Abstract

BACKGROUND: Abdominal compartment syndrome patients suffer severe obstacles such as kidney failure and shock. To evade further complications, identifying the abdominal compartment syndrome (ACS) and intra-abdominal hypertension (IAH), in critically ill individuals and hospitalised in the intensive care unit (ICU) is obligated.

AIM: The current study intended to study the abdominal compartment syndrome and the concomitant risk factors among hospitalised patients in ICU, by using the intra-abdominal pressure test.

MATERIAL AND METHODS: One hundred and twenty-five hospitalised patients at ICU entered the current survey. Abdominal pressure was measured by standard intravesical technique. The SPSS 21 analysed the preservative and intraoperative factors such as demographic records and comorbidities.

RESULTS: Seventy-three (58.4%) participants were males and 52 (41.6%) were women in the mean age of 55.1 ± 16.3 years. Eighty-nine patients (71.2%) showed normal intra-abdominal pressure since 31 patients (24.8%), and 5 patients (4%) developed IAH and ACS. The intra-abdominal pressure (IAP) applied to Glasgow Coma Scale (GCS), Acute Physiology, shock, Systemic Inflammatory Response Syndrome (SIRS), central venous oxygen saturation and Chronic Health Evaluation (APACHE II) score (P < 0.05). Patients with high IAP have shown a higher mortality frequency, compared to others (P < 0.05).

CONCLUSION: Current findings showed a correlation between IAP hospitalised patients in ICU and shock, SIRS, APACHE II, central venous oxygen saturation and GCS. Intra-abdominal pressure test, as a valuable prognosis test for the abdominal compartment syndrome (ACS) and intra-abdominal hypertension (IAH), may offer better results when added to the routine medical checkup of ICU patients.

Introduction

Despite improved survival reports following the laparotomy method, the abdominal compartment syndrome (ACS) is quite an expanding matter [1]. Increased intra-abdominal pressure (IAP) points to intra-abdominal hypertension (IAH) that influences the body function in critically ill patients and cause abdominal compartment syndrome (ACS). As stated by the World Society of the Abdominal Compartment Syndrome (WSACS), IAH is defined above 12 mmHg intra-abdominal pressure (IAP). The low-grade IAH is two types. IAP 12–15 mmHg specifies the IAH Grade I and IAP 16–20 mmHg specifies the IAH Grade II [2]. ACS is also defined as an IAP > 20 mmHg with proven signs of failure in new organs, for instance, kidney failure or increasing complications in ventilation [3]. ACS is an intra-abdominal pathology proven from an extra-abdominal source. IAH and ACS happen following reduced abdominal wall compliance and/or enlarged intra-abdominal capacities [2].

The importance of IAP detection in susceptible patients to an IAH and ACS is well known. Intravesical pressure (IVP) measurement is now the gold standard for indirect diagnosis of IAP [4]. IAH is reported in 32.1% of critically ill patients. IAH is also a predictor for mortality and is seen in 30-50% of intensive care hospitalised patients [5].

IAH and ACS develop in critically ill patients, caused by several risk factors such as abdominal...
surgery, hypoalbuminemia, trauma, hypoalbuminemia, and high-volume resuscitation [6]. Proper diagnostic techniques can accelerate future researches in evaluating the pathophysiological mechanism of IAH/ACS [5]. Several types of research have been conducted to increase the accuracy of the diagnosis of IAH/ACS, such as the new porcine model of ACS, which was introduced by Shah et al., [7].

Interestingly, there have been several reports on the growing prevalence of ACS reports in the intensive care unit (ICU) and medical ICUs (10.5%) [8]. Therefore, a rapid and right tool to rapid and exact determining the IAH is trustworthy [9].

Based on the literature, IAH characterises a severe disorder with a high incidence in ICU (18%-81%) [6]. However, because of the insidious origination and nonspecific signs of IAH, it has not been accurately studied. Hence, the object of the current study was to test abdominal compartment syndrome and the concomitant risk factors among hospitalised patients in ICU, using the Intra-abdominal pressure test.

Material and Methods

Study design

Patients who referred to the ICU of a tertiary hospital in Tehran because of surgical or non-surgical problems, included in the current study. The mean age for the patients would be > 18 years old. Demographic indexes including age, sex, Glasgow Coma Scale (GCS), BMI, AQA Acute Physiology and Chronic Health Evaluation score (APACHE II) were collected. The exclusion criteria comprised the presence of contraindications for urinary catheterisation (especially in trauma patients) and age < 18. One hundred and twenty-five patients in ICU joined current study [10]. In the current study, disease severity was measured based on APACHE II score (calculated at the time of IAP measurement) and a 12 routine physiologic point score, age, and history of health status that shows the severity of the disease. We considered an increasing score (range 0 to 71) as a risk case of hospital death [11].

Intra-abdominal pressure

The abdominal pressure was measured using the bladder catheter by a standard intravesical method. The catheter clamped and then using a portal aspiration, 25 ccs of hygienic saline was inoculated to the bladder via an attached catheter by an 18-gauge needle to the pressure manometer. Zero of manometer located on mid-maxillary line at the level of the umbilicus. IAH was recorded in Supine and end duration [10]. IAP of ≥ 12 mmHg was determined as hypertension. Also, the IAP of ≥ 12 mmHg + intra-abdominal dysfunctions with/without APP < 60 mmHg were used as ACS. The participants completed and signed informed consent. Each participant was informed about the benefits of the study and personal information kept as secret. The Ethical Committee received.

Data and analysis

Statistical analyses performed by Statistical Package for the Social Sciences (SPSS) (ver. 22.0; SPSS Inc. Chicago, IL, USA) software. The nonparametric Mann-Whitney U test determined the between treatments comparisons. Also, a Student’s t-test calculated the differences in the mean, considering a p-value of < 0.05 meant for a significant value.

Results

Tables 1 show demographic data of the study subjects.

| Diagnosis       | Frequency | Per cent |
|-----------------|-----------|----------|
| Abdominal mass  | 2         | 1.6      |
| AKI             | 3         | 2.4      |

Acute Kidney Injury (AKI), Cerebrovascular accident (CVA), Diffuse axonal injury (DAI), Diabetic ketoacidosis (DKA), Subdural hematoma (SDH), chronic obstructive pulmonary disease COPD, Pulmonary Thromboendarterectomy (PTE), Thrombotic Thrombocytopenic Purpura (TTP). Thirty-nine patients (31.2%) had trauma while 86 persons (68.8%) had no earlier trauma. Also, only 34 of the patients (27.2%) had a history of bone fracture. Thirty-nine patients had normal ventilation (31.2%) while 71 patients (56.8%) used a mechanical ventilator and the 15 of them (12%) had the tracheostomy. Table 4 presents the result of blood products transfused for the participants. Those with IAP, IAH, and ACS received 1.3 ± 2.3 ± 2.5 and 7.6 ± 3.2 units of blood products (P < 0.001).

Table 4: Blood analysis report in participants

| Blood product | Frequency | Per cent |
|---------------|-----------|----------|
| NO            | 64        | 51.2     |
| PC            | 41        | 32.8     |
| FFP           | 2         | 1.6      |
| PLT           | 3         | 2.4      |
| CRVO          | 2         | 1.6      |
| PC, FFP       | 9         | 7.2      |
| PC, FFP, PLT  | 3         | 2.4      |
| PC, FFP, PLT  | 1         | 0.8      |

As stated by the records, 11 patients had a shock, and 92 experienced none shock. Also, 11 patients among 22 SIRS-positive patients had a shock. At the first visit, patients in the ICU underwent monitoring for the IAH and ACS incidences with IAH took normal saline, and patients with IAP, IAH, and ACS received 1.3 ± 2.3 ± 2.5 and 7.6 ± 3.2 units of blood products (P < 0.001).

Table 5: The per cent of IAH, IAP and ACS and APACHE II and time duration of hospitalising of the patient in the ICU

| IAH | APACHE II ≥ 20 | APACHE II ≥ 30 | the time duration of hospitalising (day) |
|-----|----------------|----------------|-----------------------------------------|
| 5.2 | 21             | 8              | 18 ± 2.9                                 |
| IAP | 90.48          | 9              | 22                                       |
| 14.5 ± 5.9 |                  |                            |

ACS: Abdominal compartment syndrome, IAP: Increased intra-abdominal pressure, IAH: Intra-abdominal hypertension.

As shown in Figure 1, the IAP of patients with trauma was 10.04 ± 5.08 mmHg while it was 9.0504 ± 5.08 mmHg in non-traumatic patients (P = 0.19). Also, the IAH and ACS incidences were 30 and 2% in trauma patients.

The mean intra-abdominal pressure was 8.3 ± 5 mmHg in non-ventilated patients and 9.4 ± 5.6 mmHg in patients with tracheal intubation. Patients with tracheostomy had an IAP of 11.3 ± 6.3 mmHg (P = 0.15).

There was no significant correlation between positive end-expiratory pressure (PEEP) and intra-abdominal pressure, so that in patients without PEEP, the mean intra-abdominal pressure was 8.4 ± 4.9 mm. In PEEP, three centimetres of intra-abdominal pressure was 4.4 ± 7.9 mm Hg, and at a pressure of 5 cm water, the pressure inside the abdomen was 5.9 ± 9.9 mm Hg and at 7 cm water pressure, intra-abdominal pressure was 4.5 ± 7.7 mm Hg (P = 0.15).

Received fluid in patients with normal intra-abdominal pressure was 1.6 ± 2.2 litres. While the significant different received fluid volume in patients with IAH and patients with ACS was 1.5 ± 2.4 litres and 0.4 ± 4.3 litres respectively (P = 0.002) (Figure 2).

Of the patients with normal intra-abdominal pressure, six patients did not take fluids. While, 33, 16, one, six, 22, one, three and one patients took normal saline, Dextrose saline, 5% dextrose, half-saline, normal saline/dextrose saline, normal saline/5% dextrose, normal saline/half saline, normal saline/5% dextrose, monophagous in turn.

Ten of patients with IAH took normal saline, five took dextrose saline, three took the half-saline, 10 took normal/ dextrose saline, and one patient took normal/half-saline/2% dextrose water/5% amino fusion. Three and two of patients with ACS took normal saline and normal saline/dextrose saline (P = 0.89).
A significant correlation was documented between homeostasis disorders and IAP in patients (P < 0.001).

There was no significant correlation between culture types in patients with intra-abdominal pressure (Figure 3) (P = 0.07).

In the current study, 13% of the patients with normal intracranial pressure (n = 11) had acidosis, 12% of patients with IAH (n = 4) exhibited acidosis, and 100% of patients with ACS (n = 5) had acidosis (P = 0.001). As presented in Table 8, there was no significant correlation between the type of antibiotic received and intra-abdominal pressure (P = 0.46).

| Antibiotics                  | Normal IAP | IAH | ACS | Total |
|------------------------------|------------|-----|-----|-------|
| Acyclovir                    | 0          | 1   | 0   | 1     |

The SCVO2 in normal IAP patients was 76.8% ± 8.5 while in IAH and ACS patients were 74.6 ± 1 and 59.8% ± 0.8 (P = 0.001). Table 9 displays the correlation between IAP and the identification of the disease. According to the results, a significant correlation detected between IAP and diagnosis of the disease (P = 0.02).

As observed in figure 4, the IAP in normal patients detected in 89 patients and among them, 84 survived, but 5 passed away. Furthermore, in IAH patients, 21 survived, and 10 expired. Entire ACS
patients died (P = 0.001). The mean IAP of expired patients was 15.5 ± 6.7 mmHg while in endured patients the IAP was 8.1 ± 4.5 mmHg.

Nowadays IAP is performed as a safe, reliable and reproducible technique [14]. IAH and ACS left significant influences on blood factors of the participants in the current study. To avoid overloading of massive fluid, starting resuscitation is mandatory [15]. IAH takes place in about 50% of critical care patients, 32.1% of which showed IAH and 4.2% develop ACS within the first day of admitting to ICU [16].

Patients with ACS succeed with pharmacological, practical and medical trials [16]. Significant differences detected between antibiotic administration and IAP in the current observation was comparable with this. IAH and ACS are serious threats in ill patients. Nurses in the ICU train to diagnose the IAH and ACS and do the right interventions.

Nursing training has to focus on evidence-based training strategies. Nurses should run standard care dealing with patients at risk of IAH and ACS [17]. Hence, prompt screening is essential to find patients who may show IAH and ACS [18]. IAH links to elevated SOFA scores, high APACHE II, high APACHE III, a further need for mechanical ventilation and insufficient PaO2: FiO2 ratios at admission time. Longer durations of the need for mechanical ventilation and lengths of stay at ICUs in such patients reaffirm the pathophysiological damages of raised ICP [19].

Also, our result was matching the reports that shock, SIRS, APACHE II, central venous oxygen saturation and GCS associated with IAP. The mechanical ventilation is independent predisposing to develop IAH with applying PEEP [20]. Based on the observation in the current study, we think IAP measure in ICU patients may help to define a proper prognosis and complete the intervention. We think further research needed to find new methods for direct investigation of IAH in the patients in ICU. In conclusion, the pathological features of IAH and ACS are appropriate markers to report systemic disorders and mortality in the ICU. Screening the IAH to monitor the signs of ACS is an economical and valuable way can discover complications in the ICU and may adjust treatment outcomes and reduce hospitality overheads.
