible merger remnants hosting two AGNs at redshifts comparable to our sample: $z \sim 0.709$ (Gerke et al. 2007), $z \sim 0.78$ (Comerford et al. 2009a), and $z \sim 1.175$ (Barrows et al. 2012). Since galaxy mergers were more frequent at higher redshifts, we would like to investigate the dual AGN scenario for the sources in our sample.

7.2.1. Sources with No Apparent Ionization Stratification

The two [O \textsc{iii}]-selected confirmed dual AGNs for which we measured double peaks in [Ne \textsc{v}] $\lambda$3426 and [Ne \textsc{iii}] $\lambda$3869 are consistent with no apparent ionization stratification (Figure 10). Additionally, there is only one candidate dual AGN identified through the double-peaked profile of [Ne \textsc{v}] $\lambda$3426 and [Ne \textsc{iii}] $\lambda$3869, and it is also consistent with no apparent ionization stratification (Barrows et al. 2012). In these sources, the evidence for outflowing NLR material is less compelling, and the line splitting may instead be produced by orbital motion of two AGNs about each other. Likewise, the 40% of our sources plotted in Figure 10 with no apparent ionization stratification may include cases where the double peaks are the result of two SMBHs following a galaxy merger. Additionally, we see explicit double [O \textsc{iii}] $\lambda$3727 peaks for a subset (11) of our sources which perhaps suggests that the outflow scenario is less likely in these sources since [O \textsc{iii}] $\lambda$3727 should originate at a greater distance from the central AGNs, as mentioned in Section 7.1.

We note, however, that the lack of an apparent ionization stratification does not preclude the possibility of an outflow, or general gas kinematic origin of the double-peaked emission lines. For example, the two extended NLR AGNs from Fu et al. (2012) have no measurable ionization stratification but the double emission components are known to be produced by the NLR around a single AGN based on integral-field spectroscopy and high-resolution imaging. Conversely, a stratified NLR (or two stratified NLRs) does not preclude the presence of two AGNs. For example, as discussed in Section 5.3, our measurement of [Ne \textsc{v}]/[Ne \textsc{iii}] $\lambda$3869 in the confirmed dual AGN SDSS J150243.1+111557 shows some evidence for a stratification.

7.2.2. Dual AGNs with Large Velocities

As is evident from Figure 7 and discussed in Section 4, the velocity splittings in our sample are generally larger than those from [O \textsc{iii}]-selected samples, which might tend to select against likely dual AGN candidates at kpc-scale separations since they would not be bound to the merging galaxy system with such large velocities. Most strong dual AGN candidates have $|\Delta V| < 500$ km s$^{-1}$: $\Delta V = 150$ km s$^{-1}$ (Comerford et al. 2009b; Civano et al. 2010), $\Delta V = 500$ km s$^{-1}$ (Xu & Komossa 2009), $\Delta V = 530$ km s$^{-1}$ (Comerford et al. 2011), and $\Delta V = 420$ km s$^{-1}$ (McGurk et al. 2011; Fu et al. 2012).

However, there are several candidates with velocities $>500$ km s$^{-1}$: $\Delta V = 630$ km s$^{-1}$ (Gerke et al. 2007) and $\Delta V = 700$ km s$^{-1}$ (Barrows et al. 2012). Additionally, the dual AGN hypothesis could be allowed for larger $\Delta V$ if the AGN pairs are at small separations. For example, Blecha et al. (2013) find in their simulations that large $\Delta V (>500$ km s$^{-1}$) are often associated with dual AGNs at sub-kpc separations during pericentric passages. For comparison, 23% of our sample have $\Delta V < 500$ km s$^{-1}$, 45% have $500 < \Delta V < 800$ km s$^{-1}$, and 32% have $\Delta V > 800$ km s$^{-1}$, with a maximum of $\Delta V = 1665$ km s$^{-1}$. Therefore, though a fraction of our sample exhibit $\Delta V$ higher than expected for dual AGNs, two-thirds fall in the range expected for either kpc or sub-kpc separation AGN pairs. We note that recent numerical simulations suggest dual activation of the SMBHs following a galaxy merger is most likely to occur at separations smaller than 1–10 kpc (Van Wassenhove et al. 2012). Therefore, under this picture of dual activation, the correlation between Eddington ratio and line splitting seen in Figure 9 would naturally emerge for a sample of dual AGNs.
As discussed in Section 3, for dual AGNs with sufficiently large orbital velocities the broad emission line profiles may be significantly broader than expected if both components are Type 1 AGNs. To test for such additional broadening, we have compared the Mg II $\lambda$2800 FWHMs with those of Fe II, but find no evidence for systematically broadened Mg II $\lambda$2800 compared to Fe II. Furthermore, a K-S test does not indicate a significant difference between the Mg II $\lambda$2800 FWHM distribution of our sample and that of the parent sample. However, we note that the mean FWHM$_{Mg\,II}$ value for our sample (4740 km s$^{-1}$) is slightly larger than that of the parent sample (4580 km s$^{-1}$) which is perhaps suggestive of additional Mg II $\lambda$2800 broadening.

7.2.3. Testing the Dynamical Argument

In Section 5.4, we tested a dynamical argument for the presence of dual AGNs in our sample. The results are generally consistent with the theoretical expectation for a binary, Keplerian orbit (Figure 11). However, to understand the extent to which we can interpret this result, we must also strongly consider the role of alternative physical scenarios in producing such a correlation.

First, we note that for both [Ne V] $\lambda$3426 and [Ne III] $\lambda$3869, based on the Spearman rank test, the comparison sample shows slightly stronger correlations than for our sample. If this is an indication that the comparison sample shows stronger evidence for dual AGNs, it would be consistent with the notion that larger velocity splittings are less likely to be associated with dual AGNs since our sample has larger velocity splittings than the comparison sample.

Second, it is worth noting that the coefficients for the best-fit linear relations of [Ne V] $\lambda$3426 and [Ne III] $\lambda$3869 are in disagreement. This is consistent with the correlation being produced by outflows (or at least some of the sources experiencing outflows) since the red component of [Ne III] $\lambda$3869 would originate at a greater distance from the observer (compared to the red [Ne V] $\lambda$3426 component) and therefore be even more obscured relative to the blue component (Figure 12). In this case, the $L_b/L_r$ ratio should be even larger for [Ne III] $\lambda$3869, making the slope shallower as observed.

However, it is possible that if our sample contains some combination of outflows and dual AGNs then the outflows are responsible for deviations from the theoretical binary relation. For example, as discussed in Section 5.4 many of the sources at the low $L_b/L_r$, high $V_b/V_r$ portion of Figure 11 are offset above the theoretical relation. These sources may be more likely to represent outflows since they are trending in the same direction as the outflow relation. Additionally, they have large $V_b/V_r$ ratios because the red component is near the systemic redshift, consistent with attenuation of the redshifted outflow component. Lastly, the $L_b/L_r$ ratios are smaller, indicating that the red component is stronger, and the blue component is a lower luminosity, extended wing as is often seen in outflows and is seen a few of our sources. If these deviant sources are most likely to be outflows, then the remainder would be more consistent with the theoretical relation. Additionally, the remainder would have an $L_b/L_r$ distribution consistent with $\epsilon_{b,r} = 1$, similar to the result of Wang et al. (2009).

We note that an additional source of scatter in the correlation could be due to stochastic accretion, such that the luminosity ratio does not accurately reflect the true mass ratio. This effect could be particularly significant when the SMBHs are at larger separations when gas is less efficiently funneled to the nuclear regions. Interestingly, at $z = 0.8$–1.6, the 3" fiber diameter of the SDSS spectrograph corresponds to $\sim$22–25 kpc, so that our sample may contain such early-stage mergers.

7.2.4. Estimating the Fraction of Dual AGNs in Our Sample

While the completeness of our selection process as discussed in Section 4 suggests that there is a significant number of double-peaked emitters that we have missed, especially at small AVs, we cannot correct for the true number since we do not know the shape of the underlying distribution. However, at the least we can use our [O III]-selected comparison sample to estimate what fraction of [O I] $\lambda$5007 double-emitted emitters that we missed based on selection through [Ne V] $\lambda$3426 or [Ne III] $\lambda$3869. Of the 57 Type 1 AGNs from Smith et al. (2010), we could reliably measure double [Ne III] $\lambda$3869 peaks for 67% (we note that this fraction is consistent with the comparison between our completeness estimates and those of Liu et al. 2010b in Section 4.2). Based on this fraction, we arrive at a corrected number of 195 double-peaked [O III] $\lambda$5007 sources and a double-peaked [O III] $\lambda$5007 AGN fraction of $\sim$0.5% at $0.8 < z < 1.6$. This fraction is likely to be a lower estimate because the double-peaked [Ne V] $\lambda$3426 and [Ne III] $\lambda$3869 lines of the [O III]-selected sample were not selected in exactly the same way (i.e., we had a prior knowledge of the double-peaked separation). Therefore, the double-peaked [O III] $\lambda$5007 AGN fraction at $0.8 < z < 1.6$ is likely to be larger, potentially making it consistent with the fraction of $\sim$1% found by Liu et al. (2010b) at $z < 0.8$.

To actually estimate the expected fraction of dual AGNs in our sample we need the true fractions of double-peaked AGNs and of dual AGNs out of all AGNs at $0.8 < z < 1.6$, neither of which are known. However, we may make several reasonable assumptions that provide a rough estimate. First, in order to determine the true fraction of double-peaked AGNs out of all AGNs at $0.8 < z < 1.6$, we need to correct for both our selection incompleteness and random projection effects. This fraction was estimated by Shen et al. (2011a) in which they determined that the fraction of detectable double-peaked [O III] $\lambda$5007 AGN is only 20% of the actual number of AGNs with double [O III] $\lambda$5007 components. Correcting our estimated double-peaked [O III] $\lambda$5007 fraction of 0.5% yields a "true" double [O III] $\lambda$5007 fraction of $\sim$2.5% at $0.8 < z < 1.6$.

The influence of inclination and phase angle for selection of dual AGNs through double-peaked emission line profiles was also investigated by Wang & Zhou (2012) in which they found that, at a phase angle of $\phi \approx 50^{\circ}$, we miss at least 50% of all AGNs with double emission components. We note that this 50% correction is a lower limit since it does not account for instrumental resolution, and that applying additional corrections based on our completeness estimates would likely make the correction estimated in this manner similar to that of Shen et al. (2011a). Finally, if we take the dual AGN fraction at $z = 1.2$ to be $\sim$0.05% (Yu et al. 2011), then we estimate the fraction of dual AGNs out of double-peaked AGNs at $0.8 < z < 1.6$ to be 2%. This fraction is several times smaller than the results of Fu et al. (2012) (4.5%–12%) and Shen et al. (2011a) ($\sim$10%) which were obtained from follow-up observations of double-peaked [O III] $\lambda$5007 AGNs. However, the difference can be attributed, at least in part, to the small expected number of dual AGNs at $z = 1.2$ estimated by Yu et al. (2011) which is due to the redshift evolution of galaxy morphology in their analysis which yields more late-type galaxies with smaller initial SMBH masses at higher redshift.
A direct test of this through follow-up observations is therefore crucial in understanding the frequency of galaxy mergers at redshifts \( z > 0.8 \) and their role in AGN triggering. For example, NIR spectroscopy will be capable of accessing the redshifted [O \textsc{iii}] \( \lambda 5007 \) emission line for sources in our sample, allowing for a direct comparison with the \( z < 0.8 \) samples of double-peaked AGNs. This was done with the \( z = 1.175 \) dual AGN candidate CXOXB142607.6+353351 in Barrows et al. (2012) which was initially selected through double-peaked [Ne \textsc{v}]/[Ne \textsc{iii}] but for which follow-up NIR spectroscopy provided access to [O \textsc{iii}] \( \lambda 5007 \). The additional spatial information of [O \textsc{iii}] \( \lambda 5007 \) provided by two-dimensional longslit spectroscopy would enable one to determine if any of these sources are strong dual AGN candidates. Follow-up high-resolution imaging, such as radio observations, would be capable of resolving the two AGN cores, if present.

8. CONCLUSIONS

We have compiled a sample of 131 quasars at \( z = 0.8–1.6 \) which show double emission line components in either of the high-ionization narrow lines [Ne \textsc{v}] \( \lambda 3426 \) and [Ne \textsc{iii}] \( \lambda 3869 \). The purpose of this search was to identify high-redshift analogs of the double-peaked [O \textsc{iii}] \( \lambda 5007 \) sources found in several previous studies. Those double-peaked [O \textsc{iii}] \( \lambda 5007 \) sources are believed to represent complex gas kinematics, large-scale outflows, or in a few cases dual AGNs. Given the increased frequency of galaxy mergers at higher redshifts and their importance in models of galaxy evolution, we have investigated these phenomena at higher redshifts using our sample, with the following conclusions.

1. There is a clear bias toward selecting double peaks with large velocity splittings. This bias was made apparent by our comparison of the velocity offsets of the blue and red components in our sample to those of [O \textsc{iii}]-selected samples, and it is corroborated by the results of our completeness simulations. This selection bias is not surprising, and it is imposed by the relatively weaker intensities of [Ne \textsc{v}] \( \lambda 3426 \) and [Ne \textsc{iii}] \( \lambda 3869 \) compared to [O \textsc{iii}] \( \lambda 5007 \).

2. We have found two results suggesting that both the blue and red systems are influenced by kinematics in the NLR. First, the line widths of both the blue and red components are strongly correlated with the line splittings, suggesting a common origin. Second, we find that the individual offsets for both the “blue” and “red” systems are positively correlated with the quasar Eddington ratio, suggesting that the SMBH accretion rate and therefore the radiation pressure is responsible for driving the line offsets in the blueward direction for both line components.

3. We find evidence suggesting that the observed kinematics are strongest in the blue systems. This is suggested because the blue systems’ have larger velocity shifts from the quasar redshift, those velocity offsets show the strongest correlations with the Eddington ratio, and the blue systems show the highest degree of ionization stratification. This further suggests that the red outflowing components are generally more obscure.

4. We have found that a significant fraction (\( \sim 23\% \)) are radio loud, compared to the 10% radio loud fraction of the parent sample.

Taken together, the previous conclusions paint a picture in which the blue systems originate in a portion of the NLR much closer to the AGN where they are accelerated by the accretion disk radiation pressure or radio jets to high velocities. This explains the large blueshifts, the stronger correlation with Eddington ratio and the pronounced ionization stratification. The red system originates further from the AGN where it is not accelerated to the high velocities of the blue system but is nevertheless close enough so its bulk velocity offset is also influenced by the AGN radiation pressure. This explains the smaller velocity offsets, the much weaker correlation with Eddington ratio, and the relatively less pronounced ionization stratification compared to the blue systems. A generalized schematic of this scenario in Figure 12. The enhanced radio loud fraction relative to the parent sample also suggests that radio jets may be another mechanism which is capable of accelerating the NLR clouds to produce the line offsets. This sample can be used to study outflows from luminous AGNs at relatively high redshifts when AGN feedback may have been an important factor in the growth of massive galaxies.

There are several interesting results which leave open the possibility for dual AGNs in the sample. In particular, several of our correlations can be thought of as consistent with the dual AGN scenario, and even suggest that the sample is likely to include dual AGNs.

1. The correlation between velocity splitting and Eddington ratio, while consistent with the picture of radiatively driven outflows, could plausibly be consistent with orbiting SMBH pairs in which enhanced accretion is more likely to occur at smaller separations where the SMBH orbital velocities will be largest.

2. We have found that a subset of our sample (40%) are consistent with no measurable ionization stratification between [Ne \textsc{v}] \( \lambda 3426 \) and [Ne \textsc{iii}] \( \lambda 3869 \), similar to other dual AGNs and strong candidate dual AGNs.

3. We have found that our sample shows a correlation between the velocity-offset ratio and the luminosity ratio of the blue and red components. This correlation is broadly consistent with the theoretical expectation for a binary, Keplerian orbit, though our sample seems to be systematically offset above the relation. We have shown how this deviation could be produced in a sample which includes a combination of AGN outflows and dual AGNs.

4. We have estimated the fraction of dual AGNs out of double-peaked AGN that we expect at \( 0.8 < z < 1.6 \), finding a fraction (2%) which is smaller than that estimated at lower redshifts. However, we caution that a significant—and perhaps the primary—reason for this lower fraction is the small estimated number of high-redshift dual AGNs that we adopt.

Follow-up NIR observations to access the [O \textsc{iii}] \( \lambda 5007 \) line in our sources would allow for a direct comparison with the [O \textsc{iii}] \( \lambda 5007 \) velocity and spatial profiles of the \( z < 0.80 \) samples, allowing for a more robust assessment of the origin of the double peaks in the high-ionization narrow emission lines. Therefore, this sample represents an initial step toward extending the study of double-peaked emission line AGNs to higher redshifts.

We thank an anonymous referee for very helpful comments that improved the quality of the paper. We acknowledge Daniel Stern for assistance on the analysis of our data and Laura Blecha for highly useful suggestions regarding the interpretation of our results. Finally, we acknowledge constructive discussion from
