Preserving the Posttrapeziectomy Space with a Human Acellular Dermal Matrix Spacer: A Pilot Case Series of Patients with Thumb Carpometacarpal Joint Arthritis

Background: Advanced thumb carpometacarpal arthritis is widely treated with trapeziectomy and tendon interposition despite donor-site morbidity. Trapeziectomy alone leaves a postresection space, leading to proximal metacarpal migration and scaphoid/trapezoid impingement. Prosthetic implants have been unsuccessful due to particulate debris, silicone synovitis, osteolysis, and migration. Recent studies have shown successful use of allograft for interposition material in the posttrapeziectomy space both in animal and human models. To obviate the need for autologous tissue, maintain thumb length, and reduce the risk of scaphoid impingement, the senior author developed an interposition arthroplasty technique using a spacer constructed from human acellular dermal matrix (HADM).

Methods: Sixteen patients with Eaton stage III–IV thumb carpometacarpal osteoarthritis received the above procedure from the 2 senior authors. HADM was imbricated to fill the posttrapeziectomy space and secured to the volar capsule and metacarpal base. Pre- and postoperative trapezial space on radiograph, pain scores, and grip strength were recorded.

Results: Six months postoperatively, radiographs showed an average joint space loss of 11%. Heights postoperatively were not significantly different from immediate postoperative heights (P ≥ 0.01). At 6 months, patients had improved pain and grip strength (P ≤ 0.01). No infections, foreign body reactions, or other complications occurred.

Conclusions: HADM has been used extensively in other forms of reconstruction and has been shown to incorporate into surrounding tissues through neovascularization. Our early results illustrate that HADM can safely fill the dead space left by trapeziectomy. (Plast Reconstr Surg Glob Open 2013;1:e65; doi: 10.1097/GOX.0b013e3182aa8793; Published online 29 October 2013.)
T
here is no consensus regarding treatment for late-stage thumb carpometacarpal (CMC) arthritis.\(^1\) Trapeziectomy alone leaves a postresection space that allows proximal metacarpal migration and possible scaphoid/trapezoid impingement, with a markedly narrow joint space under stress.\(^2\) Although scaphoid impingement is a commonly cited but rarely documented complication, a reduced joint space is universally expected and loss of strength and stability and pain are known complications.\(^3,4\)

Numerous studies show satisfactory functional outcomes for autologous tissue interposition with or without ligament reconstruction. Joint height is reduced by 50% after 12–36 months although patients tend to have adequate pain relief for many years.\(^5,6\) Using the flexor carpi radialis tendon for ligament reconstruction and tendon interposition improves strength, pain, function, and patient satisfaction.\(^7,9\) and loss of arthroplasty height was 11–13% on long-term follow-up.\(^10,11\) Patients occasionally reported increased postoperative pain, FCR tendonitis, and decreased fatigue strength.\(^6\) Autograft procedures require more operative time and extensive dissection that leads to increased scarring and pain and altered wrist kinetics. Naidu et al\(^12\) showed that FCR tendon harvesting leads to a significant decrease in the wrist flexion extension torque ratio and wrist flexion fatigue resistance.

Variations of the LRTI include recreating of the volar beak ligament with the abductor pollicis longus\(^5,14\) or abductor pollicis brevis.\(^15\) Although these studies cite satisfactory pain improvement, trapezial space loss was 14–32%. “Double arthroplasty” using the distal FCR and flexor carpi ulnaris has significant morbidity from tendon harvests. Costochondral allograft technique by Trumble et al\(^16\) had a trapezial morbidity from tendon harvests. Costochondral allograft technique by Trumble et al\(^16\) had a trapezial space preservation was successful in a rabbit model in 2007 using acellular dermal matrix\(^20\) and in a monkey model\(^21\) in 2000 using allogenic tendon. In humans, Kokkalis et al\(^22\) used human acellular dermal matrix (HADM) to reconstruct the palmar beak ligament and fill the posttrapeziectomy space. At 12 months, they reported significantly less pain, increased grip and pinch strength (16% and 19%, respectively), 31% reduction in arthroplasty space, and no adverse reactions. Adams et al\(^23\) described arthroscopic debridement of the first CMC joint with HADM interposition arthroplasty. They reported improved pain and grip strength and high patient satisfaction with no complications. Taghinia et al\(^24\) proposed a suspended cadaveric fascia lata interposition allograft but reported a 50% loss of trapezial height despite satisfactory functional outcomes. To address current allograft shortcomings, the senior author proposes a novel technique.

**METHODS**

The senior authors began using HADM interposition with trapeziectomy in 2010. Sixteen patients with Eaton stage III or IV thumb CMC osteoarthritis qualified for this procedure and all were reviewed. All patients had 6 months of postoperative follow-up and had failed medical management of their osteoarthritis, including splinting, steroid injections, and nonsteroidal anti-inflammatory medications. Pre- and postoperatively, the trapezial space was measured with fine calipers on Rolando radiographs. All radiographs were taken on the same machine with the same specialty-trained technicians, who have 30 years of combined experience in hand films. Pain
scores, pinch strength, and grip strength were recorded pre- and postoperatively.

Statistical analyses were performed using computer software (Stata/SE. V11.0 for Windows; StataCorp LP, College Station, Tex.). Paired t test was used to determine statistical differences between the pre- and postoperative measurements. P values were 2-tailed, and values equal to or less than 0.01 were defined as statistically significant. An institutional review board approval from Cedars Sinai Medical Center and the Keck School of Medicine of the University of Southern California is in place to follow-up the patients in this study for 2 additional years.

Surgical Procedure
A longitudinal dorsoradial incision is made from the base of the first metacarpal to the radial styloid for access to the thumb CMC joint (Fig. 1). Trapeziectomy is performed piecemeal using sharp and blunt dissection (Fig. 2). The base of the first metacarpal is then decorticated with a sagittal saw. A 4 × 7 cm sheet of 0.23-mm HADM (FlexHD, Ethicon) is fashioned by suture imbrication into the size and shape of the patient’s trapezium, keeping the dermal side exposed as much as possible (Figs. 3 and 4). The allograft is secured with multiple interrupted 3-0 Ticron sutures and the bundle is placed into the posttrapeziectomy space. Additional suture fixation is performed between the HADM and the volar capsule of the trapezium and base of the thumb metacarpal using 4-0 Mersilene sutures (Fig. 5). The dorsal capsule is closed with 4-0 Mersilene sutures. Intraoperative imaging is performed to confirm satisfactory radiographic position of the first metacarpal in line with the scaphoid (See Video 1, Supplemental Digital Content 1, which highlights technical aspects of creating and securing the interposition graft, available in the “Related Videos” section of the full-text...
months postoperatively, radiographs showed that trapezial space height loss ranged from 0% to 27% with a mean of 11% (Table 1). Height 6 months postoperatively was not significantly different from immediate post-op height ($P > 0.01$). Figures 6A–C highlight radiographic changes pre- and postoperatively. Figure 6A shows preoperative destruction of the thumb CMC joint space, whereas Figure 6B shows preservation of the trapezial space at 6 months using HADM. Figure 6C shows complete preservation of the space at 9 months. Fourteen patients had pre- and postoperative visual analog pain scores recorded; pain levels decreased from an average of 93% to 14% ($P \leq 0.01$). At 6 months, all patients subjectively reported improved pain and quality of life. Thirteen patients had pre- and postoperative pinch strength recorded; 6 months after surgery, average strength improved from 4.2 kg to 8.5 kg, a 102% improvement ($P \leq 0.01$). Ten patients had pre- and postoperative grip strength recorded. Grip strength increased from an average of 37.7 kg to 46.5 kg, a 23% improvement ($P \leq 0.01$). No infections, foreign body reactions, or other complications occurred.

**DISCUSSION**

Although our procedure has an average joint height reduction of 11%, height reduction after tendon interposition alone and LRTI is 50% and 11–13%, respectively. Improved pain and strength in this study are comparable or superior to previously published results for tendon interposition and LRTI, but with no complications regarding FCR tendonitis, decreased fatigue strength, and increased postoperative pain. However, given the retrospective nature of our study, 19% of patients did not have pre- and postoperative pinch strength measurements, and 38% did not have grip strength measurements.

*Video 1. See video, Supplemental Digital Content 1, which shows technical highlights of creating and securing the Flex-HD interposition graft, available in the "Related Videos" section of the full-text article on PRSGO.com, and [http://links.lww.com/PRSGO/A10](http://links.lww.com/PRSGO/A10).*
HADM avoids past difficulties that have plagued prosthetic implants for the first CMC joint, for example, graft reactions, and persistent pain. Unlike allogenic material, in vivo studies show that HADM induces rapid fibroblast and vascular progenitor infiltration with minimal adverse inflammatory responses. In vivo rat models show that vasculogenesis begins as early as day 7 after implantation. As HADM integrates into its biologic environment, the risk of adverse reactions decreases. Although our short (6 mo) follow-up time is a caveat, our series shows no infections and no foreign body reactions to our allograft. Cross-linked porcine dermis grafts induce inflammatory responses, which may explain the early failure of Adams and Steinmann. Less collagen cross-linking leads to fewer foreign body responses and improved remodeling while certain processing solvents induce superior biocompatibility. Therefore, the preparation for each brand’s dermal matrix will determine which is better suited for trapezium replacement. Our experience with FlexHD shows that it has the potential to integrate into the posttrapeziectomy space, barring any matrix degeneration at the core of the construct. Although early results show good joint space preservation, longer follow-up will elucidate whether robust neocellularization and matrix remodeling will continue.

HADM has been used experimentally to fill soft-tissue and bony defects in plastic, oral, and cranial surgeries. Defects in periodontal surgery are often filled with HADM after gingival, mucosal, bone, or tooth resection with good integration. In these patients, HADM successfully engenders cellular infiltration without adverse reactions. Cranial base defects and large scalp with calvarial defects have been successfully patched with layered HADM with full tissue integration.

Three articles describe comparable procedures. Taghinia et al use GraftJacket for concurrent interposition and ligament reconstruction after trapeziectomy and report a 31% joint space reduction. They recreate the palmar beak ligament by suspending HADM, necessitating FCR dissection, drilling into the first metacarpal, and manipulating the intramedullary canal. Our procedure is simpler with shorter operating times and less soft tissue and bony trauma. As such, our pilot series shows results comparable to existing procedures with decreased donor-site morbidity (Table 2). The procedure by Capito et al is similar to our technique; however, their choice of allograft does not preserve the trapezial space as robustly. Adams et al reported a similar arthroscopic technique for debridement of the first CMC joint with HADM (GraftJacket) interposition. They reported favorable outcomes but treated less severe forms of osteoarthritis.

Table 2. Results Comparable to Existing Procedures with Decreased Donor-site Morbidity

| Procedure                                      | Trapezial Height Loss (%) |
|------------------------------------------------|---------------------------|
| HADM interposition with trapeziectomy†        | 11                        |
| FCR interposition with trapeziectomy          | 50                        |
| LRTI with FCR                                | 11–13                     |
| LRTI with abductor pollicis longus            | 14                        |
| LRTI with abductor pollicis brevis            | 32                        |
| Trapeziectomy with costochondral graft        | 21                        |

*Minimum postoperative time of 6 mo.
†Described herein.
As this is a pilot study, limitations include the short follow-up time and small cohort size. However, our results provide evidence that a more robust, long-term study is worthwhile. A large-scale prospective study that compares results of our procedure with trapeziectomy alone and trapeziectomy with LRTI has the potential to shift the standard of care for late-stage first CMC joint osteoarthritis. HADM is notably used in hand reconstruction for forearm muscle herniation, burns, contractures, and trauma. A comprehensive review by the senior author in the November 2012 Plastic and Reconstructive Surgery issue revealed that very few complications have occurred with HADM in the hand; when complications did occur, they usually involved an infected wound bed.  

Although the risk of immunogenic rejection or hyperactive inflammation is an inherent risk of HADM, it has not been reported in the literature on hand. In breast reconstruction, it is an inherent risk of HADM, it has not been reported into custom shapes. Although our initial results are promising, further study with a larger prospective cohort is warranted to compare our procedure with trapeziectomy alone and trapeziectomy with LRTI.
