Abstract

The finite Dirichlet series from the title are defined by the condition that they vanish at as many initial zeroes of the zeta function as possible. It turned out that such series can produce extremely good approximations to the values of Riemann’s zeta function inside the critical strip. In addition, the coefficients of these series have remarkable number-theoretical properties discovered in large scale high accuracy numerical experiments.

So far no theoretical explanation to the observed phenomena was found.

1 Introduction

One of the most important open problems in Number Theory is the famous Riemann Hypothesis stated in [Riemann 1859]. At the turn of the century, it was included by David Hilbert as part of his 8th problem, one among 23 most important, in his opinion, problems [Hilbert 1900] left open for the coming 20th century. The Riemann Hypothesis resisted all numerous attempts to (dis)proof it and was recognized by the Clay Institute as one of the 7 Millennium problems [Clay].

The Riemann Hypothesis, RH for short, is a statement about complex zeroes of Riemann’s zeta function. This function can be defined via Dirichlet series

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}. \quad (1)$$

This series converges only for Re($s$) > 1 but the function can be analytically continued to the whole complex plane with the exception of the point $s = 1$ which is its only pole.

The zeta function for real $s$ was studied already by Leonhard Euler. In particular, he gave in [Euler 1737] another definition of the function via a product, namely,

$$\sum_{n=1}^{\infty} \frac{1}{n^s} = \prod_{p \text{ prime}} \left(1 + \frac{1}{p^s} + \frac{1}{p^{2s}} + \ldots\right). \quad (2)$$
This equality can be viewed as an analytic form of the Fundamental Theorem of Arithmetic stating that
every natural number has a unique factorization into the product of powers of primes—just expand the
right hand side in \((2)\) and get its left hand side.

The fact that *Euler product*, the right hand side of \((2)\), is taken over prime numbers, explains the
role played by the zeta function in the study of these numbers. In particular, Euler proved anew the
infinitude of prime numbers, and the beauty of his proof can rival that of the original proof given by
Euclid: *if the number of primes were finite, then for \(s = 1\) the divergent harmonic series, that is, the left
hand side of \((2)\), would have finite value equal to the right hand side of \((2)\).*

Bernhard Riemann went further, he showed that the zeta function can be used for the study of the
growth of the *prime counting function* \(\pi(x)\) equal to the number of primes not exceeding \(x\). This is a
step function having a jump of size 1 at each prime number.

In a more transparent way the relationship between the zeroes of the zeta function and distribution
of prime numbers can be be expressed in terms of another step function, \(\psi(x)\), defined by Pafnutij
Chebyshev in [Chebyshev 1852] as

\[
\psi(x) = \ln(\text{LCM}(1, 2, \ldots, [x])).
\]

Similar to \(\pi(x)\), this function also has a jump at each prime \(p\) but now of increasing size \(\ln(p)\), and
besides it has a jump of the same size at every power of \(p\) as well. Hans Carl Friedrich von Mangoldt
[Mangoldt 1895] proved that for non-integer \(x\) greater than 1

\[
\psi(x) = x - \sum_{\zeta(\rho) = 0} \frac{x^\rho}{\rho} - \ln(2\pi).
\]

According to \((4)\), the growth of the difference \(\psi(x) - x\) depends on the real parts of the zeros of the
zeta function. Already Euler knew that this function vanishes at negative even integers, and they are
nowadays called the *trivial zeroes*. Riemann proved that they are the only real zeroes of the zeta function
and that all other, *non-trivial zeroes* lie inside the so-called *critical strip* \(0 \leq \Re(s) \leq 1\).

Riemann’s Hypothesis predicts that in fact the non-trivial zeroes lie on the *critical line* \(\Re(s) = \frac{1}{2}\). In
terms of Chebyshev’s function RH can be restated as

\[
\psi(x) = x + O(x^{\frac{1}{2}} \ln^2(x))
\]

and in terms of the function \(\pi(x)\) as

\[
\pi(x) = \int_1^x \frac{dt}{\ln(t)} + O(x^{\frac{1}{2}} \ln(x)).
\]

Many researchers verified the validity of RH for initial zeroes of the zeta function via finite computa-
tions giving, nevertheless mathematically rigourously, the exact value \(\frac{1}{2}\) for their real parts. The last
achievement reported in [Gourdon 2004] tells that this is so for impressive \(10^{13}\) initial (pairs of conjugate)
zeroes of the zeta function.

Numerical studies of the zeta function are valuable from the perspective of discovering interesting
patterns in its behaviour, providing preliminary evidence for undiscovered phenomena, and formulating
hypotheses that are not obvious from the analytic formulas. In this article we followed such an approach,
by studying numerically various quantities related to approximation the zeta function by finite Dirichlet
series.

The simplest form of such series is just the truncation

\[
\zeta_N(s) = \sum_{n=1}^{N} n^{-s}.
\]

Paul Turán [Turan 1948] established that for proving the Riemann Hypothesis it would be sufficient to show that

\[
\sup\{\Re(s) : \zeta_N(s) = 0\} = 1 + O(N^{-\frac{1}{2}}).
\]

However, Hugh Lowell Montgomery [Montgomery 1983] proved that in fact

\[
\sup\{\Re(s) : \zeta_N(s) = 0\} = 1 + \Omega\left(\frac{\ln \ln(N)}{\ln(N)}\right),
\]

2
which implies that (8) does not hold, and hence one cannot prove RH in that way.

Partial sums of Riemann’s zeta-function were also studied by Michel Balazard and Oswaldo Velásquez Castaño in [Balazard et al 2009], by Peter Borwein, Greg Fee, Ron Ferguson, and Alexa Van Der Waal in [Borwein et al 2007], by Steven M. Gonek and Andrew H. Ledoan in [GonekLedoan 2010], by Norman Levinson in [Levinson 1973], by Robert Spira in [Spira 1966, Spira 1968, Spira 1972], and by Sergej Voronin in [Voronin 1974].

In this article we report on numerical studies of coefficients of finite Dirichlet series that are constructed not by truncating the infinite series (1) but on the basis of a few initial non-trivial zeroes of the zeta function. Firstly, we found that such finite Dirichlet series approximate well many of the subsequent non-trivial zeroes and a number of initial trivial zeroes. This finding (originally observed for a slightly different approximation in [Matiyasevich 2012]) was quite unexpected.

Secondly, numerical experiments with very high accuracy revealed that these coefficients have very rich fine structure related to prime numbers.

The article is structured as follows. In Section 2 we introduce our objects of study. Section 3 describes the initial findings. Section 4 is devoted to technical details of performing the calculations. In Sections 5–6 we discussed numerically observed phenomena. In Section 7 we briefly present some similar experiments and our plans for new calculations. In Section 8 we summarize our discoveries.

2 Our objects for examination

We are to approximate the zeta function by finite Dirichlet series having the form

$$\Delta_N(s) = \sum_{n=1}^{N} \delta_{N,n} n^{-s}$$  \hspace{1cm} (10)

with some weight coefficients $\delta_{N,n}$. These coefficients will be selected in such a way that the finite series (10) and (the function defined by) infinite series (1) would have $N-1$ common zeroes.

The non-trivial zeroes come in conjugate pairs:

$$\cdots = \zeta(\rho_3) = \zeta(\rho_2) = \zeta(\rho_1) = 0 = \zeta(\rho_1) = \zeta(\rho_2) = \zeta(\rho_3) = \cdots$$  \hspace{1cm} (11)

Assuming that they are simple and satisfy RH, we write

$$\rho_n = \frac{1}{2} + i\gamma_n$$  \hspace{1cm} (12)

with

$$0 < \gamma_1 < \gamma_2 < \gamma_3 \ldots$$  \hspace{1cm} (13)

We will always take for $N$ an odd number, $N = 2M + 1$, put $\delta_{N,1} = 1$ and determine the remaining coefficients in (10) by the condition

$$\Delta_N \left( \frac{1}{2} \pm i\gamma_k \right) = 0, \quad k = 1, \ldots, M.$$  \hspace{1cm} (14)

This condition gives explicit expressions for the coefficients in (10), namely,

$$\delta_{N,n} = \frac{\hat{\delta}_{N,n}}{\delta_{N,1}},$$  \hspace{1cm} (15)

where

$$\hat{\delta}_{N,n} = (-1)^{n+1} \times

\begin{array}{ccccccc}
1 & 1 & \cdots & 1 & 1 \\
\vdots & \vdots & \ddots & \vdots & \vdots \\
(n-1)^{-\rho_1} & (n-1)^{-\rho_2} & \cdots & (n-1)^{-\rho_M} & (n-1)^{-\rho_M} \\
(n+1)^{-\rho_1} & (n+1)^{-\rho_2} & \cdots & (n+1)^{-\rho_M} & (n+1)^{-\rho_M} \\
\vdots & \vdots & \ddots & \vdots & \vdots \\
N^{-\rho_1} & N^{-\rho_2} & \cdots & N^{-\rho_M} & N^{-\rho_M}
\end{array}$$  \hspace{1cm} (16)
3 First observations

Our interest was to examine numerical values of the determinants (16). Originally, it was guessed that with the growth of $N$ the coefficients $\delta_{N,n}$ (defined by (15)) will approach the coefficients from (1), that is, for a fixed $n$

$$\delta_{N,n} \rightarrow 1 \quad \text{as} \quad N \rightarrow \infty. \quad (17)$$

This guess was based on an expected analogy with the Taylor series. Namely, if

$$1 + \sum_{n=1}^{\infty} a_n z^n = \prod_{k=1}^{\infty} \left(1 - \frac{z}{z_k}\right) \quad (18)$$

and

$$1 + \sum_{n=1}^{N} a_{N,n} z^n = \prod_{k=1}^{N} \left(1 - \frac{z}{z_k}\right) \quad (19)$$

then for a fixed $n$

$$a_{N,n} \rightarrow a_n \quad (20)$$

![Figure 1: Coefficients $\delta_{17,n}$](image)

Initial calculations seemed to support (17) – see Figure 1. This figure justifies our writing

$$\Delta_{17}(s) = \sum_{n=1}^{17} \delta_{17,n} n^{-s} \approx \sum_{n=1}^{\infty} n^{-s} = \zeta(s) \quad (21)$$

with the ideograph $\approx$ having here and in the sequel a very weak sense: a few initial coefficients of the two Dirichlet series are approximately equal.

It turned out that $\Delta_{17}(s)$ gives a rather good approximation to $\zeta(s)$ on the critical line, see Figures 2–3.

In particular, $\Delta_{17}(s)$ has zeroes close to a few zeta zeroes following zeroes $\rho_1, \ldots, \rho_8$ used for constructing this finite Dirichlet series, see Table 1. Nothing similar can happen for Taylor series – clearly, the finite product in (19) contains no information about the subsequent zeroes $z_{N+1}, z_{N+2}, \ldots$

The closeness of the values of $\Delta_{17}(s)$ and its zeroes to the values of $\zeta(s)$ and its zeroes is surprising for two reasons:

- the meaning of the relation $\approx$ in (21) is very week;
- the infinite series in (21) diverges on the critical line.
4 Numerical strategies and pitfalls

The initial observations prompted more thorough numerical studies of the determinants (16) in order to understand better their behaviour for larger $N$. While experimental numerical values can certainly point to some interesting patterns, inaccurate experimental results can become false leads, that are due solely to numerical artifacts. For this reason we aimed at providing numerical evidence at a very high precision level, ideally with tight error bounds, as to minimise the likelihood of false leads.

We were aware that calculation of the determinants (16) could lead to losses of accuracy, and decided to perform calculations with very high precision of over ten thousand decimal places. Such an accuracy was achieved by using multiprecision arithmetic, implemented in such packages as GMP [GMP], Arprec [Bailey 2013] and Arb [Johansson 2013]. This accuracy allowed us to separate numerical artifacts due to the loss of precision in numerical calculations from some interesting phenomena reported in the subsequent sections.

Let us describe our computational settings. The values $\delta_{N,n}$ were computed from $\gamma_1, \ldots, \gamma_M$ by calculating a sequence of determinants ($N = 1, 2, 3, \ldots, 12000$) of a matrix with entries $a_{ij} = i^{-\rho_k}$ for even $j = 2k$ and $a_{ij} = i^{-\bar{\rho}_k}$ for odd $j = 2k - 1$. The determinants were computed by using a variant of Gauss elimination as reported in [BeliakovMatiyasevich 2013], in multiprecision arithmetics, using ten thousand decimal places accuracy. The values of $\gamma_k$ were precomputed with twenty thousand decimal places by the authors using Newton-based root finding routine by Fredrik Johansson in his new system Arb [Johansson 2013].

These values are available at [MatiyasevichBeliakov 2013] and more accurate values are at [BeliakovMatiyasevich 2013a]. The library GMP [GMP] was used for multiprecision arithmetics, and computations were performed in parallel on an MPI-based cluster involving 168 processes and 400 GB
Such behaviour is “typical” for $N > 100$ in the next Section.

We detail these observations that explains why the values of $N$ appear irregularities would disappear for large $N$, and, respectively, for large $N$.

$2 + 1$ and $−1$ have shown very rich fine structure at the precision level between $10^{−1000}$ and $10^{−10000}$, the structure that unexpectedly revealed prime numbers! The patterns revealed are so remarkable and regular that we are convinced they could not be due to numerical artifacts. We detail these observations in the next Section.

High accuracy calculations for larger $N$ revealed that most likely the guess (17) was wrong, and this explains why the values of $\Delta_N(s)$ aren’t close to $\zeta(s)$ any longer. Figure 4 exhibits coefficients $\delta_{101,n}$. Such behaviour is “typical” for $N > 100$, however, every now and then a kind of “Gibbs phenomenon” occurred as illustrated on Figure 5 or even more bizarre behaviour as on Figure 6 presumably, such irregularities would disappear for $N$ big enough.

A catalog of $\delta_{N,n}$ for many values of $N$ can be found in [Matiyasevich]. Its content suggests that (17) should be replaced by

$$\delta_{N,n} \underset{N \to \infty}{\to} (-1)^{n+1}$$

and, respectively, for large $N$.

$$\Delta_N(s) = \sum_{n=1}^{N} \delta_{N,n} n^{-s} \approx \sum_{n=1}^{\infty} (-1)^{n+1} n^{-s} = \eta(s)$$

Table 1: Zeroes of $\Delta_{17}(s)$ nearby zeros of $\zeta(s)$

| $s$ | $\Delta_{17}(s)$ |
|-----|------------------|
| 0   | $\Delta_{17}(\rho_9 - 4.396 \ldots - 10^{-3} + 5.711 \ldots - 10^{-3} i)$ |
| 0   | $\Delta_{17}(\rho_{10} - 1.141 \ldots - 10^{-2} - 3.345 \ldots - 10^{-3} i)$ |
| 0   | $\Delta_{17}(\rho_{11} - 1.498 \ldots - 10^{-2} + 1.762 \ldots - 10^{-3} i)$ |

combined RAM, thanks to VPAC and Monash e-research centre [http://www.vpac.org] and [http://www.monash.edu.au/eresearch/]

The loss of accuracy in Gauss elimination was estimated by computing the same quantities with 20000 decimal places (but for smaller $N$ up to 6000, due to limitations on computer resources available at the time). Thus we had an estimate for the accuracy of the computed coefficients $\delta_{N,n}$. This estimate suggested that the chosen accuracy of 10000 decimal places was in fact warranted due to cancelation errors, and that it was also sufficient for numerical studies up to $N = 12001$.

The multiprecision calculations for large $N$ up to 12001 produced interesting findings. Firstly, we found that for large $N$ the series $\Delta_N$ (10) continues to provide very accurate approximations to the zeros of the zeta function but doesn’t approximate its value at other points any longer; these phenomena will be discussed in this Section. Secondly, high accuracy experiments allowed us to look “under a microscope” at the fine structure of the coefficients $\delta_{N,n}$. Coefficients which unsuspiciously looked as alternating values $+1$ and $−1$ have shown very rich fine structure at the precision level between $10^{−1000}$ and $10^{−10000}$, the structure that unexpectedly revealed prime numbers! The patterns revealed are so remarkable and regular that we are convinced they could not be due to numerical artifacts. We detail these observations in the next Section.

5 Discoveries for larger $N$

The multiprecision calculations for large $N$ up to 12001 produced interesting findings. Firstly, we found that for large $N$ the series $\Delta_N$ (10) continues to provide very accurate approximations to the zeros of the zeta function but doesn’t approximate its value at other points any longer; these phenomena will be discussed in this Section. Secondly, high accuracy experiments allowed us to look “under a microscope” at the fine structure of the coefficients $\delta_{N,n}$. Coefficients which unsuspiciously looked as alternating values $+1$ and $−1$ have shown very rich fine structure at the precision level between $10^{−1000}$ and $10^{−10000}$, the structure that unexpectedly revealed prime numbers! The patterns revealed are so remarkable and regular that we are convinced they could not be due to numerical artifacts. We detail these observations in the next Section.

High accuracy calculations for larger $N$ revealed that most likely the guess (17) was wrong, and this explains why the values of $\Delta_N(s)$ aren’t close to $\zeta(s)$ any longer. Figure 4 exhibits coefficients $\delta_{101,n}$. Such behaviour is “typical” for $N > 100$, however, every now and then a kind of “Gibbs phenomenon” occurred as illustrated on Figure 5 or even more bizarre behaviour as on Figure 6 presumably, such irregularities would disappear for $N$ big enough.

A catalog of $\delta_{N,n}$ for many values of $N$ can be found in [Matiyasevich]. Its content suggests that (17) should be replaced by

$$\delta_{N,n} \underset{N \to \infty}{\to} (-1)^{n+1}$$

and, respectively, for large $N$.

$$\Delta_N(s) = \sum_{n=1}^{N} \delta_{N,n} n^{-s} \approx \sum_{n=1}^{\infty} (-1)^{n+1} n^{-s} = \eta(s)$$

There were at least two kinds of small $\Delta$-values that were closer to $0$ than to $\zeta(s)$, thus we can draw some conclusions about their possible significance in the arguments around the critical point with some accuracy.
where
\[ \eta(s) = (1 - 2 \cdot 2^{-s})\zeta(s) \] (24)
is the alternating zeta function.

Indeed, \( \Delta_{3001}(s) \) has zeroes close to zeroes of the factor \( 1 - 2 \cdot 2^{-s} \) which have the form \( 1 + \frac{2k}{\ln(2)} \), \( k = \pm 1, \pm 2, \ldots \) (see Table 2). It also has zeroes close to the non-trivial zeroes \( \rho_{1501}, \ldots \) (see Table 3) and, surprisingly, to the trivial zeroes as well (see Table 4). In other words, the initial non-trivial zeroes “feel” the presence of the pole of the zeta function (canceling it by the factor \( 1 - 2 \cdot 2^{-s} \) in (24)) and “know” about the trivial zeroes not used in the definitions (15)–(16). Nothing similar can happen for a meromorphic function approximated by polynomials with the same zeroes – they would know nothing about the poles.

The values of \( \Delta_{3001}(s) \) are close to the values of \( \eta(s) \) for \( s \) inside the critical strip and even much to the left of it (see Table 5). In other words, we have a surprisingly good approximation to \( \zeta(s) \) of the form
\[ \zeta(s) \approx \frac{\Delta_N(s)}{1 - 2 \cdot 2^{-s}} = \frac{\sum_{n=1}^{N} \delta_{N,n} n^{-s}}{1 - 2 \cdot 2^{-s}}. \] (25)
In fact, if we allow more terms in the denominator, we can obtain (see Matiyasevich 2013) much better approximations
\[ \zeta(s) \approx \frac{\sum_{n=1}^{N} \delta_{N,n} n^{-s}}{\sum_{n=1}^{L} \mu_{N,n} n^{-s}} \] (26)
for a small value of \( L \) where numbers \( \mu_{N,n} \) are defined via formal division of the two Dirichlet series:
\[ \frac{\Delta_N(s)}{\zeta(s)} = \frac{\sum_{n=1}^{N} \delta_{N,n} n^{-s}}{\sum_{n=1}^{\infty} n^{-s}} = \sum_{n=1}^{\infty} \mu_{N,n} n^{-s}. \] (27)

6 Fine structure of the coefficients \( \delta_{N,n} \)

6.1 Sieve of Eratosthenes

Clearly, the extreme closeness of the zeroes and values of the alternating zeta function \( \eta(s) \) and that of finite Dirichlet series \( \Delta_N(s) \) is due to the very peculiar values of the coefficients \( \delta_{N,n} \), and now we are to look at their finer structure “under a microscope”. To this end we change to the logarithmic scale – see Figure 11.
Table 2: Zeroes of $\Delta_{3001}(s)$ nearby zeroes of $1 - 2 \cdot 2^{-s}$

| 0    | $\Delta_{3001}(\rho_{2701} + 6.698 \ldots \cdot 10^{-354} + 3.094 \ldots \cdot 10^{-353}i)$ |

Table 4: Zeroes of $\Delta_{3001}(s)$ nearby trivial zeroes of $\zeta(s)$

| Zero | Expression |
|------|------------|
| 0    | $\Delta_{3001}(-100 - 8.196 \ldots \cdot 10^{-1220})$ |
| 0    | $\Delta_{3001}(-200 - 4.236 \ldots \cdot 10^{-1017})$ |
| 0    | $\Delta_{3001}(-300 - 4.763 \ldots \cdot 10^{-830})$ |
| 0    | $\Delta_{3001}(-400 - 1.441 \ldots \cdot 10^{-654})$ |
| 0    | $\Delta_{3001}(-500 - 1.187 \ldots \cdot 10^{-488})$ |
| 0    | $\Delta_{3001}(-600 - 4.600 \ldots \cdot 10^{-331})$ |
| 0    | $\Delta_{3001}(-700 - 6.183 \ldots \cdot 10^{-181})$ |
| 0    | $\Delta_{3001}(-800 - 1.648 \ldots \cdot 10^{-51})$ |
Figure 5: Coefficients $\delta_{221,n}$ (disks for even $n$ and triangles for odd $n$)

Figure 7: Graph of $\log_{10}|\delta_{10001,n} - 1|$.

Here we can observe several horizontal rows of dots. The top row corresponds to even values of $n$ for which $\delta_{10001,n}$ is, according to (22), close to $-1$. The second row corresponds to odd values of $n$ divisible by 3. The third row corresponds to those values of $n$ that are divisible by 5 but are relatively prime to $2 \cdot 3$. The fourth row corresponds to those values of $n$ that are divisible by 7 but are relatively prime to $2 \cdot 3 \cdot 5$, and so on. The seventh row, the last one that we can see, contains only two dots corresponding to $n = 17$ and $n = 289$.

The remaining dots correspond to prime values of $n$. So we can say that the initial part of the plot of
\( \delta_{233,n} \)

Figure 6: Coefficients \( \delta_{233,n} \) (disks for even \( n \) and triangles for odd \( n \))

\[ \log_{10} |\delta_{10001,n} - 1| \]

represents the Sieve of Eratosthenes. Respectively, the horizontal rows corresponding to the values of \( n \) divisible by 2, by 3, … but not by the previous primes will be called Eratosthenes levels.

Figure 8: Graph of \( \log_{10} |\delta_{10001,n} - 1| \).

Figure 8 extends Figure 7 up to \( n = 10001 \). We see that the Eratosthenes levels break off when they touch a mysterious “smooth curve” of increasing values of \( \log_{10} |\delta_{10001,n} - 1| \). The larger \( N \), the more to the right is the smooth curve.
Table 5: Calculation of $\zeta(s)$ via $\Delta_{3001}(s)$

| $s$         | $|\Delta_{3001}(s) - \zeta(s)|$ |
|-------------|---------------------------------|
| 25          | $4.2671\ldots \times 10^{-135}$ |
| 2           | $3.9256\ldots \times 10^{-128}$ |
| 1000i       | $4.4184\ldots \times 10^{-128}$ |
| $\frac{1}{2} + 10i$ | $1.0953\ldots \times 10^{-127}$ |
| $-1 + 100i$ | $3.6324\ldots \times 10^{-127}$ |
| $-25$       | $1.6415\ldots \times 10^{-126}$ |
| $2 + 1000i$ | $2.3063\ldots \times 10^{-125}$ |
| $\frac{1}{2} + 1000i$ | $3.9630\ldots \times 10^{-124}$ |
| $-1 + 1000i$ | $1.4867\ldots \times 10^{-118}$ |
| $-10 + 1000i$ | $8.2377\ldots \times 10^{-103}$ |
| $\frac{1}{2} + 5000i$ | $6.5116\ldots \times 10^{-64}$ |
| $-1 + 5000i$ | $2.6548\ldots \times 10^{-59}$ |
| $-10 + 5000i$ | $2.5001\ldots \times 10^{-32}$ |

Figure 9 presents results of our computations for $N = 12001$. It again shows the Eratosthenes levels but also gives an impression of a new phenomenon – dots corresponding to all primes greater than 80 look like lying on a horizontal line with the ordinate $-7157$. Actually, this is due to the fact that the calculated values of the coefficients have only about 7157 correct decimal digits.

Figure 9: An artifact caused by insufficient accuracy.

6.2 Fractal structure

Figure 10: Graph of $\log_{10} |\delta_{12001, m} - 1|$ showing Eratosthenes sublevels.

Figure 10: Graph of $\log_{10} |\delta_{10001, 3m} - \delta_{10001, 3m}|$ showing Eratosthenes sublevels.
The Eratosthenes levels on Figures 7–8 look like lying on straight lines. However, closer examination reveals that each of the levels in its turn contains sublevels corresponding to a slightly modified Sieve of Eratosthenes. Figure 10 shows such sublevels for the main Eratosthenes level corresponding to prime $p = 3$ in the case $N = 10001$. These sublevels correspond to deleting composite numbers according to their divisibility at first by 2, then by 5, 7, 11, 13, etc.

The general rule seems to be as follows. The dots representing $\delta_{N,n}$ for $n$ from an arithmetical progression $d, 2d, \ldots, md, \ldots$ with $d = 2^k 3^a \ldots$ split into Eratosthenes sublevels according to the divisibility of $m$ by $p_1, p_2, \ldots, p_j, \ldots$.

\[ p_1^{k_1+1} < p_2^{k_2+1} < \cdots < p_j^{k_j+1} < \cdots \quad (28) \]

7 Related and Further Research

Originally, the second author (Matiyasevich 2012, Matiyasevich 2013) examined the determinants slightly different from those in (16) for which $\Delta_\Gamma N(s)$, the counterpart of (10), vanishes at $2N - 2$ zeroes of $\zeta(s)$. This becomes possible thanks to the so-called functional equation established by Riemann [Riemann 1859]. Properties of $\Delta_\Gamma N(s)$ are similar but not the same as those of $\Delta_N(s)$. In particular, the Eratosthenes sieve manifests itself not so spectacular. On the other hand, $\Delta_\Gamma N(s)$ allows one to calculate approximations not only to the zeroes and the values of the zeta function but to its first derivative as well.

We plan to examine the counterparts of $\delta_{N,n}$ and $\Delta_{N,n}$ for the cases when zeroes of the zeta function are replaced by zeroes of Dirichlet $L$-functions, as well as to perform computations in interval multiprecision arithmetics using Arb [Johansson 2013] to obtain rigorous bounds on the resulting values.

This ongoing research can be followed on [Matiyasevich].

8 Conclusion

We performed large-scale high-accuracy computations of the coefficients of the finite Dirichlet series approximating nontrivial zeroes of Riemann’s zeta function. Our aim was to reveal experimentally new relations between these coefficients and various related quantities, such as the zeroes of the alternating zeta function. The results of our computations are somewhat unexpected. Firstly they revealed that the finite Dirichlet series also approximates (with high accuracy) other zeroes of zeta function (trivial and subsequent non-trivial zeroes), not used in computations. Secondly, the coefficients inconspicuously looking as $+1$ and $-1$ have in fact a rich structure related to prime numbers.

We want to underline the necessity for performing computations with very high accuracy, which was crucial in discovering the patterns presented here, that would not be detected otherwise. The calculations performed were costly, of order of 200,000 CPU hours, which were made possible by collaborative work of mathematicians, computer scientists, programmers and support engineers.

Of course, in Number Theory there are many examples of conjectures that were at first substantiated by calculation for many initial values of the parameters, but then were disproved either theoretically or by finding a numerical counterexample. Nevertheless, we find it highly desirable to extend our calculations to higher sizes of determinants in order to study subtler properties of the intriguing numbers $\delta_{N,n}$. This requires significant computational resources and multi-party collaboration. Our recent experiences with computational aspects of multiprecision calculations are presented in [BeliakovMatiyasevich 2013].

Acknowledgements

The multiprecision values of the zeroes of the zeta function were first computed using Mathematica and Sage. The author is grateful to Oleksandr Pavlyk, special functions developer at Wolfram Research, for performing part of the calculations, and to Dmitrii Pasechnik (NTU Singapore) for hands-on help with setting up and monitoring the usage of Sage.

More recently Fredrik Johansson developed a more efficient algorithm in his new system Arb [Johansson 2013], and zeta zeroes were recalculated with 40,000 digits; they are made publicly available [MatiyasevichBeliakov 2013].
Calculations of zeta zeroes were also performed on computers from ArmNGI (Armenian National Grid Initiative Foundation), Isaac Newton Institute for Mathematical Sciences, UK, LACL (Laboratoire d’Algorithmique, Complexité et Logique de Université Paris-Est Créteil), LIAPA (Laboratoire d’Informatique Algorithmique: Fondements et Applications, supported jointly by the French National Center for Scientific Research (CNRS) and by the University Paris Diderot–Paris 7), SPIIRAS (St.Petersburg Institute for Informatics and Automation of RAS), Wolfram Research.

The most time-consuming part, calculation of the sequence of determinants $\delta_{N,n}$, was performed on the “Chebyshev” supercomputer at Moscow State University Supercomputing Center and MASSIVE cluster.

The second author was supported in the framework of the Program of Fundamental Research of the Division of Mathematical Sciences of the Russian Academy of Sciences “Modern problems of theoretical mathematics”.
