PROBLEMS OF PERTURBATION SERIES
IN NON-EQUILIBRIUM QUANTUM FIELD THEORIES

Abstract
In the standard framework of non-equilibrium quantum field theories, the pinch singularities associated to multiple products of $\delta$-functions do not cancel in a perturbative expansion unless the particle distributions are those for a system in thermal and chemical equilibrium.
Since the pioneering work of Keldysh \[1\], there have been many attempts to develop a formalism for non-equilibrium systems. Most of the studies follow the original method of Schwinger \[2\], which uses a Closed-Time-Path (CTP) in the complex-time plane \[3\]. Unlike the imaginary-time formalism, but closely related to the real-time formalism, this approach leads to a $2 \times 2$ matrix structure for the propagator \[4\].

One other approach, which is more recent, is Thermo-Field Dynamics \[5\]. There, the doubling of the degrees of freedom is assumed from the beginning. For equilibrium systems, one can show that the theory is completely equivalent to the real-time formalism \[4\]. The non-equilibrium version of TFD has been intensively studied over the last few years \[6\].

In this letter, we shall not discuss the relative advantages of one method over the other, but shall just make a very simple remark about the perturbative expansion, when one is using non-equilibrium particle distributions. We consider the scalar case. The most common form of the free propagator that is used in the literature is \[3, 4\]

$$
\begin{pmatrix}
D_{11}(K) & D_{12}(K) \\
D_{21}(K) & D_{22}(K)
\end{pmatrix}
= 
\begin{pmatrix}
\Delta(K) & 0 \\
0 & \Delta^*(K)
\end{pmatrix}
+ 
\begin{pmatrix}
n(k) & \theta(k_0) + n(k) \\
\theta(-k_0) + n(k) & n(k)
\end{pmatrix}
2\pi\delta(K^2 - m^2) \text{,}
$$

with the usual vacuum Feynman propagator

$$
\Delta(K) = \frac{i}{K^2 - m^2 + i\epsilon},
$$

and where $n(k)$ is an arbitrary distribution function (positive-definite). As a matter of fact, this is the only difference with the equilibrium case, where the propagator is exactly the same as in eq. \[4\], except that $n(k) = 1/(e^{|k_0|/T} - 1)$.
Self-interactions are taken as in the equilibrium case, i.e. one needs to distinguish two types of vertices, which will be called type-1 and type-2 vertices in the following. For a Feynman diagram with a certain configuration of type-1 and type-2 vertices, one uses a $D_{ab}(K)$ propagator when the momentum $K$ flows from a type-$a$ vertex to a type-$b$ one. For a $g^n \phi^n/n!$ interaction, type-1 vertices get a factor $(ig)$, whereas type-2 vertices get an opposite factor, $(-ig)$. These Feynman rules set up a formalism for non-equilibrium systems. They have been used many times in the literature [1–9].

Let us now see if the above Feynman rules give a well-defined perturbative expansion. Knowing the problems which arise at equilibrium, the first obvious question is the absence of pathologies, or “pinch singularities”. This is due to the presence of several $\delta(K^2 - m^2)$ terms in eq. (1). They appear as multiple products in high order calculations, and for individual graphs, lead to mathematically ill-defined expressions. At equilibrium, one has to sum over the different types of vertices in order to obtain the cancellation of such pathologies [4]. Surprisingly, this very question has almost always been occulted for the non-equilibrium case [7, 8].

We first consider the simplest case where such a cancellation should occur, if any. Suppose that we want to calculate the tadpole contribution at the 2-loop level shown in fig. 1, in the $g(\phi^4)_4$ interaction model. It is given by

$$g^2 \int \frac{d^4P}{(2\pi)^4} \int \frac{d^4K}{(2\pi)^4} \left[ (D_{11}(P))^2 D_{11}(K) - D_{12}(P) D_{21}(P) D_{22}(K) \right]. \quad (3)$$

Observing that the tadpole does not have any imaginary part and that $\text{Re}D_{11}(K) = \text{Re}D_{22}(K)$, one can factorize the $K$-integral and obtain

$$g^2 \int \frac{d^4K}{(2\pi)^4} \text{Re}D_{11}(K) \int \frac{d^4P}{(2\pi)^4} \left[ (D_{11}(P))^2 - D_{12}(P) D_{21}(P) \right]. \quad (4)$$
Then an easy algebraic manipulation shows that the term in the square brackets simplifies to

\[ [... = (\Delta(P))^2 + n(p) \left( (\Delta(P))^2 - (\Delta^*(P))^2 \right), \] (5)

which shows the absence of pinch singularities, or \( \Delta(P)\Delta^*(P) \) terms in the final result. The cancellation procedure works essentially the same way as in the equilibrium case and is here totally independent of the distribution function \( n(p) \). This result had previously been found in [7].

One should not claim victory too soon, though. This simple exercise in the \( \phi^4 \) model does not illustrate well the game of cancellation that is at play. In particular, in the previous example only two terms are involved, although the general case involves four terms.

Let us next consider a more complicated case. The only place where the pinch singularities can occur is in repeated self-energy insertions. Consider for instance the diagram shown in fig. 2. It contains the following expression

\[
\sum_{a,b} D_{1a}(P)\Sigma_{ab}(P)D_{b2}(P) = D_{11}(P)\Sigma_{11}(P)D_{12}(P) + D_{11}(P)\Sigma_{12}(P)D_{22}(P) \\
+ D_{12}(P)\Sigma_{21}(P)D_{12}(P) + D_{12}(P)\Sigma_{22}(P)D_{22}(P),
\] (6)

which must be free of pinch singularities, as it enters directly, at the two-loop level, into the calculation of a physical quantity (the decay rate), as we shall see in the following. For the same reason, the cancellation must also take place separately for \( p_0 > 0 \) and for \( p_0 < 0 \).

The different components of the self-energy can be related to each other by

\[
\Sigma_{11}(P) = -\Sigma_{22}^*(P) \\
\text{Im}\Sigma_{11}(P) = \frac{i}{2}(\Sigma_{12}(P) + \Sigma_{21}(P)).
\] (7)
These relations follow from the definition of the two-point matrix Green’s function in different chronological products, using the standard CTP contour \[3\]. They are independent of perturbation theory. Then, using (7), one can show that eq. (6) is free of pinch singularities provided

\[
(\theta(p_0)n(p) - \theta(-p_0)(1 + n(p))) \Sigma_{12}(P) = \epsilon(p_0)(\theta(p_0) + n(p))\Sigma_{21}(P). \tag{8}
\]

For \( p_0 > 0 \), one has

\[
n(p)\Sigma_{12}(P) = (1 + n(p))\Sigma_{21}(P), \tag{9}
\]

and when \( n(p) = 1/(e^{p_0/T} - 1) \), this gives

\[
\Sigma_{12}(P) = e^{p_0/T}\Sigma_{21}(P), \tag{10}
\]

which shows that eq. (8) can in fact be regarded as a non-equilibrium extension of the KMS relation.

The quantities \( \Sigma_{12} \) and \( \Sigma_{21} \), which are related through eq. (8), are two independent physical quantities. For a \( \lambda \phi^3 \) interaction model in \( n \) space-time dimensions, one has, at one loop,

\[
-i\Sigma_{12}(P) = \lambda^2 \int \frac{d^nK}{(2\pi)^{n-2}} (\theta(k_0) + n(k)) (\theta(p_0 - k_0) + n(p - k)) \\
\delta(K^2 - m^2)\delta((P - K)^2 - m^2). \tag{11}
\]

The kinematics are the same as in the equilibrium case, i.e. \( (E - p)/2 \leq k_0 \leq (E + p)/2 \), for \( p_0 = E \geq 0 \) and \( P^2 \geq m^2 \). Then, the statistical factors in the above equation are just the ones corresponding to outgoing particles. As in the equilibrium case, this allows us to relate \( \Sigma_{12} \) with the absorption (or decay) rate of the particle \[3\]. Similarly

\[
-i\Sigma_{21}(P) = \lambda^2 \int \frac{d^nK}{(2\pi)^{n-2}} (\theta(-k_0) + n(k)) (\theta(-p_0 + k_0) + n(p - k)) \\
\delta(K^2 - m^2)\delta((P - K)^2 - m^2) \tag{12}
\]
is related to the emission (or creation) rate. Strictly speaking, when $P$ is on shell, there is no kinematical phase space anymore in eqs. (11) and (12) and both expressions are equal to zero. But this is only true at the one-loop level. Beyond one-loop calculations, $\Sigma_{12}$ and $\Sigma_{21}$ no longer vanish when the external momentum goes on shell. Another way of looking at the problem is to consider two types of particles, $\phi_1$ and $\phi_2$, with two different masses and a coupling such as $\lambda \phi_1 \phi_2^2$ (for details see [9]). In this case, the interpretation of $\Sigma_{12}$ and $\Sigma_{21}$ as, respectively, the decay and emission rates, is more transparent.

According to the above discussion, the time evolution of the particle number density follows [9]

$$-2i p_0 \frac{d n(p, t)}{d t} = (1 + n(p)) \Sigma_{21}(P) - n(p) \Sigma_{12}(P).$$

(13)

We see that in order to have the cancellation of pinch singularities, one must have

$$\frac{d n(p, t)}{d t} = 0,$$

(14)

which is quite disappointing for a non-equilibrium framework! This is the first contradiction. However, this is not a real problem as it can be realized that for the propagator defined in (1), it must be assumed that the time variation of the density matrix is slow compared with the typical time scale between the particle interactions. If this is not the case, the Fourier transform in (1) just does not make sense. In the context of using (1), there is reversibility at the microscopic level, but one can impose some irreversibility at the macroscopic level.

But the main trouble is that, even assuming a slow variation of the density matrix, eq. (8) is not guaranteed to hold. The point is that the micro-reversibility conditions are well-known to be satisfied only by equilibrium
distributions \[10\]. This can be verified by explicit calculations using eqs. \(11\) and \(12\). Equation \(8\) can only be satisfied if the distribution \(n(p)\) is of the Bose–Einstein type. The only alternative to this result is to give up energy conservation at the vertices, which is not very satisfactory.

To see how deeply rooted the problem is, let us consider again the case of two types of particles, with two different initial temperatures \(T_1\) and \(T_2\), and a single weak interaction \(\lambda \phi_1 \phi_2^2\), which is switched on at some arbitrary time \(t_0\). Then the free propagators for \(\phi_1\) and \(\phi_2\) are just the same as in eq. \((1)\), with \(n(p)\) the Bose–Einstein distribution, but different temperatures for \(\phi_1\) and \(\phi_2\). At one loop, the self-energy for \(\phi_1\) involves only \(\phi_2\) fields, and it obeys the relation

\[
\Sigma_{12}(P) = e^{p_0/T_2} \Sigma_{21}(P),
\]

as \(\phi_2\) is thermalized with temperature \(T_2\). On the other hand, the temperature that enters \(n(p)\) in eq. \((8)\) is \(T_1\), not \(T_2\), so that the cancellation of pathologies occurs only when \(T_1 = T_2\).

Perhaps the most disappointing lesson of all this is to realize that it is not even possible to look at small deviations from equilibrium. Also, this problem is not specific to the relativistic case: it shows up in the same fashion in the non-relativistic limit.

Except for \[8\], this fact seems to have gone unnoticed in the literature. One way of solving this problem is to use Schwinger–Dyson equations. By using only exact propagators in one-loop calculations, there is no possibility of having pinch singularities. This is equivalent to giving up perturbation theory. As a matter of fact, this has been the usual way of doing calculations for non-equilibrium systems \[3\]. However, at some point, and unless the problem can be solved exactly, which is rather rare, one is forced to use some
perturbative input. In the light of our results, this has very weak justification as the bare perturbation series is ill-defined. In particular, terms that are associated with pinch singularities (which can be regularized by introducing some finite width in the propagator) are likely to give large and uncontrollable contributions.

In conclusion, it is impossible to make use of perturbation series with the propagators (1) outside an equilibrium framework. One must use time-independent Bose–Einstein distribution functions (the same is true for fermion fields, which have to obey the Fermi–Dirac statistics). This guarantees the cancellation of pinch singularities at all orders of the perturbation series. This cancellation is intimately tied to the micro-reversibility conditions. Note also that the same conditions ensure the cancellation of infrared and mass singularities (KLN theorem), which defines a well-behaved perturbation series [10].

The problem can clearly be solved in principle by working in the $T = 0$ representation of the system, but then the calculation is computationally intractable because of the complexity of the system. If we choose to work with any fixed-$T$ representation, then the system quickly leaves the vacuum state. We cannot treat the problem using the propagators (1), because then the $\delta$-function pathologies discussed here arise, so our only choice is to allow the state of the system to depart from the thermal vacuum; again, the problem quickly becomes computationally intractable because of the complexity of the state. Finally, we could choose the closest finite-$T$ vacuum to approximate the state of the system at each time, but then we are faced with the intractable task of transforming the state of the system as a function of time as the Fock states change with the changing thermal vacua.
We stress again that anything perturbative beyond linear response theory does not seem easily realizable. At present, there does not exist any correct way for deriving a consistent perturbative Green’s function formalism for a system that is even slightly out of equilibrium, without losing all of the advantages of working in finite-$T$ vacua.
