ABSTRACT
We have detected the optical counterpart of the proposed double degenerate polar RX J1914+24. The I-band light curve is modulated on the 9.5-min period seen in X-rays. There is no evidence for any other periods. No significant modulation is seen in J. The infrared colours of RX J1914+24 are not consistent with a main-sequence dwarf secondary star. Our ASCA spectrum of RX J1914+24 is typical of a heavily absorbed polar and our ASCA light curve also shows only the 9.5-min period. We find that the folded I-band and X-ray light curves are out of phase. We attribute the I-band flux to the irradiated face of the donor star.

The long-term X-ray light curve shows a variation in the observed flux of up to an order of magnitude. These observations strengthen the view that RX J1914+24 is indeed the first double degenerate polar to be detected. In this light, we discuss the synchronizing mechanisms in such a close binary and other system parameters.

Key words: accretion, accretion discs – stars: individual: RX J1914+24 – novae, cataclysmic variables – X-rays: stars.

1 INTRODUCTION

Cropper et al. (1998) reported X-ray observations of the cataclysmic variable (CV) RX J1914+24 which was discovered by Motch et al. (1996) in the ROSAT All-Sky Survey. Motch et al. also found that the X-ray flux was modulated at 9.5 min (= 569 s). This period is characteristic of intermediate polars (IPs: the non-synchronous magnetic CVs, Patterson 1994), but the shape of the folded light curve showed no X-ray flux for approximately half the 9.5-min period. This property is difficult to reconcile with our current understanding of IPs. Given the absence of any other periods, Cropper et al. (1998) suggested that RX J1914+24 was a polar, or AM Her system – the synchronous magnetic CVs (Cropper 1990, Beuermann & Burwitz 1995). This would imply that the binary orbital period is 9.5 min.

An orbital period of 9.5 min would be the shortest period of any known binary star. It would also exclude the secondary from being a main-sequence star (the shortest period allowed is ~80 min). For a non-degenerate He burning secondary, the minimum orbital period is ~13 min (Iben & Tutukov 1991). However, a degenerate He secondary can have a period in the range ~6–50 min (Tutukov & Yungelson 1996). Confirmation that RX J1914+24 is a double degenerate polar would have important implications for how magnetic binaries evolve. It would also be the first known magnetic system in which the accretion flow was predominately He-dominated.

Comparison between the X-ray position of RX J1914+24 (determined using the High Resolution Imager, HRI, on ROSAT) and the optical image of Motch et al. (1996) showed that star ‘H’ was the most likely optical counterpart (Cropper et al. 1998). This star is heavily reddened ($A_V$ ~5.6: Motch et al. 1996). To detect the optical counterpart of RX J1914+24 and search for periods other than the 9.5-min period seen in X-rays we have obtained images of the field of RX J1914+24 in the I band and at IR wavelengths, the rationale being that if no other periods were seen then this would strengthen the conclusion of Cropper et al. (1998) that RX J1914+24 is a double degenerate polar. We also report another set of X-ray data obtained using ROSAT and one obtained using ASCA.

2 X-RAY OBSERVATIONS

2.1 ROSAT data

Cropper et al. (1998) presented X-ray observations of RX J1914+24 taken using ROSAT (0.1–2.0 keV) at three distinct epochs. While the shape of the folded light curve was similar at each epoch, the peak intensity varies over time. To monitor the shape and intensity of the X-ray light curve we obtained a further set of data using the ROSAT HRI in 1997 October with a total exposure of 21.5 ks. We extracted a background-subtracted light curve in the same way as Cropper et al. (1998) and show it along
with the other ROSAT data in Fig. 1. We also show the folded light curve of the HRI data taken in October 1995 which was not shown in Cropper et al. (1998) as the exposure time was only 2.4 ks. These data show a range of maximum brightness: using a spectrum similar to that found in Section 2.2 for the ASCA data, the system was a factor of ~3 fainter in September 1993 compared with that in April 1996.

The data shown in Fig. 1 were folded on the linear ephemeris obtained by fitting the start of the rise from zero flux. From four epochs we obtained 108 timings. This gave a best-fitting ephemeris:

\[ T_0 = \text{HJD} 2449258.03941(6) + 0.0065902334(4). \]

The numbers in brackets give the standard error on the last digit. This allows us to phase all our data from 1993 September to 1998 July within 0.02 cycles.

### 2.2 ASCA observations

We obtained a 20-ks observation of RX J1914+24 in 1998 April 9–10 using ASCA (~0.5–10 keV). The data were extracted by applying the standard data selection criteria. The background was generated using a concentric annulus around the source. RX J1914+24 was detected only in the SIS detector and only below 1 keV. The light curve from the SIS0 detectors (the peak flux of the folded SIS1 data is approximately half that of SIS0) were analysed using a Discrete Fourier Transform code (DFT; Deeming 1975; Kurtz 1985). The amplitude spectrum is shown in Fig. 2: the most prominent amplitude peak corresponds to the 9.5-min period seen in the ROSAT data. The amplitude spectrum pre-whitened by the 9.5-min period (and harmonic) is also shown in Fig. 2. There is no evidence for a significant modulation at any other period.

The light curve derived from the SIS0 data was folded on the ephemeris determined in Section 2.1. We show the folded light curve in Fig. 1. The shape of the light curve during the bright phase is more peaked than the ROSAT HRI data taken in October 1997 but similar to that taken in April 1996. Using the spectral parameters found below we find that RX J1914+24 was fainter in X-rays by a factor of ~3 at the epoch of the ASCA observation compared with October 1997.

The ASCA spectrum (Fig. 3) could be fitted reasonably well (the best fit gave \( \chi^2 = 1.31 \), 20 degrees of freedom), with a low-temperature \( (kT \sim 40 \text{ eV}) \) blackbody plus interstellar absorption \( (N_H \sim 1 \times 10^{20} \text{ cm}^{-2}) \). The temperature and absorption were not well constrained. The upper limit (90 per cent confidence) to a thermal bremsstrahlung component (using an assumed temperature of 10 keV) corresponds to a 2–10 keV flux of 7.8 \( \times 10^{-14} \text{ erg cm}^{-2} \text{s}^{-1} \) (9 \( \times 10^{28} \text{ erg s}^{-1} \) at 100 pc). The bolometric luminosity of the blackbody component is \( \sim 1 \times 10^{38} \text{ erg s}^{-1} \) at 100 pc. This agrees very well with the estimate derived from the ROSAT spectrum (Cropper et al. 1998). The low flux from the bremsstrahlung component and the very large ratio between the soft blackbody component and the hard bremsstrahlung component is typical of polars (e.g. Ramsay et al. 1994). X-ray spectra of IPs typically have a strong medium energy component and rarely show a strong soft component.

### 3 OPTICAL–IR OBSERVATIONS

#### 3.1 I-band polarimetry

Observations were obtained on the nights 1998 June 25–27 using the 2.5-m Nordic Optical Telescope (NOT) on La Palma and the Andalucia Faint Object Spectrograph and Camera (ALFOSC) used in its imaging mode. On the first night, data were obtained over 7 h 26 min while this figure was 4 h 19 min and 7 h 55 min on the second and third nights respectively. The conditions were good and the seeing was typically 1 arcsec or better. To obtain circular polarimetry data a 1/4 waveplate was inserted into the optical path: this split the light into \( \sigma \) and \( \epsilon \) rays on the Loral 2k \( \times \) 2k CCD so that two images of each star were recorded. The instrument was orientated in such a way that images of field stars did not overlap with any of the stars of interest. The images were bias-subtracted and flat-fielded. A typical image is shown in Fig. 4. In the I-band finding chart of Motch et al. (1996) star ‘H’ is shown as a single star: in our I-band images (which were taken under good seeing) we find that star ‘H’ is made up of more than one star. This is consistent with our K-band image taken using United Kingdom Infrared Telescope (UKIRT) in service time in October 1997.

Profile-fitting photometry was carried out on the stars in the field using DAOPHOT (Stetson 1992). Since the profiles of the stellar images in the \( \sigma \) and \( \epsilon \) rays differed, two profiles had to be constructed – one for each ray. We obtained differential photometry between star ‘A’ and the stars in the immediate vicinity of star ‘H’ and Fourier Transformed their light curves.

© 2000 RAS, MNRAS 311, 75–84
The brightest component making up star ‘H’ was found to show a significant amplitude peak at 9.5 min in both the ‘upper’ and ‘lower’ polarized beams (see Fig. 5). This period corresponds to the period found in X-rays: this star is therefore the optical counterpart of RX J1914+24 (arrowed in Fig. 4). Neither star ‘B’ nor the fainter component of star ‘H’ were found to show any significant modulation. Whilst there are minor amplitude peaks at longer periods in both the ‘upper’ and ‘lower’ amplitude spectra, there is no peak which is seen in both spectra: therefore we conclude that these peaks are not significant.

We folded the $I$-band optical data of RX J1914+24 on the ephemeris in Section 2.1. These data are also shown in Fig. 1. The peak-to-peak amplitude is $\sim 0.07$ mag and the mean magnitude is $I \sim 18.2$ assuming the magnitude of star ‘A’ is $I \sim 13.4$ (Motch et al. 1996). This contrasts with the approximate magnitude of star ‘H’ as seen by Motch et al. in June 1993 of 16.6 mag. Even taking into account that star ‘H’ consists of more than one component (RX J1914+24 being 18.2 mag, the next brightest $\sim 19.6$), RX
J1914+24 was over 1 mag fainter in $I$ in June 1998 compared with June 1993.

If there is a second period hidden in the $I$-band data then its amplitude must be very small. From the noise level in the amplitude spectrum (Fig. 5.), any second period shorter than $\sim 5 $h must have a peak-to-peak amplitude less than 0.02 mag. This is much less than the variation generally seen in $I$-band photometry of other magnetic CVs. For example, in the case of the IP YY Dra, the orbital period of 3.97 h is clearly seen as a modulation with an amplitude of 0.12 mag in the $I$ band (Haswell et al. 1997). Since YY Dra is expected to have an accretion disc, the modulation of the secondary star will be diluted by the presence of a disc. In the case of discless systems such as RX J1914+24 (cf. Section 8.1), the amplitude is expected to be greater. For instance, $I$-band photometry of the polar V895 Cen in a low state (where there is no additional flux from cyclotron emission) shows a peak-to-peak amplitude of $\sim 0.4$ (Stobie et al. 1996). The lack of such a pronounced modulation in RX J1914+24 is further evidence that the secondary star in this system is not a main-sequence star.

The 1/4 waveplate and calcite block in the optical path allowed us to search for circular polarization in RX J1914+24. The circular polarization was derived for stars `A' and `B' in the finding chart of Motch et al. (1996) and also RX J1914+24. The instrumental polarization was found to depend on the position of the stellar image on the CCD. We made a first-order correction for instrumental polarization based on the assumption that star `A' has no intrinsic circular polarization. The corrected data of star `B' and RX J1914+24 were then folded on the ephemeris in Section 2.1 and are shown in Fig. 6. Star `B' shows a small net negative circular polarization indicating that there is probably some small residual effects of the polarization varying on the field position. In the case of RX J1914+24 there is a small positive ($\sim 0.3$ per cent) residual polarization, although there is no significant modulation over the 9.5-min period. We conclude that there is no intrinsic circularly polarized emission from RX J1914+24 in the $I$ band.

### 3.2 Infrared photometry

RX J1914+24 was observed using UKIRT on Mauna Kea on the nights 1998 July 2–3 mainly in the $J$ band, but images were also obtained in $H$ and $K$. On the first night conditions were good but in the second half of the second night conditions were poor and unusable. Images were obtained using IRCAM 3 operating in ND_STARE mode. In the $J$ band, a 12-s exposure was made then the telescope was shifted: this allowed us to make a flat field. Each resulting image was the result of six exposures.

Profile fitting was performed on the stars in each image using DAOPHOT (Stetson 1992). As with the NOT data, differential photometry was performed on star `B' and the optical counterpart of RX J1914+24 using star `A' as the comparison. The differential light curves were Fourier Transformed. The amplitude spectrum of RX J1914+24 is shown in Fig. 7: no significant modulations were seen in the light curves of either RX J1914+24 or star `B'. In the case of RX J1914+24 we folded the differential photometry on the ephemeris shown in Section 2.1 as shown in Fig. 1. As expected from the amplitude spectrum there is no evidence for a significant modulation on the 9.5-min period. However, the scatter is much greater than the folded $I$-band light curve and it is possible that a modulation similar to that seen in $I$ is hidden in the noise.

What amplitude do we expect to see in the $J$ band in normal CVs with main-sequence secondary stars? A modulation of

---

**Figure 5.** The amplitude spectra from the lower and upper polarized images of the brightest component of star `H' are shown in the top panel. The prominent amplitude peak corresponds to the 569-s (9.5-min) period seen in X-rays. The middle panel shows their window functions and the lower panel shows their amplitude spectra pre-whitened by the 569-s period.
~0.4 mag is seen in the IP FO Aqr (de Martino et al. 1994), while no significant modulation (<0.08 mag) is seen in the IP RX J1238−38 (Buckley et al. 1998) which at an orbital period of 84 min is below the period gap. From the noise level of the amplitude spectrum of the J-band photometry (Fig. 7), the upper limit for a modulation is an order of magnitude lower than observed in RX J1238−38. We conclude that this is a very low level for a main-sequence secondary star.

In addition to the J-band data we also obtained single images in H and K bands. As before, differential photometry was performed between the optical counterpart of RX J1914+24 and star ‘A’ and ‘B’. These differential magnitudes were placed onto the standard systems from observations of faint UKIRT standard stars. Table 1 shows the reduced magnitudes. We also show the dereddened magnitudes and fluxes assuming an extinction of $A_V = 5.6$ mag (Cropper et al. 1998). This corresponds to $A_I = 2.72$, $A_J = 1.59$, $A_H = 0.97$ and $A_K = 0.63$ assuming $R = 3.1$ and the observed ratios in Fitzpatrick (1999). The K-observed magnitude of 17.1 compares with 16.4 when we obtained our service observation in October 1997.

### Table 1.
The apparent, together with the dereddened magnitudes and dereddened fluxes of RX J1914+24 assuming an extinction of $A_V = 5.6$ mag on 1998 July 2, 3.

| Band | Mean magnitude | Dereddened magnitude | Dereddened flux (erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$) |
|------|----------------|---------------------|-----------------------------------------------|
| I    | 18.2 ± 0.05    | 15.5                | 8.1 ± 0.3 × 10$^{-16}$                         |
| J    | 17.3 ± 0.10    | 15.7                | 1.7 ± 0.2 × 10$^{-16}$                         |
| H    | 17.4 ± 0.15    | 16.4                | 3.3 ± 0.06 × 10$^{-17}$                        |
| K    | 17.1 ± 0.15    | 16.5                | 1.0 ± 0.06 × 10$^{-17}$                        |

We now use the dereddened fluxes shown in Table 1 to estimate whether the spectral continuum could be fitted with a simple

4 THE OPTICAL NEAR-IR FLUX

The dereddened colours in Table 1 do not depend greatly on the precise value of the assumed extinction. Decreasing the extinction from $A_V = 5.6$ to 5.0 changes the colours $(I - K)$, $(J - H)$ and $(H - K)$ by 0.17, 0.06 and 0.03 mag respectively. To compare the dereddened infrared colours of RX J1914+24 with late-type dwarf stars we show in Fig. 8 the colours of RX J1914+24 in the $(I - K)$, $(J - H)$ and $(I - K)$ planes together with old disc dwarfs with spectral types K7 to M7.5 (Bessell 1991). It is clear that the dereddened infrared colours of RX J1914+24 are not consistent with a dwarf late main-sequence secondary star. (We should add a note of caution at this stage that our I-band observations were not simultaneous with our JHK observations, but were earlier by a week.)

We now use the dereddened fluxes shown in Table 1 to estimate whether the spectral continuum could be fitted with a simple
blackbody model as would be roughly the case for a low-temperature white dwarf. The errors in our data increase rapidly from $K_t$ towards $I_t$, since they are dominated by the uncertainty in the amount of reddening involved (the errors shown in Fig. 9 include the uncertainty in the photometric mean magnitude and also an uncertainty in the extinction of $A_V$): 5). Despite this, it is clear from our blackbody fits, plotted in Fig. 9, that the spectrum is far too hot to be explained simply by the blackbody component alone. In Fig. 9 we show the data and three fixed-temperature blackbody fits. No satisfactory blackbody fit was found to fit the data well, although a higher temperature fit is less poor than a cooler one. If the blackbody temperature is left as a free parameter in the fit, it will tend towards infinity. Were we to assume that the extinction towards RX J1914+24 was lower than $A_V = 5.6$, (say $A_V = 4.0$) then we can obtain a good fit and lower temperature ($\sim 13,000$ K).

Taking the extinction found by fitting the X-ray spectra as representative of the optical extinction, these results suggest that in the optical-IR region of the spectrum there is a component, additional to a blackbody, which adds to the emission at shorter wavelengths. This could be due to emission from the accretion stream, cyclotron emission from the white dwarf or an irradiated component on the donor white dwarf. We now address these possibilities in turn.

Although we cannot exclude emission from a hot accretion stream this seems unlikely because the $I$-band-folded light curve (Fig. 1) would be double peaked unless we are viewing the system at a low inclination. For a magnetic field of a few MG (see Section 8.1) the optically thin (and hence polarized) part of the cyclotron spectrum is likely to be in red wavebands. Since we do not observe a significant circularly polarized flux in $I$ the magnetic field is either stronger than we expect (in which case the optically thin cyclotron harmonics would be in the UV) or it is very low (in which case the optically thin cyclotron harmonics would be in the far-IR). On the other hand, it is also possible that a shock does not form above the accretion region on the primary star.

Because the binary components are unusually close, we expect the secondary white dwarf to intercept an appreciable part of the accretion flux. Observations of conventional polars show that the irradiated surface of the secondary is brighter in the trailing hemisphere (e.g. Southwell et al. 1995). Assuming that the irradiated surface is much larger than the accretion region on the primary star, then this would imply that the $I$-band flux peaks between $\phi = 0.2$–0.6 cycles after the X-ray peak – which is indeed what we observe (Fig. 1). We conclude therefore that the variation in $I$ is probably due to irradiation of the secondary by the X-rays produced at the accretion region on the primary star.

If this is indeed the case, then we can also make the assumption that the origin of the 9.5-min period seen in the $I$-band amplitude spectrum (Fig. 5) is caused by the secondary star. On the other
hand, the 9.5-min period seen in the ASCA amplitude spectrum (Fig. 2) is due to the accretion region on the white dwarf. The fact that the amplitude peaks in the ASCA and 1-band amplitude spectra are indistinguishable is further evidence that RX J1914+24 is synchronized.

### 5 THE MASS OF THE SECONDARY STAR

For semidetached binaries, the Roche lobe filling condition implies a unique relation between the average density of the donor star and the binary orbital period (see e.g. Frank, King & Raine 1992, equation 4.8). Assuming that the 9.5-min period detected in RX J1914+24 is indeed the orbital period and that the Roche lobe approximation is valid for degenerate stars, the average density of the secondary star will be about $4600 \text{ g cm}^{-3}$. The typical density of a main-sequence star is $\approx 100 \text{ g cm}^{-3}$. Thus, the deduced high density of the secondary star immediately places it into the class of degenerate dwarfs. Using the Nauenberg (1972) mass-radius relation for white dwarfs and the Eggleton (1983) approximation for the Roche lobe volume radius, we estimate that the mass of the secondary star is about $0.08 \text{M}_\odot$.

### 6 THE DISTANCE TO RX J1914+24

If we assume for the sake of argument the 9.5-min seen in RX J1914+24 is the spin period and there is a second period (the orbital period) which has been missed for some reason (i.e. the system is an IP) – what would the minimum distance be to the system? Taking the empirical relation for the spin and the orbital periods for IPs

$$P_\text{orb} \approx 10P_\text{spin}$$

(Barrett, O’Donoghue & Warner 1988), we estimate that the orbital period would be $\approx 95 \text{ min}$. If the secondary star is a main-sequence star filling its Roche lobe, a 95-min orbital period implies a mass and radius of $0.12 \text{M}_\odot$ and $0.16 \text{R}_\odot$ respectively (e.g. Warner 1995).

Bailey (1981) derived a surface-brightness relationship

$$S_K = K + 5 - 5 \log D + 5 \log r_2,$$

from which we can deduce the distance if the surface brightness of the star in the $K$ band ($S_K$), the distance ($D$, in pc) and the radius of the secondary star ($r_2$, in solar units) are known. The mass and radius of the secondary star in RX J1914+24, deduced from the assumed 95-min orbital period, implies a spectral type of K7–M3 for the star. We have already noted that this is not consistent with our IR colours. For main-sequence stars, $S_K \approx 4.4$ (Ramsay 1994). Using the dereddened $K$ magnitude in Table 1, we obtain a value of 310 pc for the lower limit to distance of RX J1914+24. This distance is consistent with the mean distance of known CVs. However, if RX J1914+24 is at a distance of 310 pc, the bolometric luminosity given in Cropper et al. (1998) should be increased by a factor of $\sim 10$. Then the mass-transfer rate of the system is now as high as $6 \times 10^{-6} \text{M}_\odot \text{yr}^{-1}$. Such a high mass-transfer rate is difficult to be explained by current orbital evolution theories. We therefore consider this as further evidence for a double degenerate interpretation. If we have a longer orbital period, i.e. $P_\text{orb} > 10P_\text{spin}$, then this problem is significantly worse.

We now go on to determine a distance based on the measurement of the extinction to RX J1914+24. The solar system lies in a region of space which has a lower hydrogen density compared with the surrounding region (e.g. Warwick et al. 1993). The distance to the edge of this low-density region depends on the direction. This has been determined, for instance, by the distribution in the sky of white dwarfs visible in the soft X-ray band (e.g. Barstow et al. 1997). Because the X-ray spectrum of RX J1914+24 is heavily reddened (Section 2.2), this implies that it is at a distance greater than the distance to the edge of the low-density region. Using the map of distance to the edge of the low-density region as a function of galactic coordinates in Barstow et al. (1997) we find that the distance to RX J1914+24 is greater than $\sim 100 \text{ pc}$, assuming that the absorption we observe is not internal to the binary system.

If we assume that the 1-band flux can be characterized by a blackbody, we find that a blackbody with the volume of a secondary Roche lobe for a 9.5-min period will give the dereddened 1-band flux (Table 1) at a distance of 100 pc if it has a temperature of $\sim 9500 \text{ K}$. For a distance of 400 pc we need to increase the temperature to $\sim 60000 \text{ K}$ to match the dereddened 1-band flux. While caution should be exercised when comparing the temperatures of accreting white dwarfs with non-accreting white dwarfs (since the latter have no external heat source), non-accreting white dwarfs generally have temperatures $\approx 60000 \text{ K}$ (Barstow et al. 1993). Whilst there is some uncertainty regarding the appropriateness of adopting a blackbody, it nevertheless suggests that RX J1914+24 lies at a distance of $\sim 100–400 \text{ pc}$. If there is significant heating of the secondary in the form of irradiation, then the upper limit will be less than 400 pc.

### 7 LONG-TERM VARIATIONS IN INTENSITY

In Fig. 1 we show the X-ray folded light curves taken at various epochs over a space of 5 years. To compare the peak count rate using ROSAT PSPC and ASCA to that of the ROSAT HRI we used the best-fitting spectral parameters of fitting the ASCA spectrum with an absorbed blackbody (Section 2.2). The equivalent HRI count rate as a function of time is shown in Fig. 10. We find that this X-ray flux varies by approximately an order of magnitude. If this X-ray variation is reflected in the optical–IR flux then this would correspond to a range in optical brightness of 2.5 mag. This is similar to the range seen in the long-term optical light curve of the polar AM Her (Feigelson, Dexter & Liller 1978). On the other hand, IPs (which have a reservoir of material in the form of a disc), do not (in general) show such a large range in brightness. We also show the I- and K-band magnitudes at two epochs which are broadly consistent with the change in the X-ray flux. There is no evidence for a correlation between the shape of the light curve (Fig. 1) and the intensity.

The most obvious cause for the long-term intensity changes is a variation in the mass-transfer rate. In conventional polars various schemes have been proposed to explain these variations although none have been fully developed. One such scheme is that of magnetic activity, such as star spots, near the L1 point on the secondary somehow affects $M$ (e.g. Barrett, O’Donoghue & Warner 1988; Livio & Pringle 1994).

### 8 DISCUSSION

Cropper et al. (1998) argued that RX J1914+24 was a double degenerate polar to account for the lack of a second period in the ROSAT data and the shape of the X-ray light curve. This is
supported by our \( I \) band and ASCA light curves and by the lack of any variation at any other period in the \( J \) band. Further, the long-term X-ray light curve and the ASCA spectrum is typical of polars. These observations reinforce the proposal of Cropper et al. (1998) that RX J1914.124 is a double degenerate polar. We now go on to discuss system parameters such as the magnetic field strength of primary stars and the forces which would be needed to keep RX J1914.124 synchronized.

8.1 Lower limit to the magnetic field of the primary

As no other periods apart from the 9.5-min period have been detected in either the X-ray or \( I \)-band light curves, we conclude that RX J1914.124 does not have an accretion disc. For accreting white dwarfs, the absence of an accretion disc can be due to a strong white-dwarf magnetic field. When the Alfvén speed, which depends on the local magnetic field strength and the density of the accretion flow, is much larger than the Keplerian speed at the circularization radius, an accretion disc cannot be formed. As an approximation, we may use the criterion:

\[
\mu_1 > 1.7 \times 10^{33} \left( \frac{\eta}{0.3} \right) \left( \frac{P_{\text{orb}}}{60 \text{ min}} \right)^{7/6} \left( \frac{M_1}{M_\odot} \right)^{5/6} \left( \frac{L}{10^{36} \text{ erg s}^{-1}} \right)^{1/2} \tag{3}
\]

(Wickramasinghe, Wu & Ferrario 1991) to deduce the lower limit to the magnetic moment of the primary star, \( \mu_1 \), and hence the corresponding limit to the white-dwarf polar magnetic field strength. Here, \( M \) is the accretion rate and \( \eta \), which approximately equals 0.3, is a parameter which takes into account the angle of the stream as it leaves the inner Lagrangian point (Lubow & Shu 1975).

Using equation (3) we show in Fig. 11 the surface field strength required to equate the Alfvén speed and the Keplerian speed at the circularization radius, as a function of the accretion rate. We also show the lower limit to the polar magnetic field of the primary white dwarf in binaries for various white-dwarf masses \( M_1 \) and accretion luminosities \( L \). The orbital period of the binary is fixed at 9.5 min. As shown, if the accreting white dwarf is not massive \((\leq 1 M_\odot)\) and accretion rate is low \((\leq 10^{18} \text{ g s}^{-1})\), a small polar field \((\leq 1 \text{ MG})\) is sufficient to prevent the accretion-disc formation.

From the ROSAT PSPC data, Cropper et al. (1998) deduced that the bolometric accretion luminosity of RX J1914+24 is \( \sim 10^{35} - 10^{36} \text{ erg s}^{-1} \) (for a distance of 100 pc and hydrogen column density \( N_H \approx 1 \times 10^{22} \text{ cm}^{-2} \)). If the mass of the primary white dwarf in RX J1914+24 is about 1.0 \( M_\odot \), the surface polar field strength of the white dwarf is probably \( \sim 1 \text{ MG} \).

8.2 The synchronizing torques

While it is possible that an orbital period longer than the 9.5-min period is hidden in the data, let us assume that RX J1914+24 is indeed synchronized. The geometrical configuration and synchronization of conventional polars have been investigated by many authors (e.g. Chanmugam & Wagner 1977; Joss, Katz & Rappaport 1979; Lamb et al. 1983; Campbell 1983, 1997; Lamb & Melia 1987; King, Frank & Whitehurst 1990; Wu & Wickramasinghe 1993). Some earlier studies (e.g. Chanmugam & Wagner 1977) implied that the discless and synchronization conditions are equivalent. Although synchronization ensures discless accretion, discless accretion may not imply perfect synchronism. A proper treatment of synchronization involves magneto-hydrodynamic (MHD) interaction between the stars and the
plasma between them (see Campbell 1997) and also the physics of stellar structures of magnetic stars. The issue of synchronization and formation of ultra-short period double degenerate binaries is beyond the scope of this paper and deserves a separate study. Here we discuss synchronism in RX J1914+24 briefly only in terms of a crude comparison between the strengths of the accretion torque and the restoring magnetic torques.

The accretion torque which operates about the spin axis of an accreting star is given by

\[ N_{acc} = \frac{2\pi MR^2}{P_{orb}} \approx 2 \times 10^{35} \text{ dyne cm} \]

\[ \times \left( \frac{M}{10^3 \text{ g s}^{-1}} \right) \left( \frac{P_{orb}}{10 \text{ min}} \right)^{1/3} \left( \frac{M_\odot}{1.0 \text{ M}_\odot} \right)^{2/3} \]

where \( P_{orb} \) is the orbital period and \( R \) is the Roche lobe of the star. For a system with an accretion luminosity of about \( 10^{36} \text{ erg s}^{-1} \), which corresponds to a mass-transfer rate of \( \sim 10^{18} \text{ g s}^{-1} \), the accretion torque is \( \sim 10^{35} \text{ dyne cm} \). Taking the accretion luminosities deduced in Cropper et al. (1998), we find that the accretion torque on the primary white dwarf in RX J1914+24 is 10–100 times that of conventional polars (see Wu & Wickramasinghe 1993). We now investigate whether this exceeds the available synchronizing torque.

In conventional polars, the accretion torque is counter-balanced by the magnetic torque and the system maintains synchronism. Two types of magnetic restoring torque have been proposed. The first type is due to the torque arising from magneto-static dipole/multipole interaction between the primary and the secondary star. The second type is due to the torque arising from the MHD interaction between the stars and the plasma between the stars. In general the second type of torque requires that the secondary star, which is a main-sequence star, has a convective envelope threaded by the magnetic field of the primary degenerate star. Ohmic dissipation occurs at the envelope of the secondary star when the system departs from synchronism.

We can make an estimate of the torque due to magneto-static interaction between the dipole/multipole components of the primary star and the dipole of the secondary star using the equations in Wu & Wickramasinghe (1993). For an orbital period of 9.5 min, the orbital separation is \( \sim 10^{19} \text{ cm} \). The ratio of orbital separation to the radius of the accreting white dwarf is \( \sim 20 \) for a 1 M\(_\odot\) white dwarf. For \( B = 10 \text{ MG} \) and \( \mu = 1 \times 10^3 \text{ G cm}^3 \) we find from Wu & Wickramasinghe (1993) that the torque due to magneto-static interaction is of the order of \( 10^{35} \text{ dyne cm} \) or less. (There is some uncertainty since we do not know the magnetic field configuration). This is of the same order or less than the accretion torque (equation 4). Therefore it is not clear if this mechanism alone is able to maintain the synchronism of RX J1914+24.

Degenerate white dwarfs are highly conducting bodies. When synchronism is disturbed, ohmic dissipation occurs much more efficiently in the plasma between the stars than in the stellar envelopes of the white dwarfs. Thus, the large-scale MHD instabilities of the field configuration will determine the strength of the restoring magnetic torque (Lamb et al. 1983). According to Lamb & Melia (1988), if both the primary and secondary stars have non-negligible magnetic moments, the MHD torque acting on the primary star is

\[ N_{\text{MHD}} = 5 \times 10^{35} \text{ dyne cm} \left( \frac{\gamma}{0.5} \right) \left( \frac{a}{10^{10} \text{ cm}} \right)^{-3} \]

\[ \times \left( \frac{\mu_1}{10^{33} \text{ G cm}^3} \right) \left( \frac{\mu_2}{10^{33} \text{ G cm}^3} \right) \]

where \( \mu_1 \) and \( \mu_2 \) are the magnetic moments of the primary and the companion stars respectively, \( \gamma \) is the pitch angle of the dipole magnetic field of the primary star at the companion star and \( a \) is the orbital separation. For the configurations of polars, the value of \( \gamma \) is approximately 1 (Low 1982; Lamb et al. 1983).

For a primary with mass \( \sim 1 \text{ M}_\odot \), Fig. 11 implies that the surface magnetic field of the primary is \( \sim 1 \text{ MG} \) and the companion stars has a similar intrinsic or induced magnetic moment. Equation (5) implies that the MHD synchronizing torque is of the order of \( 5 \times 10^{35} \text{ dyne cm} \). If the mass-transfer rate is not much higher than \( 10^{18} \text{ g s}^{-1} \), the MHD synchronizing torque is several orders of magnitude greater than the accreting torque (equation 4) and is able to ensure that the system is in synchronous rotation.

It is worth noting that in deriving equation (4) the magnetic field is ignored and the angular momentum is assumed to be transferred from the accretion flow to the star directly. For a magnetically channelled flow, the interaction between the accretion flow and the star is more complicated. A recent study (Li, Wickramasinghe & Rüdiger 1996) has shown that angular momentum can be transferred from the accretion flow to the star only via the magnetic stress. In non-synchronously rotating systems, the accretion flow interacts with the magnetic field of the accreting star. In polars, as the field lines of the two stars are interconnected, the accretion flow interacts magnetically with both stars. This may allow the angular momentum of the accretion flow to distribute between the two stars and hence to be transferred to the orbit. Thus, equation (4) probably overestimates the strength of these first-order considerations of the destabilizing torque due to accretion. The synchronism of RX J1914+24 is therefore likely to be more stable than expected from a balance between the MHD torque and the conventional accretion torque.

### 8.3 Mass-transfer rate

The mass transfer in low-mass semidetached binaries is generally driven by the orbital evolution. When the orbital angular momentum of a binary decreases, the orbital separation shrinks, causing matter to overflow the Roche lobe of the secondary star and accrete onto the primary star. For short (\( \lesssim 3 \text{ h} \)) period systems, gravitational radiation is an efficient process for angular momentum loss, while for long (\( \gtrsim 3 \text{ h} \)) period systems magnetic braking is the dominant process (e.g. Verbunt & Zwaan 1981).

Magnetic braking requires the presence of a stellar wind from the secondary star by which the angular momentum is transported. In double degenerate systems there is no stellar wind. Magnetic braking therefore cannot operate, regardless of the orbital period and whether the system is synchronized or not (see Li, Wu & Wickramasinghe 1994). If RX J1914+24 is indeed a double degenerate system, then the orbital evolution of RX J1914+24 should be solely driven by gravitational radiation.

The mass-transfer rate for gravitational radiation-driven orbital
evolution is:
\[
M \approx 1.5 \times 10^{-6} M_\odot \text{ yr}^{-1} \\
\times \left[ \frac{m_1^2 m_2^2}{(m_1 - m_2)} \left( \frac{P_{\text{orb}}}{10 \text{ min}} \right)^{-8/3} \right] 
\]
\[
\approx \left( \frac{1}{(m_1 - m_2)} \right) \left( \frac{P_{\text{orb}}}{10 \text{ min}} \right)^{-8/3},
\]  
(Eq. 6)

(cf. Faulkner 1971; Wickramasinghe & Wu 1994), where \(m_1 = M_1/M_\odot, m_2 = M_2/M_\odot\) and \(\alpha = 5/6 + n/2\), where \(n\) is related by the form \(R \sim M_1^2\). For normal stars, \(n = 1\), giving \(\alpha = 4/3\), while for low-mass He white dwarfs, \(n = -1/3\), giving \(\alpha = 2/3\). For \(m_1 = 1.0, m_2 = 0.08\) (cf. Section 5) and an orbital period of 9.5 min, the expected mass-transfer rate is \(M \approx 1.8 \times 10^{-8} M_\odot \text{ yr}^{-1} \approx 1.1 \times 10^{18} \text{ g s}^{-1}\) for a He white dwarf. This is consistent with the value (Cropper et al. 1998) deduced from the ROSAT PSPC data. As mass transfer in RX J1914+24 cannot be driven by magnetic braking or nuclear evolution, the agreement between the observed accretion luminosity and predicted mass-transfer rate shows evidence of the operation of gravitational radiation in close binaries.

9 CONCLUSIONS

We have found the optical counterpart of RX J1914+24. Our new optical and X-ray data strengthen the suggestion of Cropper et al. (1998) that RX J1914+24 is the first-known double degenerate polar and has the shortest orbital period of any known binary system. We suggest that the variation in the \(I\)-band flux is due to the irradiated face of the secondary white dwarf. The long-term X-ray light curve shows a variation in flux of an order of magnitude (typical of polars). We estimate that the secondary white dwarf has very low mass (0.08 \(M_\odot\)) and the primary white dwarf has a magnetic field strength greater than a few MG. For double degenerate binaries the dominating synchronizing torque is that of MHD interaction between the two stars and the accretion stream while mass transfer is driven solely by gravitational radiation.

ACKNOWLEDGMENTS

We would like to thank both the staff of the NOT and the UKIRT for their help at the telescopes. Some of the data presented in this paper have been taken using ALFOSC, which is owned by the Instituto de Astrofísica de Andalucia (IAA) and operated at the Nordic Optical Telescope under agreement between IAA and the NBIFaA of the Astronomical Observatory of Copenhagen. UKIRT is operated by the Joint Astronomy Centre on behalf of PPARC. We gratefully acknowledge Darragh O'Donoghue for the use of his period analysis software. KW acknowledges the support from the ARC through an Australian Research Fellowship and PH acknowledges the support from the Academy of Finland.
