Abstract

Motivated by recent results on charmed baryons from CLEO and FOCUS, we reexamine the couplings of the orbitally excited charmed baryons. Due to its proximity to the Σ_cπ threshold, the strong decays of the Λ_c(2593) are sensitive to finite width effects. This distorts the shape of the invariant mass spectrum in Λ_c(2593) → Λ_c^1 → Σ_cπ from a simple Breit-Wigner resonance, which has implications for the experimental extraction of the Λ_c(2593) mass and couplings. We perform a fit to unpublished CLEO data which gives \( M(Λ_c^+(2593)) - M(Λ_c^+) = 305.6 \pm 0.3 \) MeV and \( h_2^2 = 0.24_{-0.11}^{+0.23} \), with \( h_2 \) the \( Λ_c1 \rightarrow Σ_cπ \) strong coupling in the chiral Lagrangian. We also comment on the new orbitally excited states recently observed by CLEO.
The charmed baryon system is a convenient testing ground for the ideas and predictions of heavy quark symmetry. This is due to the rich mass spectrum and the relatively narrow widths of the resonances. The properties of these states are the subject of active experimental study at both fixed target experiments (FOCUS, SELEX, E-791) and $e^+e^-$ machines (CLEO, BaBar, Belle). For a recent review of the experimental situation, see Ref. [1].

In addition to the usual quantum numbers ($I, J^P$), the charmed baryon states can be labelled also by the spin-parity of the light degrees of freedom $f_ℓ^n$, which are good quantum numbers in the limit of an infinitely heavy charm quark. This property leads to nontrivial selection rules for the strong couplings of these states to light hadrons [2]. These predictions are automatically built into an effective Lagrangian describing the couplings of the heavy baryon states to Goldstone bosons [3].

The lowest lying charmed baryons are $L = 0$ states and live in $\mathbf{3}$ and $\mathbf{6}$ representations of flavor SU(3). It is convenient to group them together into superfields defined as in Ref. [4], a vector $T_i = \frac{1+i\sqrt{2}}{2} (\Xi^0, -\Xi_c^+, \Lambda_c^+)$, for the $\mathbf{3}$, and a tensor $S_{ij}^{\mu} = \frac{1}{\sqrt{2}} (\gamma_\mu + v_\mu) \gamma_5 B^{ij} + \bar{B}_{ij}^{\mu}$ for the $\mathbf{6}$. These superfields satisfy the constraints from heavy quark symmetry $yT = T$, $yS_{ij} = S_{ij}$ and the condition $\frac{1+i\sqrt{2}}{2} \gamma^\mu S_{ij} = 0$, which can be used to restrict the form of their Lagrangian interactions [3]. The strong couplings of the lowest lying heavy baryons are described by the effective Lagrangian containing two couplings $g_{1,2}$ [4] (we use here the normalization of Ref. [11] for these couplings)

$$\mathcal{L}_{\text{int}} = \frac{3}{2} i g_1 \varepsilon_{\mu\nu\sigma\lambda} (\bar{S}_{ik}^{\mu} v^\nu A_i^\sigma S_{jk}^\lambda) - \sqrt{3} g_2 \varepsilon_{ijk} (T_i A_j^i S_k^\mu) ,$$

where $A_\mu = \frac{i}{2} (\xi^\dagger \partial_\mu \xi - \xi \partial_\mu \xi^\dagger) = -\frac{1}{f_\pi} \partial_\mu M + \cdots$ is the usual nonlinear axial current of the Goldstone bosons, defined in terms of $\xi = \exp(i M / f_\pi)$ with $f_\pi = 132$ MeV.

In this paper we focus on the negative parity $L = 1$ orbitally excited charmed baryons. Combining the quark spins with the $L = 1$ orbital momentum gives 7 $\Lambda$-type and 7 $\Sigma$-type states without strangeness [2, 10] (see Table I). In the constituent quark model, these states fall into two distinct groups, corresponding to the symmetric and antisymmetric irreducible representations of $S_2$. The symmetric (antisymmetric) states are denoted in Table I with unprimed (primed) symbols. Quark model estimates for the masses of these states [8, 10] suggest that symmetric states are lighter than the antisymmetric ones. Although the permutation symmetry $S_2$ is not a true symmetry of QCD beyond the quark model, we will continue to refer to the higher mass charm baryon states as ‘antisymmetric’, as opposed to the lower ‘symmetric’ states. The properties of these states were studied in the quark model in Refs. [3, 10, 11, 18] and using large $N_c$ methods in [13, 14, 15].

The CLEO, ARGUS and E687 Collaborations [6] observed two negative parity charm baryons, $\Lambda_c^+ (2593)$ and $\Lambda_c^+ (2625)$. In accordance with the expectations from the constituent quark model, these states were identified with the $\Lambda_c(\frac{1}{2}, \frac{3}{2})$ states in Table I. Their average masses and widths are [7]

$$M(\Lambda_c^+(2593)) - M(\Lambda_c^+) = 308.9 \pm 0.6 \text{ MeV}, \quad \Gamma(\Lambda_c^+(2593)) = 3.6^{+2.0}_{-1.3} \text{ MeV} \quad (2)$$
$$M(\Lambda_c^+(2625)) - M(\Lambda_c^+) = 341.7 \pm 0.6 \text{ MeV}, \quad \Gamma(\Lambda_c^+(2625)) < 1.9 \text{ MeV (90% CL)}$$
| State      | $(j, J)$             | $j_{P^i}^r$ |
|------------|----------------------|-------------|
| $\Lambda_c(\frac{1}{2}, \frac{3}{2})$ | $(0, \frac{1}{2}), (0, \frac{3}{2})$ | 1$^-$     |
| $\Sigma_c(\frac{1}{2})$              | $(1, \frac{1}{2})$         | 0$^-$     |
| $\Sigma_c(\frac{1}{2}, \frac{3}{2})$ | $(1, \frac{1}{2}), (1, \frac{3}{2})$ | 1$^-$     |
| $\Sigma_c(\frac{3}{2}, \frac{3}{2})$ | $(1, \frac{3}{2}), (1, \frac{5}{2})$ | 2$^-$     |
| $\Sigma'_c(\frac{1}{2}, \frac{3}{2})$ | $(1, \frac{1}{2}), (1, \frac{3}{2})$ | 1$^-$     |
| $\Lambda'_c(\frac{1}{2})$              | $(0, \frac{1}{2})$         | 0$^-$     |
| $\Lambda'_c(\frac{1}{2}, \frac{3}{2})$ | $(0, \frac{1}{2}), (0, \frac{3}{2})$ | 1$^-$     |
| $\Lambda'_c(\frac{3}{2}, \frac{3}{2})$ | $(0, \frac{3}{2}), (0, \frac{5}{2})$ | 2$^-$     |

**Table I.** The quantum numbers of the expected $p$-wave strangeless charmed baryons. The corresponding states with strange quarks can be constructed by completing the SU(3) multiplets to which the above states belong.

Motivated by these data, the lowest lying states $\Lambda_c(\frac{1}{2}, \frac{3}{2})$ were studied in a chiral Lagrangian approach in Ref. [8], where their couplings to Goldstone bosons were first derived. These states can be grouped together into a superfield $R^i_\mu = \frac{1}{\sqrt{3}}(\gamma_\mu + v_\mu)\gamma_5 R^i + R^{(s)}_\mu$ with $R^{(s)} = (\Xi^{0}_{c1}, -\Xi^{+}_{c1}, \Lambda^{+}_{c1})$, subject to the same constraints as the superfield $S_\mu$.

At leading order in the heavy quark expansion, the pion couplings of these states to the sextet ground state baryons $S_\mu$ are given by two terms, corresponding to $S-$ and $D-$wave pion emission, respectively

$$\mathcal{L}_{int} = h_2 \epsilon_{ijk} S^j_\mu v_\nu A^\nu A^i_\mu R^k_\mu + i h_8 \epsilon_{ijk} S^j_\mu \left( D^\mu A^\nu + D^\nu A^\mu + \frac{2}{3} g^{\mu \nu} (v \cdot D)(v \cdot A) \right) R^k_\mu + h.c. \quad (3)$$

with the covariant derivative $D_\mu A_\nu = \partial_\mu A_\nu + [V_\mu, A_\nu]$ and $V_\mu = \frac{1}{2}(\xi^\dagger \partial_\mu \xi + \xi^\dagger \partial_\mu \xi^\dagger)$. This formalism was extended to the other $p-$wave charmed baryons in Table I in Refs. [11, 12], where prospects were given for their discovery. A total of 6 $S-$wave and 8 $D-$wave couplings are required for a complete description of the strong couplings of the states in Table I.

Knowledge of the pion couplings $h_2, h_8$ of the lowest orbital excitations $\Lambda_c(\frac{1}{2}, \frac{3}{2})$ will provide information about the other excited baryons, and could thus help guide the search for the missing states. For example, assuming SU(3) symmetry, the widths of the orbitally excited charm baryons containing strange quarks $\Xi'_c(\frac{1}{2}, \frac{3}{2})$ can be predicted [11, 12], with results in good agreement with the CLEO data on $\Xi'_c(\frac{1}{2})$ [16] and $\Xi'_c(\frac{3}{2})$ [17]. Furthermore, in the constituent quark model, the couplings of all unprimed states in Table I can be shown to be related to $h_2, h_8$ [11, 18]. Assuming that the masses of these states are known, these relations can be therefore used to predict the decay modes and widths of all these states. Finally, once determined in the charm system, the same couplings would also give the properties of the excited bottom baryons. Clearly, a precise determination of the two couplings $h_2, h_8$ is of great interest.

There are a few issues which complicate such a determination, following from the peculiarities of the actual mass spectrum. The states $\Lambda_c(\frac{1}{2}, \frac{3}{2})$ are observed through their 3-body decays in the $\Lambda^+_c \pi^+ \pi^-$ channel. These are resonant decays, proceeding through intermediate $\Sigma^+_c \pi$ states. The masses, and recently the widths of the $\Sigma_c$ baryons have been measured by the FOCUS [20] and CLEO [21] Collaborations. The average results of these measurements are [7]

$$M(\Sigma^+_c) - M(\Lambda^+_c) = 167.67 \pm 0.15 \text{ MeV}, \quad \Gamma(\Sigma^+_c) = (2.05^{+0.41}_{-0.38}) \pm 0.38 \text{ MeV} \quad (4)$$
\[ M(\Sigma^+_c) - M(\Lambda^+_c) = 166.4 \pm 0.4 \text{ MeV}, \quad \Gamma(\Sigma^+_c) \leq 4.6 \text{ MeV}(90\% \text{ CL}) \]
\[ M(\Sigma^0_c) - M(\Lambda^+_c) = 167.32 \pm 0.15 \text{ MeV}, \quad \Gamma(\Sigma^0_c) = (1.55^{+0.41}_{-0.37}) \pm 0.38 \text{ MeV} \]

In the heavy quark limit, the only allowed resonant channels are \( \Lambda_{c1}(\frac{3}{2}) \rightarrow [\Sigma_c\pi]_S, [\Sigma^*_c\pi]_D \), and \( \Lambda_{c1}(\frac{2}{2}) \rightarrow [\Sigma_c\pi]_D, [\Sigma^*_c\pi]_{S,D} \), where the subscript denotes the orbital angular momentum. From [2] and [4] it follows that the dominant \( S \)-wave decays of the \( \Lambda_{c1}(2593) \) proceed very close to threshold. Furthermore, the available energy in the decay is comparable or less than the width of the decaying state \( \Lambda_{c1}(2593) \)

\[ \Lambda_{c1}(2593) \sim \left[ \frac{(\Sigma^0_c(2455) + \pi^-)}{(\Sigma^+_c(2455) + \pi^+)} \right] \sim \left( \frac{2 \text{ MeV}}{1.7 \text{ MeV}} \right) \leq \Gamma(\Lambda_{c1}^+(2593)) \]  

On the other hand, the decay into the \( \Sigma^+\pi^0 \) channel takes place \( \sim 7.5 \text{ MeV} \) above threshold, such that it turns out to dominate the width of the \( \Lambda_{c1}(2593) \).

The situation with the spin-\( \frac{3}{2} \) state \( \Lambda_c(2625) \) is somewhat different. For this case, the decay is dominated by the \( D \)-wave channel \([\Sigma_c\pi]_D\), which is well above threshold \((\sim 45 \text{ MeV})\), while the \( S \)-wave accessible modes \([\Sigma^*_c\pi]_S\) lie about \( 30 \text{ MeV} \) below threshold and are thus nonresonant.

This suggests that finite width effects are important in the \( \Lambda_c(2593) \) decays. The situation is somewhat similar to \( e^+e^- \rightarrow t\bar{t} \) production close to threshold, which is mediated by a very broad toponium resonance. The net effect is a distortion of the shape of the invariant mass spectrum in \( \Lambda_{c1}(2593) \rightarrow \Lambda^+_c\pi^+\pi^- \) from a simple Breit-Wigner shape. The resulting line shape depends both on the unknown couplings \( h_{2,8} \) and on the masses and widths of the intermediate \( \Sigma_c \) states. This should be taken into account for the extraction of the mass and width of the \( \Lambda_{c1}(2593) \). The purpose of this paper is to present a detailed calculation of these effects.

Consider the amplitude for producing the \( \Lambda_{c1} \) resonance, followed by its decay to a 3-body state \( \Lambda_{c1}^+ \rightarrow \Lambda_c^+\pi\pi \), of total momentum \( p_\mu = M_{\Lambda_c^+}v_\mu + k_\mu \) and invariant mass \( M(\Lambda_c^+\pi\pi) = \sqrt{p^2(\Lambda_c^+\pi\pi)} \). This is written in the factorized form

\[ A(i \rightarrow \Lambda_{c1}X \rightarrow \Lambda_c^+\pi\pi X) = \frac{i}{\Delta - \Delta_{\Lambda_c^+} + i\Gamma_{\Lambda_{c1}}(\Delta)/2} \left[ U(\Delta) \frac{1 + \gamma}{2} V(\Delta, X) \right], \]  

where \( \Delta = v \cdot k = M(\Lambda_c^+\pi\pi) - M(\Lambda_c^+) \) is the residual energy of the propagating resonance \( \Lambda_c(2593) \) and \( \Delta_{\Lambda_c} = M(\Lambda_{c1}) - M(\Lambda_c^+) \). \( U_\alpha(\Delta) \) and \( V_\alpha(\Delta, X) \) are spinor amplitudes parameterizing the decay \( \Lambda_{c1}^+ \rightarrow \Lambda_c^+\pi\pi \) and its production, respectively. \( U_\alpha(\Delta) \) depends on the momenta and spins of the \( \Lambda_c^+\pi\pi \) state, and is calculable in heavy hadron chiral perturbation theory for values of the residual energy \( \Delta \ll 1 \text{ GeV} \). On the other hand, not much is known about the production spinor \( V_\alpha(\Delta, X) \), which depends on all the details of the production process.

Squaring the amplitude [6], adding the phase space factors and summing over the unobserved states \( X \), one finds the following expression for the \( \Lambda_c^+\pi\pi \) production cross-section as a function of the invariant mass \( \Delta \):

\[ \frac{d\sigma(\Delta)}{d\Delta} \sim \frac{1}{(\Delta - \Delta_{\Lambda_{c1}})^2 + \Gamma_{\Lambda_{c1}}(\Delta)^2/4} \left[ \frac{U(\Delta)}{2} \omega(\Delta) \frac{1 + \gamma}{2} U(\Delta) \right] d\text{Lips}(\Lambda_{c1} \rightarrow \Lambda_c^+\pi\pi) \]

We have introduced here the density matrix \( \omega_{\alpha\beta}(\Delta) \) parameterizing the production of a \( \Lambda_{c1} \) resonance in the process \( i \rightarrow \Lambda_{c1}X \)

\[ \omega_{\alpha\beta}(\Delta) \equiv \sum_X d\mu(X) V_\alpha(\Delta, X) \bar{V}_\beta(\Delta, X)(2\pi)^4 \delta(p_i - p_X - p_{\Lambda_{c1}}) \]  

4
The matrix \( \omega \) depends on the resonance momentum \( p_{\Lambda c} \) and details of the experimental setup such as the total beam momentum and polarization. Fortunately, the spin structure of the matrix \( \omega \) is not required if one sums over the spins and momenta of the final decay products in \( \Lambda_{c1}^+ \rightarrow \Lambda_c^+ \pi^+ \pi^- \). If this is done, the amplitudes in Eq. (7) can be written as

\[
\sum_{s_{\Lambda c}} \int d\text{Lips}(\Lambda_{c1} \rightarrow \Lambda_c^+ \pi^+ \pi^-) U_{\alpha}(\Delta) \bar{U}_\beta(\Delta) = \left( \frac{1 + \gamma}{2} \right)_{\alpha\beta} \Gamma(\Lambda_{c1}^+ \rightarrow \Lambda_c^+ \pi^+ \pi^-) \tag{9}
\]

Inserting this into (7) one finds that the production cross section as a function of invariant mass \( \Delta + \Sigma + M \) can be expected to introduce a slow variation with a characteristic scale \( \varepsilon \). This can be neglected when compared with the much faster variation of the denominator. The width \( \Gamma(\Delta) \) is given by

\[
\Gamma(\Lambda_{c1}^+ \rightarrow \Lambda_c^+ \pi^+ \pi^-) = \frac{g_2^2}{16\pi^3 f^4} M_{\Lambda_c^+} \int dE_1 dE_2 \left\{ \bar{p}_2 |A(E_1, E_2)|^2 + \bar{p}_1 |B(E_1, E_2)|^2 + 2\bar{p}_1 \cdot \bar{p}_2 \text{Re} [A(E_1, E_2)B^*(E_1, E_2)] \right\} \tag{10}
\]

where \( E_1, E_2 \) are the pion energies in the rest frame of the \( \Lambda_{c1} \) resonance and we have defined

\[
A(E_1, E_2) = \frac{h_2 E_1}{\Delta - \Delta \Sigma_0 - \bar{E}_1 + i\Gamma_{\Sigma_0}/2} \\
+ h_8 \left( \frac{2\bar{p}_1^2}{\Delta - \Delta \Sigma_0 - \bar{E}_1 + i\Gamma_{\Sigma_0}/2} + \frac{2\bar{p}_1 \cdot \bar{p}_2}{\Delta - \Delta \Sigma_0^+ - \bar{E}_2 + i\Gamma_{\Sigma_0^+}/2} \right) \\
B(E_1, E_2; \Delta \Sigma_0^{(\ast)} + \Delta \Sigma_0^{(\ast)0}) = A(E_2, E_1; \Delta \Sigma_0^{(\ast)+} + \Delta \Sigma_0^{(\ast)0}) \tag{11}
\]

The decay rate \( \Gamma(\Lambda_{c1}^+ \rightarrow \Lambda_c^+ \pi^0 \pi^0) \) is given by a similar relation, with an additional factor of 1/2 to account for the identical pions in the final state, and with the replacements \( \Delta \Sigma_0^{(\ast)+}, \Delta \Sigma_0^{(\ast)0} \rightarrow \Delta \Sigma_0^{(\ast)+} \).

In these expressions we work at leading order in the \( 1/m_c \) expansion in matrix elements, but use the exact 3-body phase space. This procedure includes formally subleading contributions in the \( 1/m_c \) expansion, which are however enhanced by kinematics and are required for reproducing the data in other similar situations \[19\]. We neglect the radiative decay channel \( \Lambda_{c1}^+ \rightarrow \Lambda_c^+ \gamma \), which is expected to contribute about 20 keV to the total width \[13\].

After integration over the Dalitz plot, the decay width (11) can be written as

\[
\Gamma_{+-}(\Delta) = g_2^2 \left\{ h_2^2 a_{+-}(\Delta) + h_8^2 b_{+-}(\Delta) + 2h_2 h_8 c_{+-}(\Delta) \right\} . \tag{14}
\]

A similar result is obtained for the rate into \( \Lambda_c^+ \pi^0 \pi^0 \) with coefficients \( a_{00}, b_{00}, c_{00} \). The coupling \( g_2 \) appears here both explicitly, and implicitly through the \( \Sigma_0^{(\ast)} \) widths in the denominators of \( A(E_1, E_2) \) and \( B(E_1, E_2) \). These are given by

\[
\Gamma(\Sigma_0^{(\ast)}) = \frac{g_2^2}{2\pi f^2} \frac{M_{\Lambda_c}}{M_{\Sigma_0^{(\ast)}}} |\bar{p}_\pi|^3 . \tag{15}
\]
On the other hand, the threshold in the neutral pion channel lies lower, at \( \Delta = 301 \) MeV, the rate rises much faster, which explains the ‘kink’ seen in Fig. 1(a) in the \( g_2^\pi \) channel. Since the central value of the \( \Lambda_c \) mass lies around 307 MeV, the rapid variation of the \( \Lambda_c \) partial widths [12] is the pion momentum in \( \Lambda_c \) decays. Neglecting isospin violation in the

\[
\langle \Lambda_c^+ \rightarrow \Lambda_c^+ \pi^+ \pi^- \rangle = \Gamma(\Lambda_c^+ \rightarrow \Sigma_c^0 \pi^+) + \Gamma(\Lambda_c^+ \rightarrow \Sigma_c^{++} \pi^-) = a(\pi^+)|\vec{p}_\pi| \quad (16)
\]

\[
\Gamma_{NW}(\Lambda_c^+ \rightarrow \Lambda_c^+ \pi^0 \pi^0) = \Gamma(\Lambda_c^+ \rightarrow \Sigma_c^0 \pi^0) = a(\pi^0)|\vec{p}_\pi| \quad (17)
\]

where \( \vec{p}_\pi \) is the pion momentum in \( \Lambda_c \rightarrow \Sigma_c \pi \) decays. Neglecting isospin violation in the

Using the observed masses this gives \( \Gamma(\Sigma_c^{++,++;0}) = \{6.15, 7.06, 6.01\} g_2^\pi \) MeV, and \( \Gamma(\Sigma_c^{+++,++;0*}) = \{47.9, 47.4, 46.3\} g_2^\pi \) MeV. The extracted values for \( g_2 \) from the \( \Sigma_c \) and \( \Sigma_c^* \) experimental widths are somewhat different: \( \langle g_2^\pi \rangle_{\Sigma_c} = 0.25 \pm 0.17 \) and \( \langle g_2^\pi \rangle_{\Sigma_c^*} = 0.33 \pm 0.15 \), which can be attributed to an \( 1/m_c \) effect. Although the uncertainty in this coupling is rather large, \( g_2^\pi = 0.29 \pm 0.23 \), the resulting effect on our predictions [14] is very small, because they are very close to the narrow-width case for the \( \Sigma_c \) (see the discussion around Eqs. [16], [17]).

Our main interest here is in the functional dependence of \( a_{+-,00}(\Delta) \), which dominate numerically the rates \( \Gamma_{+-,00} \). These coefficients are plotted in Fig. 1(a) as functions of \( \Delta \); the qualitative features of these curves can be understood without a detailed computation, as follows. The coefficients \( a(\Delta) \) give the partial widths into the \( [\Sigma_c^+ \pi^-]_S \) channel, which start at threshold \( \Delta = 2M(\pi^+) \), and rise slowly up to the threshold for production of \( [\Sigma_c^0 \pi^+]_S \) and \( [\Sigma_c^{++} \pi^-]_S \) at \( \Delta = 306.9 \) MeV and \( \Delta = 307.2 \) MeV, respectively. Above this threshold, the rate rises much faster, which explains the ‘kink’ seen in Fig. 1(a) in the \( \pi^+ \pi^- \) channel. On the other hand, the threshold in the neutral pion channel lies lower, at \( \Delta = 301.4 \) MeV, corresponding to the opening of the \( [\Sigma_c^+ \pi^0]_S \) channel. Since the central value of the \( \Lambda_c \) mass lies around 307 MeV, the rapid variation of \( a_{+-}(\Delta) \) in this region will likely affect the extraction of \( \Delta_{\Lambda c1} \).

It is instructive to compare these results with those obtained in the narrow width approximation, where the mass-dependent partial widths in [11] are approximated with 2-body widths [12].
The invariant mass spectrum in $\Lambda_c^+(2593) \rightarrow \Lambda_c^+ \pi^+ \pi^-$ as explained in the text.

In the limit $g_2 \to 0$, the exact result (11) reduces to the narrow width approximation in Eqs. (16) and (17), that is $\Gamma \rightarrow \Gamma_{NW}$. As one can see from Fig. 1(a), the narrow width results give a good approximation to the exact widths (computed with $g_2^2 = 0.34$), for $\Delta$ not too close to threshold.

In Fig. 1(b) we show invariant mass distributions $\Delta = M(\Lambda_c^+ \pi \pi) - M(\Lambda_c^0)$ in $\Lambda_c^+(2593)$ decays, in both charged and neutral pions channels. The shape of the invariant mass distribution in the charged pions channel $\Lambda_c^+ \pi^+ \pi^-$ is distorted towards larger values of $\Delta$ compared to a simple Breit-Wigner curve. In particular, extractions of the $\Lambda_c^+(2593)$ parameters from the charged pions channel alone could overestimate the mass of this resonance by a few MeV, which is larger than the present $1\sigma$ uncertainty $\langle 2 \rangle$ on this parameter. These effects are not present in the neutral pions channel, for which the shape of the mass spectrum comes closer to a pure Breit-Wigner resonance.

The first observation of the $\Lambda_c^+ \pi^0 \pi^0$ mode has been presented in unpublished CLEO data $\langle 22 \rangle$, where the corresponding invariant mass distribution was used to extract the mass of the $\Lambda_c^+(2593)$. The result is lower than that obtained from the $\Lambda_c^+ \pi^+ \pi^-$ channel $\langle 2 \rangle$, in agreement with our expectations,

$$[M(\Lambda_c^+(2593)) - M(\Lambda_c^0)]_{\Lambda_c^+ \pi^0 \pi^0} = 306.3 \pm 0.7 \text{ MeV}.$$  (19)
Experimental difficulties connected with the low $\pi^0$ detection efficiency could limit the precision of such a determination. We propose therefore that the shape of the $\Lambda^+_c\pi^+\pi^-$ invariant mass spectrum be fit to the distribution \cite{11} with parameters $(\Delta_{\Lambda c}, h_2)$ (instead of a Breit-Wigner curve with parameters $(\Delta_{\Lambda c}, \Gamma)$).

In Fig. 2 we show the results of such a fit, performed using the CLEO data presented in \cite{22} (see Fig. 5.5 in this reference), including detector resolution effects. The parameters of the $\Lambda_c(2593)$ resonance extracted from this fit are \cite{21}

$$M(\Lambda_c^+(2593)) - M(\Lambda_c^+) = 305.6 \pm 0.3 \text{ MeV}, \quad h_2^2 = 0.24^{+0.23}_{-0.11},$$

and correspond to a resonance mass in reasonably good agreement with \cite{19}. A conventional fit of this same data using a Breit-Wigner function, yields a mass difference of around 308 MeV, in agreement with the published measurements \cite{6}. Note that the threshold effects effectively lower the resonance mass \cite{20} compared with the previous determinations \cite{2}. Our treatment also leads to a reduction in the uncertainties connected with the poorly measured $\Sigma_c$ widths. The result for the coupling $h_2^2$ is somewhat lower than previous determinations of this coupling \cite{12} ($h_2^2 = 0.30^{+0.21}_{-0.14}$) and \cite{11} ($h_2^2 = 0.33^{+0.20}_{-0.13}$).

Finally, we comment on the recent evidence by the CLEO Collaboration \cite{23} for new charmed baryon states, lying above the $\Lambda_c(2593)$ and $\Lambda_c(2625)$. The lower signal $X_1$ is relatively broad, while the higher peak $X_2$ is narrow, with masses and widths

$$M(X_1) - M(\Lambda_c^+) = 480.1 \pm 2.4 \text{ MeV}, \quad \Gamma(X_1) = 20.9 \pm 2.6 \text{ MeV} \quad (21)$$

$$M(X_2) - M(\Lambda_c^+) = 595.8 \pm 0.8 \text{ MeV}, \quad \Gamma(X_2) = 4.2 \pm 0.7 \text{ MeV} \quad (21)$$

The higher narrow peak $X_2$ has been identified in \cite{23} with the antisymmetric state $\Lambda'_c(\frac{1}{2}+)$, while the lower broad peak $X_1$ has been interpreted as the overlap of the peaks corresponding to the two $\Sigma_c(\frac{3}{2}^-, \frac{8}{2}^-)$ states in Table I, which can both decay to $[\Lambda_c^+\pi]_D$ and $[\Sigma_c^*\pi]_D$. In the heavy quark limit, the $\Lambda'_c(\frac{1}{2}+)$ does not decay to any of the lower lying charmed baryons. The only such mode allowed by isospin and heavy quark symmetry is to $\Xi_c K$, which is however kinematically forbidden. According to the interpretation of \cite{23}, it can lie in the $\Sigma_c\pi$ channel through its mixing with the $\Lambda'_c(\frac{1}{2}+)$ at subleading order in $1/m_c$. This is consistent with the experimental observation of $\Sigma_c\pi$ resonant substructure (which is accessible in $\Lambda'_c(\frac{1}{2}+) \to [\Sigma_c\pi]_S$), but not of $\Sigma_c^*\pi$, which can only proceed through $D-$wave $\Lambda'_c(\frac{1}{2}+) \to [\Sigma_c^*\pi]_D$ and is therefore expected to be suppressed.

The mass measurement \cite{21} of the $X_2$ state shows that it lies above the threshold for $[ND]$ ($\Delta = 524$ MeV for $nD^+$ and $\Delta = 518$ MeV for $pD^0$). Both the $\Lambda'_c(\frac{1}{2}+)$ and $\Lambda'_c(\frac{1}{2})$ can decay to this mode in an orbital $S-$wave in the heavy quark limit (which would give thus the dominant decay mode in the absence of $1/m_c$ effects). Therefore we would like to suggest that one search for the $X_2$ state also in the $ND$ channel, where it should show up as well. Observing such a signal would definitely rule out alternative interpretations of this state as $\Sigma_c(\frac{3}{2}^-, \frac{8}{2}^-)$ or $\Lambda'_c(\frac{3}{2}^+)\Lambda'_c(\frac{3}{2}^+, \frac{8}{2}^-)$, which can decay to $ND$ only in $D-$wave.

In conclusion, we have discussed in this paper the impact of threshold effects on the determination of the $\Lambda_c^+(2593)$ parameters from its strong decays into $\Lambda_c^+\pi\pi$, and we have presented theory motivated fits of the mass and couplings of this state. Our results suggest that the excitation energy of the $\Lambda_c^+(2593)$ is about 2-3 MeV lower than obtained in previous determinations.

\[24\] The data shown in Fig. 2 was obtained in Ref. \textit{22} by adding the measured mass difference to a fixed $\Lambda_c^+$ mass of 2286.7 MeV. Thus, for consistency, we subtracted this value from our fitted mass to obtain the result \textit{20}.
