ABSTRACT

We propose that the remarkable object Swift J1644+57, in which multiple recurring hard X-ray flares were seen over a span of several days, is a system in which a white dwarf was tidally disrupted by an intermediate-mass black hole. Disruption of a white dwarf rather than a main-sequence star offers a number of advantages in understanding the multiple, and short, timescales seen in the light curve of this system. In particular, the short internal dynamical timescale of a white dwarf offers a more natural way of understanding the short rise times ($\sim$100 s) observed. The relatively long intervals between flares ($\sim$5 × $10^4$ s) may also be readily understood as the period between successive pericenter passages of the remnant white dwarf. In addition, the expected jet power is larger when a white dwarf is disrupted. If this model is correct, the black hole responsible must have a mass $\lesssim 10^5 M_\odot$.

Key words: accretion, accretion disks – black hole physics – galaxies: nuclei – white dwarfs

1. INTRODUCTION

On 2011 March 28, the Swift Burst Alert Telescope (BAT) detected a most unusual object, Swift J164449.3+573451 (Levan et al. 2011; Burrows et al. 2011). Although in many ways this object (whose name we abbreviate to Swift J1644+57) initially appeared to resemble a classical $\gamma$-ray burst, its light curve soon showed that it was quite different. Still bright more than $6 \times 10^6$ s after the initial trigger (see Figure 1), in its initial activity it exhibited repeated extremely short timescale flares (see Figure 2). After holding roughly steady for $\sim 700$ s, the flare causing the BAT trigger rose by a factor of 10 in flux over the next $\sim 400$ s. Less than 1000 s later, the flux had fallen by a factor of 20, and $\sim 10^4$ s after that, although still detectable, the flux was only 0.5% of what it had been at the peak. Most surprisingly, there was a comparable flare $\sim 50,000$ s later, similarly lasting for only $\sim 1000$ s, and a third, slightly brighter than the first, $\sim 60,000$ s after that. Like the first two, the third flare continued to show very short timescale variation.

Several more brief flares of comparable brightness followed, likewise separated by periods of flux two orders of magnitude weaker. Gradually, the duration of the flares stretched and their amplitudes diminished, until after $\sim 2 \times 10^5$ s the system began a long, gradual decline in flux in which it has remained bright enough to be detected for more than $1.5 \times 10^7$ s. Thus, there appears to be a number of characteristic timescales of variation, spread over quite a wide dynamic range: rise times as short as $\sim 100$ s, flare durations $\sim 1000$–$10,000$ s, quiescent periods $\sim 5 \times 10^4$ s, and a total event duration of more than $10^7$ s. After $10^5$ s, the best power-law fit to the light curve is that the observed flux decays $\propto t^{-4/3}$, but its large variability and spectral changes mean that it might still be consistent with the expected $t^{-5/3}$ bolometric decay.

Still another surprise came when BAT data preceding the trigger were examined. Approximately three days earlier, there was a precursor whose peak flux was $\sim 0.07$ times the flux of the first flare (Burrows et al. 2011). Searches for earlier episodes of emission from the same source in archival data revealed only upper limits.

Optical, near-infrared, and radio observations combine to show that the source lies within 150 pc of the center of a galaxy at $z = 0.354$ (Levan et al. 2011). The peak luminosity associated with these flares (interpreted as isotropic) is then $\sim 4 \times 10^{48}$ erg s$^{-1}$ (Burrows et al. 2011). Even at its faintest detected level, the (isotropic) luminosity is $\sim 1 \times 10^{46}$ erg s$^{-1}$ (Burrows et al. 2011). Although relativistic beaming that could enhance the flux by a factor $\sim 100$ is likely (Burrows et al. 2011), the beaming-corrected power is still very large: $\sim 4 \times 10^{46}$ erg s$^{-1}$ at the peak, and a total emitted energy $\sim 5 \times 10^{51}$ erg within the first $1 \times 10^7$ s of the event if the X-Ray Telescope (XRT) flux is $\sim 1/3$ of bolometric, as suggested by Bloom et al. (2011).

During flaring episodes, the observed $vF_v$ is greatest between 10 and 100 keV; it appears to be strongly absorbed by interstellar gas below $\lesssim 5$ keV in the rest frame. By the time the near-IR measurements were performed, two to four days after the event began, their fluxes were $\sim 10^{-3}$ of the hard X-ray flux at its peak and $\sim 10^{-2}$ of its flux during quiescent periods (Burrows et al. 2011).

Within six weeks of its discovery, several models were proposed to explain it, most concentrating on a picture in which a main-sequence star was tidally disrupted by passing too close to a $10^6$–$10^7 M_\odot$ black hole (Bloom et al. 2011; Burrows et al. 2011; Cannizzo et al. 2011; Socrates 2011). Although these models differ from one another in some of their details, they share a common outline: a main-sequence star is thoroughly disrupted as it passes near a black hole and much of its mass is distributed into an accretion disk around the black hole. A powerful jet is then created, whose radiation, created by the synchro-Compton mechanism, dominates what we observe. In this picture, the rise time of the flares is interpreted as indicating (after allowance for relativistic effects) the size of individual knots in the jet, and these are related to the gravitational radius of the black hole. The duration of the entire event is thought to indicate either the expected $t^{-5/3}$ scaling (Burrows et al. 2011) due to the orbital period distribution of tidal streams (Rees 1988; Phinney 1989) or the inflow time of the accretion disk (Socrates 2011). Although plausible in many respects, this consensus model leaves a number of questions unanswered. The tidal disruption
radius in units of the black hole gravitational radius is

\[ \frac{R_T}{R_g} = R_\ast \left( \frac{k}{f} \right)^{1/6} \left( \frac{M_{\ast}/M_\ast}{f} \right)^{1/3} \left( \frac{G M_{\ast}/c^2}{f} \right) \]

\[ = 50 \left( \frac{k}{f} \right)^{1/6} M_{\ast}^{-2/3} M_{\ast}^{2/3}, \]

(1)

where \( k \) is the apsidal motion constant (determined by the star’s radial density profile) and \( f \) is its binding energy in units of \( GM_{\ast}^2/R_\ast \) (Phinney 1989). Here, \( M_\ast \) is the mass of the star in solar units, and we have taken the approximate scaling that \( R_\ast \propto M_\ast \) on the main sequence. The ratio \( k/f \) is \( \approx 0.02 \) for radiative stars, but 0.3 for convective stars (Phinney 1989). The circular orbital period at the tidal radius is then proportional to \( M_\ast \) and independent of \( M_{\ast}\) because the dynamical time at the tidal radius is \( \sim (G \rho_\ast)^{-1/2} \), and on the main sequence the mean stellar density \( \rho_\ast \propto M_\ast^{-2} \).

\[ P_{orb}(R_T) = 1.0 \times 10^4 M_\ast \text{ s}. \quad (2) \]

However, the actual orbital period of matter captured in tidal disruption is likely to be considerably longer. As pointed out by Rees (1988), if the disrupted star approached on a nearly parabolic orbit, the tidal streams follow highly eccentric elliptical orbits with a wide range of energies, and therefore of semimajor axes and orbital periods. Their mean energy is likely to be comparable to the star’s self-gravitational binding energy because the gravitational force of the black hole does that much.

Figure 1. Long-term Swift/XRT light curves in the 3–10 keV band (blue: WT; red: PC). Top: linear-in-time representation of the first 300,000 s, illustrating the recurring brief flares that gradually widen. Bottom: logarithmic-in-time representation of the entire light curve as of 2011 August 29, five months after activity began. Both of these light curves and those in the following figure were generated using the graphing tools of the online Swift Data Repository (Evans et al. 2007).

(A color version of this figure is available in the online journal.)

Figure 2. Detailed time structure of the flares. Top: short timescale structure of the first flare. Middle: overview of the first flare. Bottom: short timescale structure in the flare \( \approx 110,000 \text{ s} \) after the BAT trigger. Note that the entire span of the data in the bottom panel is only 1500 s.

(A color version of this figure is available in the online journal.)
work expanding and disrupting the star. On the other hand, tidally induced rotation and the gradient of the gravitational potential across the star can lead to some gas being trapped on orbits with semimajor axis as small as $a_{\text{d}} \sim R_T (M_{\text{BH}} / M_\ast)^{1/3}$, even while the typical stream's orbit is larger by a factor of $(M_{\text{BH}} / M_\ast)^{1/3}$. It follows that even the shortest orbital period is larger than that of a circular orbit at $R_T$ by $\sim (M_{\text{BH}} / M_\ast)^{1/2}$, here a factor $\sim 10^3$, and the typical period is likely another factor of $\sim 10^4$ longer than that. Intersections between stream orbits could lead to conversion of orbital energy to heat, diminishing these orbital periods, but in no case would they become shorter than $P_{\text{orb}} (R_T)$. In fact, numerical simulation of the disruption of a main-sequence star by a $10^6 M_\odot$ black hole (Ayal et al. 2000) shows a rather continuous accretion rate with a rise time of a few times $10^3$ s and an overall duration of a few times $10^4$ s, as expected from these analytic estimates.

It is hard to reconcile these timescales to those seen in the light curve. The rise time in the consensus model is said to reflect the light-crossing time across the black hole's horizon, but it is not clear what dynamics link that quantity to triggering a flare, nor is there any natural explanation for the flare duration. The circular orbital period at $R_T$ is comparable to the interflare interval, but the orbital period of the tidal streams following eccentric orbits, which is the timescale at which the $t^{-5/3}$ decay begins, appears to be at least two orders of magnitude longer than the time at which the flares merged into a smoother light curve. These difficulties have led some (e.g., Cannizzo et al. 2011) to pose special requirements on this model. They suggest that the pericenter distance must not be a great deal larger than the black hole's innermost stable circular orbit (ISCO), so that inflow is largely dynamical. If so, the black hole mass is $\sim 10^6 M_\odot$. By the estimate of Equation (1), the pericenter distance must then be a small fraction of $R_T$.

Another question is how exactly the accretion drives a jet. If, as is generally believed, jets associated with black holes are powered by some variant of the Blandford–Znajek mechanism (Blandford & Znajek 1977; McKinney 2005; Hawley & Krolak 2006), substantial magnetic field must be attached to the black hole horizon. The Poynting luminosity in the jet is then $\sim B^2 r_2^2 \phi$, where $\phi$ is a dimensionless quantity that depends on the field geometry and increases with black hole spin parameter $a / M$, but is generally significantly less than unity. In this object, the field on the horizon must then be $\sim 1 \times 10^6 B_{\text{crit}}^2 L_\ast^{-1} P_{\text{orb}}^{-1} M_{\text{BH}}^{-1} G$. When the system has a long lifespan (e.g., in active galactic nuclei), the magnetorotational instability (MRI) stirs MHD turbulence in the accretion disk and builds the magnetic field; numerical simulations of MRI-driven MHD turbulence show that generally $\sim 10$ orbital periods are required to reach saturation (Stone et al. 1996). Accretion may also accumulate magnetic flux on the horizon (Beckwith et al. 2009); its buildup rate depends, of course, on the structure of the large-scale magnetic field. Here, the accretion flow must plunge into the black hole on a dynamical time and it is unclear whether such a strong field could be generated.

Still another problem raised by this model is how to understand the very large amplitude and very rapidly varying flares. As recognized by Bloom et al. (2011), relativistic jets in blazars behave very differently: their characteristic fluctuation amplitudes are more typically factors of a few than factors of a few orders of magnitude, and their duty cycle at high flux is usually considerably greater than it is during the first several flaring episodes of this event. One could rephrase this question as, “What generates the extremely bright, compact, and short-lived knots that in this model are assumed to account for the flares?”

In this paper, we propose an alternative version of the tidal disruption model that we believe holds some promise for supplying answers to all of these questions. We suggest that the star that is tidally disrupted is a white dwarf, not a main-sequence star, and that it is not disrupted all at once, but instead loses pieces of itself in several passes before dissolving (see Figure 3 for a schematic cartoon) an idea previously considered in the context of white dwarfs on more nearly circular orbits by Sesana et al. (2008) and Zalamea et al. (2010). This suggestion is motivated by the fact that the fundamental timescale of a tidal disruption is dictated by the mean density of the star; the greater density of a white dwarf makes it much easier to achieve the short timescales of this event. In both our picture and the main-sequence star model, the accretion flow drives a jet, which produces the observed radiation; as we shall see, this, too, is favored quantitatively by the higher density of a white dwarf. The remainder of this paper will develop the consequences of these ideas.

Tidal disruption of a white dwarf by a black hole has been also previously discussed in the context of the possible nuclear ignition of the white dwarf (Wilson & Mathews 2004; Dearborn et al. 2005; Rosswog et al. 2008). This requires a rather small black hole and a deep encounter, with pericenter a small fraction of $R_T$. Here, we focus on larger black holes and more distant tidal disruptions that do not lead to such an explosion.

2. TIMESCALES

Using the mass–radius relations of Nauenberg (1972), we find that a white dwarf is disrupted at

$$R_T / R_g \simeq 8 M_{\text{max}}^{1/3} M_{\text{BH}}^{-2/3} [1 - 0.64 (M_\ast / M_{\text{max}})^{1/3}],$$

where $M_{\text{max}} \simeq 1.4$ is the maximal mass of a white dwarf in units of $M_\odot$. In this estimate, we used an apsidal motion constant $k \simeq 0.14$ (Sirotkin & Kim 2009) and a binding energy factor $f = 6/7$, both appropriate to an $n = 3/2$ polytrope. Note that we have changed our fiducial black hole mass from $10^6$ to $10^5 M_\odot$ because the higher densities of white dwarfs require smaller mass black holes in order to keep $R_T / R_g > 1$. In fact, white dwarf tidal disruption requires $M_{\text{BH}} < 2 \times 10^5 M_\odot$, and somewhat less than that if the black hole rotates slowly or it is desired that $R_T$ exceed the ISCO. The period of a circular orbit at the white dwarf tidal radius is (ignoring black hole spin)

$$P_{\text{orb}} (R_T) \simeq 6 M_\odot^{-1} s,$$

three orders of magnitude shorter than for a disrupted main-sequence star. In this regard, it is worth noting that the white dwarf mass distribution appears to be centered at $\simeq 0.6$–$0.7 M_\odot$ (Hansen & Liebert 2003).

Matter torn from a white dwarf, like that taken from a main-sequence star, will travel initially on a wide range of highly eccentric orbits. Following the arguments of Rees (1988), the most tightly bound matter might be expected to have an orbital period $\sim 900 M_{\text{BH}}^{1/4} M_\odot^{3/2}$ s. However, there are several potential mechanisms that could substantially shorten this period. If the black hole mass is not greatly smaller than its upper bound, the orbital pericenters will be in the strongly relativistic regime. There, as pointed out by Cannizzo et al. (1990), because relativistic effects cause differential pericenter precession, different stream orbits can intersect, so that dissipation transfers energy from orbital motion to heat and
possibly photons. This process may be able to circularize the orbits on a timescale of a few orbital periods. When the black hole spins rapidly and its mass is close to the upper bound for tidal disruption, $R_T/R_g$ may be small enough that the orbital precession rate becomes comparable to the orbital frequency, enhancing this effect (we thank the anonymous referee for this suggestion).

Multi-pass tidal breakups may also lead directly to tighter orbits for tidally disrupted matter. The orbital time of the white dwarf remnant is $\sim 10$ disk drainage times, so the only mass remaining in the disk by the time the remnant returns is the mass pushed outward absorbing the angular momentum of the accreted mass. If the mass remaining in the disk from the previous encounter is a fraction $\epsilon$ of the newly arriving mass, the momentum of the matter breaking off the star near $R_T$ will be reduced by that fraction and its kinetic energy reduced by $2\epsilon$. The semimajor axis of the resulting orbit for matter with the mean incoming orbital energy (i.e., near zero) is then $R_T/(4\epsilon)$, giving an orbital period $P_{\text{orb}}(R_T)(4\epsilon)^{-3/2}$. If $\epsilon$ is as little as 0.05, the resulting period is only $\sim 10 P_{\text{orb}}(R_T)$. Because there was a precursor to this event, it is possible that this sort of process may have occurred as early as the flare that caused the BAT trigger.

As remarked before, internally generated magnetic field requires $\sim 10$ orbital periods to reach saturation. When the period is as short as $P_{\text{orb}}(R_T)$ for a white dwarf tidal disruption, the magnetic field can grow to full strength within $\sim 100$ s. Such rapid growth would then be consistent with explaining the rapid rise time of the flares.

The $\sim 1000–10,000$ s duration of individual flares might now be reinterpreted as the drainage time for the small, temporary accretion disk formed from captured material. Once the turbulence has reached saturation, this timescale $t_{\text{in}} \sim (P_{\text{orb}}/2\pi)\alpha^{-1}(R_T/H)^2$ if matter moves inward only by the action of internal disk stresses, where $\alpha \sim 0.1$ is the ratio of vertically integrated magnetic stress to vertically integrated pressure, and the disk density scale height is $H$. Close to the ISCO, however, the mean stress overestimates the inflow time because stress fluctuations can remove enough angular momentum from fluid elements to send them all the way into the plunging region, permanently removing them from the disk. As a
result, Krolik et al. (2005) found that for $R < 3 R_{\text{ISCO}}$ in a disk with saturated MHD turbulence, $t_{\text{in}} \sim 10 P_{\text{orb}}(R)$. Allowing for some material on orbits with periods greater than $P_{\text{orb}}(R_T)$, $\gtrsim 1000$ s might then be a reasonable estimate for the total duration of a single flare, including both buildup of the magnetic field and inflow.

If the initial pericenter of the white dwarf’s orbit is $\sim R_T$, in its first passage it may lose only a fraction of its mass (indeed the detection of a precursor flare $\sim 3$ days before the BAT trigger (Burrows et al. 2011) suggests that the very first passage may have been slightly outside $R_T$). If that is the case, some of its mass is captured into orbiting streams by the black hole, but the rest of the star remains a coherent bound object, albeit substantially degenerate. The equivalent temperature of the Fermi level which the white dwarf is completely disrupted onward.

Thus, the electrons and ions can be expected to thermally equilibrate very rapidly, and at these densities and temperatures, the electrons (now no longer degenerate) will also rapidly thermally equilibrate with radiation. However, the radiative cooling time of the system is much longer than any of the relevant timescales:

$\tau_{\text{cool}} \sim 1 \times 10^{11} (H/R)(\Delta M/M_*) M_7^{7/3} M_*^{-2/3}$ s. (8)

The radiation pressure is therefore effectively trapped within the material. Because shrinking the highly eccentric orbits to nearly circular requires dissipating an energy comparable to the orbital energy, the disk can therefore be expected to be geometrically thick, $H/R \sim 1$. This is the regime of photon-trapping associated with super-Eddington accretion (Begelman 1979; Abramowicz et al. 1988). Because the diffusion time is long compared to the inflow time, the radiation intensity distribution is far from steady state, and the emergent luminosity is much less than the rate at which heat is dissipated. Consequently, the ratio of thermal disk luminosity to rest-mass accretion rate is much less than the conventional $\sim 0.1 M_*^2$.

The total pressure in the inner disk can be expected to be of order the electron density times the local virial temperature,

\[ P_{\text{disk}} \sim 5 \times 10^{21} (\Delta M/M_*) M_* M_{\text{BH,4}}^{-1} (H/R)^{-1} \times \left( \frac{R}{10 R_8} \right)^{-4} \text{dyne cm}^{-2}. \] (9)

If the magnetic pressure on the event horizon is limited by the inner disk pressure (the simulations of Beckwith et al. (2009) suggest that it may be a factor of three to four smaller), the expected field strength would be

\[ B_{\text{hor}} \lesssim 4 \times 10^{11} (\Delta M/M_*)^{1/2} M_*^{1/2} M_{\text{BH,4}}^{-3/2} (H/R)^{-1/2} \times \left( \frac{R}{10 R_8} \right)^{-2} \text{G}. \] (10)
One might then predict a jet Poynting power as much as
\[ L_{\text{jet}} \sim 3 \times 10^{50} \phi \frac{B_{\text{jet}}^2}{8\pi P_{\text{disk}}} (\Delta M/M_*) \Omega M_{\text{BH}}^{-1} \text{ erg s}^{-1}. \] (11)

Even after allowing for a field rather less intense than the disk pressure, \( \Delta M/M_* < 1 \), and a small coefficient \( \phi \), it would seem that the jet power could easily reach the level seen (peak power after allowance for beaming of \( \sim 3 \times 10^{46} \) erg s\(^{-1}\)). Note, also, that \( L_{\text{jet}} \propto M_{\text{BH}}^{-1} \), so models requiring larger black holes tend to generate weaker jets. As pointed out by our anonymous referee, the smaller (in \( R_p \) terms) disks characteristic of white dwarf disruptions also minimize Compton drag (Phinney 1987).

Numerical general relativistic MHD simulations of accretion have shown that the luminosity of the jet can also be estimated in terms of an effective “efficiency” per unit rest-mass accreted that is a function of the black hole spin (McKinney 2005; Hawley & Krolik 2006). Using the expression found in the latter reference, one might predict
\[ L_{\text{jet}} \sim 4 \times 10^{49} [1 - |a/M|]^{-1} (\Delta M/M_*) \Omega M_{\text{BH}}^2 \text{ erg s}^{-1} \] (12)
if the inflow time is \( \sim 10 P_{\text{orb}}(R_p) \). For a black hole with spin parameter \( a/M \approx 0.9 \), this estimate agrees with the previous one evaluated for the fiducial parameters. That it should do so is no coincidence—as assumed in the previous estimate, the magnetic field intensity on the horizon is comparable to the inner disk pressure in these simulations. However, it should be borne in mind that the energy for this jet is actually drawn from the reducible mass (the rotational kinetic energy) of the black hole, not the accretion flow. The function of the accretion is solely to sustain a strong magnetic field on the black hole horizon.

Although nominally independent of black hole mass, in fact this second estimate has an implied dependence through the bound on black hole mass placed by the density of the disrupted star. In rough terms, the second jet luminosity estimate simply mirrors the accretion rate, which is \( \propto \Delta M \Omega (R_p) \). In both the main-sequence star and white dwarf models, the amount of mass placed in orbit is \( \sim M_* \). Where they differ is exactly the point we have emphasized in the context of the light curve’s timescales: \( \Omega (R_p) \sim (G \rho_{\text{in}})^{1/2} \), which is \( \sim 10^4 \) times larger for white dwarfs than for main-sequence stars.

When the disk is drained, the inner disk pressure falls. If that permits the flux on the horizon to expand, so that the magnetic field there becomes weaker, the jet would be correspondingly diminished. Without continuing accretion—that is, between episodes of tidal capture—radiation from the jet would be much reduced. This is, of course, what one would expect in those intervals when the remnant of the white dwarf is out near apocenter.

4. SUMMARY

We propose that the remarkable event known as Swift J1644+57 is more likely the tidal disruption of a white dwarf than a main-sequence star. The fact that white dwarfs are typically \( \sim 10^6 \) times denser than main-sequence stars makes it much easier to understand the very short timescales characteristic of this object’s light curve. Postulating that the initial encounter was not close enough to disrupt the white dwarf completely explains the remarkable flares seen over the event’s first few days (see Figure 3). The \( \sim 100 \) s fluctuations during the flares may then be identified with the inflow timescale from radii \( \sim R_T \), which in this case is likely only \( \sim 10 R_p \). This timescale is imprinted on the light curve if the radiation emerges from the jet when it has traveled less than a few hundred seconds (in the observer’s frame) from the black hole, a distance equivalent to \( \sim 10^3 \) to \( 10^4 R_T \). The disk drainage time is longer because the disk can be expected to spread to radii somewhat larger than \( R_T \); this accounts for the flare durations, \( \sim 10^3 \) to \( 10^4 \) s. The interflare time \( \sim 5 \times 10^4 \) is the orbital period of the white dwarf remnant. Because the remnant orbital period is rather longer than the drainage time, there is an extended period after most of the disk mass has been accreted, but before it is refilled by the next pericenter passage of the white dwarf, when the accretion rate is low, and the jet is therefore weak.

The higher densities of white dwarfs also explain both why the observed radiation is dominated by a jet and the jet’s high luminosity. The very high surface density of the disk thoroughly traps thermal photons, while the associated high pressure can support a stronger magnetic field on the black hole. Although the jet luminosity associated with a main-sequence star event is nominally just enough to supply the observed radiated power (after beaming corrections), that may still be inadequate. The numbers quoted refer only to luminosity in observed bands; it is possible there is additional luminosity elsewhere in the spectrum (e.g., between 100 keV and 100 MeV). More importantly, in most jet radiation models (e.g., Celotti & Ghisellini 2008), the photon luminosity is only \( \sim 1\% - 10\% \) of the kinetic power; the jet powers estimated on the basis of the disk pressure or accretion rate refer to the total, so that \( L_{\text{jet}} \) must be significantly greater than the observed luminosity.

Although the space density of white dwarfs (\( \sim 3 \times 10^{-3} \) pc\(^{-3} \) in the solar neighborhood; Rowell & Hambly 2011) is very similar to the space density of solar-mass main-sequence stars (\( \sim 3.5 \times 10^{-3} \) pc\(^{-3} \); Reid et al. 2002), their effective cross section for coming close enough to a black hole to be tidally disrupted is smaller by the ratio of their tidal disruption radii, \( \sim 2 \times 10^{-3} (M_{\text{wd}}/M_{\text{ms}})^{2/3} \) (Burrows et al. 2011). Estimated the total number of solar-mass main-sequence star disruptions within the volume detectable by Swift to be \( \sim 10^4 \) yr\(^{-1} \), suggesting that the rate of white dwarf tidal disruptions should be \( \sim 10^4 \) yr\(^{-1} \). If they are all relativistically beamed so that we see only \( \sim 1\% \) of all events, the observable rate falls to \( \sim 0.1 \) yr\(^{-1} \), and is reduced further by a factor \( \sim 10 \) to account for BAT’s field of view and observing efficiency (Burrows et al. 2011). Thus, we might expect BAT to detect perhaps \( \sim 0.01 \) yr\(^{-1} \), rather than the actual \( \sim 1/6 \) yr\(^{-1} \). On the other hand, the rates estimated by Burrows et al. (2011); and similarly by Zauderer et al. (2011) were based on theoretical predictions that are an order of magnitude smaller than some empirically based rate estimates (Gezari et al. 2008; Maksym et al. 2010). Given the many uncertainties (and small-number statistics), we believe the rate of white dwarf disruptions is consistent with the Swift detection rate. Moreover, a large part of the contrast between our predicted rate and the rate expected for main-sequence stars would be removed if the required pericenter distance for a main-sequence tidal disruption is \( \sim 0.1 R_T \), as suggested by Cannizzo et al. (2011).

We close with a final significant contrast between white dwarf and main-sequence star models for this event. The black holes most effective at tidal disruption of white dwarfs are smaller by the ratio \( (\rho_{\text{ms}}/\rho_{\text{wd}})^{1/3} \sim 10^{-2} \). Although there has long been good evidence for black holes of \( \sim 10^6 M_\odot \) or more in the central regions of galaxies (beginning with the Milky Way) and somewhat shakier evidence for black holes in galactic nuclei with masses \( \gtrsim 10^5 M_\odot \) (collected in Xiao et al. 2011; these masses are all based on the assumption that gravitational dynamics dominate broad-line gas motions, and in most cases
use only scaling arguments to estimate the broad-line region’s size), this event represents the first indication of a black hole in the $\sim 10^4$–$10^5 M_\odot$ mass range. On the basis of the $M_{\text{BH}}$–bulge luminosity correlation, Burrows et al. (2011) estimated that this galaxy should have a nuclear black hole with mass $\sim 2 \times 10^7 M_\odot$.

If we are correct in our suggestion that this event was due to disruption of a white dwarf rather than a main-sequence star, the correlation estimate may be too large by a factor of 100 or more in this galaxy. Alternatively, the black hole responsible for this disruption could be a second, smaller black hole orbiting a larger one, whose mass is closer to the correlation estimate.

We thank Phil Evans for supplying the Swift light curves, Re’em Sari for helpful discussions, and an anonymous referee for several insightful suggestions. This work was partially supported by NSF Grants AST-0507455 and AST-0908336 (J.H.K.) and by an ERC advanced research grant and the ISF center for High Energy Astrophysics (T.P.). J.H.K. also thanks the Racah Institute for Physics at the Hebrew University for its generous hospitality while much of the work on this paper was accomplished.
