INTRODUCTION

Assimilate partitioning has long been recognized as a target for crop improvement because it can limit the yield potential of the crop plants. Despite the great importance of rice as a major crop, most of the mechanisms of photoassimilate allocation in rice are yet to be elucidated. Utilizing mutants that exhibit phenotypes relevant to a particular biological phenomenon can be a powerful approach to uncovering potential regulators of that phenomenon. In the source leaves of higher plants, both starch and sucrose are the major primary products of photosynthesis; therefore any anomaly in the accumulation of the two compounds may arise from mutations in the genes involved in assimilate allocation. In particular, the accumulation of an extraordinarily high level of leaf starch is easily recognizable by iodine staining, and thus has been repeatedly reported as the “starch excess” phenotype. Starch excess in the leaves is often observed when any inhibition occurs (1) in the export of photoassimilate from source leaves or (2) in starch metabolism in the leaves. The former case includes disruption or suppression of the phloem-loading sucrose transporter (Bürkle et al., 1998; Gottwald et al., 2000) and blockade of the route of assimilate transport (Russin et al., 1996). Cold-girdling of the stem is also known to induce the starch excess phenotype through the impairment of photoassimilate transport (e.g., Krapp et al., 1993). As an instance of the latter case, the Arabidopsis thaliana Starch EXcess 1 (SEX1) mutant (Caspar et al., 1991) is the most well-known because of its significant contribution to the current understanding of leaf starch metabolism, i.e., \(\alpha\)-glucan water dikinase (GWD, EC 2.7.9.4)-mediated degradation. Disruption of the plastid-localized maltose translocator (Niytya et al., 2004) is also known to result in starch excess in the leaf, as well as some other mutations of starch degradation-related enzymes (Crichley et al., 2001). As is clear from the above described examples, the study of mutant plants exhibiting the starch excess phenotype in their leaves is a good approach to acquiring a better understanding of the mechanisms and regulation of photoassimilate allocation.

Thus far, no rice mutant that accumulates a high level of starch in the leaf blades has been reported. However, in our preliminary experiments, we found that pronounced starch accumulation occurred in detached leaf blades when sucrose was fed through their cut ends. This finding suggested that a rice mutant exhibiting the starch excess phenotype could exist and that it might be caused by a disorder in the mechanism controlling photoassimilate partitioning. We therefore decided to screen for mutant lines accumulating high levels of starch in their leaf blades. Here we report the isolation and characterization of the first leaf starch excess mutant of rice.

Keywords: assimilate partitioning, gene disruption mutant, \(\alpha\)-glucan water dikinase, leaf starch, rice
MATERIALS AND METHODS
SCREENING OF THE LEAF STARCH EXCESS MUTANTS
In this study, we used a collection of rice mutant lines induced by the insertion of the endogenous retrotransposon Tos17 (Miyao et al., 2003). To screen for mutants displaying the leaf starch excess (LSE) phenotype, 20 seeds of the M2 or M3 generation of Tos17 mutant lines were grown to the fourth leaf stage in the greenhouse. The terrestrial parts were sampled in the morning and leaf starch was visualized by iodine staining.

GENE MAPPING
Mapping populations were obtained from crosses between mutants with the japonica background and an indica/japonica crossbred rice cultivar “Takakari.” In the F2 generation, mutant plants were selected by iodine staining of the terrestrial parts. DNA was extracted according to the method reported by Wang et al. (1993) from the leaf segments of plants showing the mutant phenotype. Gene mapping was carried out using micro-satellite SSR markers (McCouch et al., 2002).

ANALYSIS OF THE GENE STRUCTURE
Genomic DNA was extracted from green leaves by using the DNeasy Plant Kit (Qiagen, Valencia, CA, USA) and was used as the template for polymerase chain reaction (PCR) with PrimeStar GXL DNA Polymerase (Takara Bio Inc., Shiga, Japan) following the manufacturer’s instructions. The nucleotide sequences of the PCR primers are listed in Table 1. For the analysis of the transcript structures, total RNA was extracted from the leaf blades and reverse-transcribed as below, and the resultant cDNA was used as the template for PCR with ExTaq DNA polymerase (Takara Bio Inc.).

GENERATION OF TRANSGENIC RICE PLANTS
For complementation analysis a 13.2-kb genomic DNA fragment containing the entire open reading frame (ORF) along with 2.2-kb sequence upstream of the putative translation start point of OsGWD1 (Os06g0498400) was amplified by PCR using the primer pair, GWD1-PL2/R14 (Table 1), genomic DNA of the rice cultivar Nipponbare (as the template), and PrimeStar GXL DNA polymerase (Takara Bio Inc.). The DNA fragment was introduced into a transformation vector, pZH28 (Kazoda et al., 2010). For gene suppression analysis, a 0.4-kb fragment of OsGWD1 was amplified using ExTaq DNA polymerase (Takara Bio Inc.), with the GWD1-L4/R2 primer pair (Table 1) and cDNA from green seedlings, and introduced into the RNAi transformation vector, pANDA (Miki and Shimamoto, 2004). Transgenic rice plants were generated using the Agrobacterium tumefaciens-mediated method described by Hiei et al. (1994), and grown in a temperature-controlled glasshouse (30/23°C, day/night).

QUANTITATIVE RT-PCR ANALYSIS
For the analyses of mRNA abundance, rice plants were grown in plastic pots filled with nursery soil for rice seedlings. For tissue-specific expression analysis, rice seedlings were grown in a greenhouse under natural light conditions. For expression analyses of diurnal changes, rice plants were grown in a growth chamber with a 14-h light (27°C)/10-h dark (23°C) photoperiod. The light intensity in the light period was 350 μmol m−2 s−1 and the light was emitted by fluorescent light tubes. Once the tissue samples were obtained from the plants, they were immediately frozen in liquid nitrogen and stored at −80°C until use. Total RNA was extracted from various tissue samples using the extraction buffer described by Chang et al. (1993), although polyvinylpyrrolidone and spermidine were excluded. The extracted RNA was then purified using an RNeasy Mini Kit (Qiagen) followed by a TURBO DNA-free Kit (Ambion, Austin, TX, USA) to remove DNA. The purified RNA was reverse-transcribed and then an aliquot of the first-strand cDNA mixtures corresponding to 5 ng of total RNA was used as the template for real-time quantitative reverse transcription (RT)-PCR analysis using the SuperScriptIII Platinum Two-Step qRT-PCR Kit with SYBR Green (Life Technologies, Austin, TX, USA). The reaction was carried out using an ABI7300 system (Applied Biosystems, Foster City, CA, USA) with the gene-specific primers listed in Table 1. In preliminary experiments, aliquots of the PCR reactions were electrophoretically separated on agarose gels to verify the specificity of the primers. The specificity of each PCR amplification was also checked using a heat dissociation protocol with temperatures changing from 60 to 95°C following the final cycle of the PCR. The results obtained for each cDNA were standardized to the expression of the rice polyubiquitin gene (RUBIQ1), which is a constitutively expressed gene in rice (Wang et al., 2000).

DETERMINATION OF STARCH AND SOLUBLE SUGAR CONTENTS
Frozen leaf samples were ground using a mortar and pestle under cryogenic conditions. A portion of the ground tissue (~25 mg per sample) was immediately weighed and then extracted twice with 80% ethanol at 80°C. After centrifugation at 8500 g for 5 min, the supernatant was dried in vacuo, dissolved in distilled water, and used to assay sucrose, glucose, and fructose by the enzymatic method using F-kit #716260 (F. K. International, Tokyo, Japan), which contains an invertase, a hexokinase, a glucose-6-phosphate dehydrogenase (G6PDH), and a phosphoglucomutase. The residual pellet obtained after centrifugation was dried in air, resuspended in distilled water, gelatinized by boiling for...
contamination from the G6PDH enzyme solution was negligible. Above, Next, as for the same digested starch samples, we also measured CO2-assimilation rates in the leaf blades were measured using the method described by Sasaki et al. (2005) with modifications. In brief, 13CO2 was fed to rice seedlings under the light intensity of around 750 μmol m⁻² s⁻¹, in a controlled glasshouse (27/23 °C, 14-h day/10-h night, the day period from 5:00 to 19:00). 13C gas was liberated from BaCO3 powder (≥98 atom%), Cambridge Isotope Laboratories, Andover, MA, USA) mixed with 7.3 M H3PO4 inside the box. All the 13C-feeding was ceased by removing the plastic box, the aboveground parts of the seedlings were sampled at designated times, immediately after the cessation of 13C-feeding (13:00), in the evening of the same day (19:00), and in the morning of the next day (7:00). The aboveground samples were divided into leaf blades and sheaths, and then stored at −80°C until use. 13C contents, the frozen tissue samples were freeze-dried, followed by measuring dry weight. The dried tissue materials were ground to a fine powder, and a portion (ca. 200 μg) of the tissue powder was used for the determination of 13C content. The total carbon and 13C contents were determined using an elemental analyzer (NC2500, Thermoquest, San Jose, CA, USA) and a mass spectrometer (Delta Plus System, Thermoquest). The 13C content in each tissue sample was calculated according to the equation of Sasaki et al. (2005). Partitioning of 13C-photosynthate to the leaf blades was calculated from the total amounts of 13C in leaf blades, 13C in leaf sheaths, 13C in the leaf blades, and 13C in the leaf sheaths, according to the following equation:

\[
\frac{\text{[13C]LB}}{\text{[13C]LB} + \text{[13C]LS}} \times 100 = \frac{\text{13C-partitioning to leaf blades}}{\text{(leaf blades)}}
\]

Rice leaf starch excess mutant

**SCREENING OF THE LEAF STARCH EXCESS MUTANTS AND THE LSE1 PHENOTYPE**

Of 6377 T0 T07 mutant lines, 5 were selected by iodine staining to detect distinct accumulation of leaf starch (stain-positive plants). One of the five lines designated as ND0717, exhibited dark staining for starch in the entire terrestrial portion while the wild-type plants did not show any discernible staining (Figure 1). Because the seeds originally used for the screening were M2 seeds, i.e., those borne...
on the M1 generation plants, they segregated into stain-positive and stain-negative plants. The progeny of these M2 plants were further tested for leaf starch accumulation, and in the M3 generation, the progeny of some stain-negative M2 plants segregated into stain-positive and stain-negative ones at a ratio of 1:3, suggesting that the LSE phenotype was due to the recessive mutation of a single gene. To establish homozygously mutated lines, the progeny of stain-positive M2 plants were examined to check whether all the individuals showed the stain-positive phenotype. Based on the results of this analysis, of the 15 original M2 plants, 2 were identified as having the homozygous mutant genotype, 2 as wild-type, and the remaining 11 as having the heterozygous genotype. After this, we used the progeny of the two putative homozygous mutant plants as the pure line for the mutation and designated this mutation LSE1, while the progeny of the two putative wild-type genotype plants were used as controls in the various assays in this study and were designated “wild-type.” The starch content in the mature leaf blades of LSE1 plants was 5- to 10-fold higher than that in the wild-type plants throughout the day (Figure 2A). Contrasting, the sucrose content in the leaf blades was not different between the two (Figure 2B).

**GENE MAPPING OF THE LSE1 MUTATION**

Southern blot analysis revealed that the LSE phenotype of LSE1 was not tagged by the Toxs17 retrotransposon; it was therefore believed to be caused by some other mutation (data not shown). In order to identify the responsible gene for the mutation, gene mapping was carried out. The responsible gene was mapped to a 1.16-Mb region on chromosome 6 flanked by two genetic markers RM20061 and RM20104 (McCouch et al., 2002). Although as many as 77 genes are annotated within this region, it was significant that a gene for a putative GWD, Os06g0498400, was located in this region because disruption of the corresponding orthologs in both Arabidopsis (SEX1 mutant; Caspar et al., 1991) and Lotus japonicus (Vriet et al., 2010). Therefore, we decided to further explore this gene as a major candidate gene causing the LSE1 phenotype, and the gene Os06g0498400 was designated as OsGWD1. As the first
step, we examined whether the structure of the OsGWD1 gene was different between the LSE1 mutant and the original cultivar Nipponbare, by genomic PCR analysis using several primer combinations designed based on the published DNA sequence of Os06g0498400. OsGWD1 has been predicted to be a relatively complex gene structure comprising as many as 32 exons, and it was found that the OsGWD1 gene in the LSE1 mutant had a long deletion of 3434 bp corresponding to the nucleotide position from 7415 to 10758 of the reference sequence in the database, NC_008399. As a result, OsGWD1 in the LSE1 mutant lacks the exons from the 22nd to the 32nd (Figure 3A).

**EXPRESSION ANALYSIS OF OsGWD1 IN LSE1 AND THE WILD-TYPE PLANTS**

The transcript of OsGWD1 in the leaf blades was analyzed in both LSE1 and the original cultivar Nipponbare by RT-PCR. According to the gene structure and the sequences of the cDNA clones in the database, the transcript of OsGWD1 was predicted to be ~4.4 kb in wild-type plants and to contain a 1421-bp deletion in the case of LSE1, and the primer pairs were designed to check the structure of the transcript (Figure 3B). With a primer pair that spanned the LSE1 deletion (L18/R14; Figure 3C), a shorter PCR product was amplified with the expected size in LSE1, and no PCR product was detected with a left primer that was located within the deletion (L4/R14; Figure 3C).

To determine the expression pattern of OsGWD1 in normal rice plants, real-time RT-PCR analysis was conducted using various tissues from 2-week-old plants and 4-day-old germinating seeds of Nipponbare. The mRNA levels in both leaf blades and sheaths were relatively high, while those in the roots were much lower (Figure 4A). The diurnal change in the mRNA level of OsGWD1 was also examined using the fully expanded leaf blades of 2-week-old plants, grown with a 14-h light period (Figure 4B). The mRNA level of OsGWD1 was highest in the early night (20:00) and then decreased until the next noon (12:00).

**FUNCTIONAL COMPLEMENTATION OF OsGWD1 IN THE LSE1 MUTANT**

To examine whether OsGWD1 is responsible for the LSE1 mutation, the mutant plants were introduced with a genomic DNA fragment from Nipponbare containing the entire ORF along with a 2.2-kb sequence upstream of the putative translation start point.
of OsGWD2. As expected, it was observed that OsGWD2 from Nipponbare restored the LSE1 phenotype to wild-type; the starch content in the leaf blades of the transgenic LSE1 plants was lower and was similar to that seen in the controls (Figure 5). In addition, when the RNAi construct for OsGWD2 was introduced into Nipponbare plants, the starch level in the leaf blades increased significantly compared to that in the controls (Figure 5). This hypothesis was strongly supported by the complementation test for the LSE1 mutation with an intact OsGWD1 in wild-type plants. As a result, grain yield reductions of 20–40% were observed in LSE1 compared with the control lines, in all the field trials conducted.

DISCUSSION

To date, a number of mutants have been reported for the hyper-accumulation of starch in their leaves. In maize, several mutant lines exhibiting the LSE phenotype have already been reported, for example, Sdx1 (Russin et al., 1996), Tdy1 (Braun et al., 2006), and Psc (Slewinski and Braun, 2010), all of which are related to photoassimilate export from the leaves. In rice, however, no such mutation has been documented so far; to our knowledge, LSE1 is the first such case. Gene mapping and gene structure analysis revealed that the LSE1 mutant has a deletion of as much as 3.4 kb in OsGWD1, a putative gene for α-glucan water dikinase, and consequently, accumulates aberrant mRNA lacking one-third of the coding region in the leaf blades (Figure 3). Therefore, LSE1 was assumed to be a loss-of-function mutant of OsGWD1. This hypothesis was strongly supported by the complementation test for the LSE1 mutation with an intact OsGWD1 and by RNAi-mediated suppression of OsGWD1 in Nipponbare plants (Figure 5). Disruption of the genes for GWD has already
been reported to lead to the LSE phenotype in Arabidopsis (SEX1; Caspar et al., 1991), L. japonicus (Vriet et al., 2010), and tomato (Nashaliev et al., 2009), all of which are observed to show LSE phenotype. In normal plants, a higher level of the OsGWD1 transcript was observed in leaf blades and sheaths but a much lower level was seen in roots (Figure 4A), showing agreement with the pattern of starch accumulation in LSE plants visualized by iodine staining (Figure 1). The transcript level of OsGWD1 in leaf blades changed diurnally and peaked just after the onset of the dark period (Figure 4B), which seems reasonable as it is believed to play a role in the degradation of starch accumulated during the light period. A similar diurnal change in the GWD transcript level has been reported in Arabidopsis (Yu et al., 2001; Smith et al., 2004). However, GWD protein level was shown not to change diurnally (Yu et al., 2001; Lu et al., 2005). Further investigation including diurnal change in GWD activity is needed to better understand this problem. The biochemical and physiological functions of GWD have been extensively studied in the Arabidopsis SEX1 mutant and are now believed to involve phosphorylation of the glucosyl residues in starch, which facilitates amylolytic degradation (see Blennow et al., 2002 for a review). In the present study, it was observed that leaf starch from the LSE1 plants contained less G6P than that from wild-type plants, consistent with observations in Arabidopsis SEX1 (Yu et al., 2001). Accordingly, OsGWD1 appears to fulfill the same role in the process of leaf starch degradation in rice as in other plant species in which disruption mutants of GWD genes are reported. In other words, it was suggested that GWD has universal importance in the degradation of leaf starch among higher plants.

While LSE1 shares considerable similarity in its phenotype with the reported mutants of GWD, a conspicuous difference was found in the vegetative growth; LSE1 grows normally unlike the GWD mutants of Arabidopsis and L. japonicus (Figure 6A). The reason for this difference is not clear. However, it may be relevant to the physiological priority of leaf starch in the photosynthetic assimilates. In rice leaf blades, newly fixed carbon is preferentially directed to sucrose biosynthesis rather than starch, in contrast to other plant species such as Arabidopsis. This is evident from the fact that the content of starch and sucrose in rice leaf blades at the end of the day is ca. 5 and 20 mg per gram flesh weight (gFW$^{-1}$), respectively, while that reported for Arabidopsis in the literature is around 10 and 1 mg gFW$^{-1}$, respectively (Figures 2A,B; e.g., Chai et al., 2004). Accordingly, rice may have sufficient capacity for the synthesis of sucrose to achieve normal growth without the transient starch in the chloroplast, and thus may experience limited impact on growth when the mobility of the transient starch is impaired by a lesion in OsGWD1. This view is reinforced by the observation that a knockout mutant of the ADP-glucose pyrophosphorylase (AGPase) gene, OaAPL1, grows normally although it accumulates less than 5% of starch in the leaf blades in comparison with wild-type plants (Rösti et al., 2007). In addition, the sucrose synthesized in photosynthetic cells was considered to be exported from the source leaves of LSE1 as efficiently as wild-type plants, consistent with observations in Arabidopsis SEX1 (Yu et al., 2001). Accordingly, OsAPL1 appears to fulfill the same role in the process of leaf starch degradation in rice as in other plant species in which disruption mutants of GWD genes are reported. The biochemical and physiological functions of GWD have been extensively studied in the Arabidopsis SEX1 mutant and are now believed to involve phosphorylation of the glucosyl residues in starch, which facilitates amylolytic degradation (see Blennow et al., 2002 for a review). In the present study, it was observed that leaf starch from the LSE1 plants contained less G6P than that from wild-type plants, consistent with observations in Arabidopsis SEX1 (Yu et al., 2001). Accordingly, OsGWD1 appears to fulfill the same role in the process of leaf starch degradation in rice as in other plant species in which disruption mutants of GWD genes are reported. In other words, it was suggested that GWD has universal importance in the degradation of leaf starch among higher plants.

While LSE1 shares considerable similarity in its phenotype with the reported mutants of GWD, a conspicuous difference was found in the vegetative growth; LSE1 grows normally unlike the GWD mutants of Arabidopsis and L. japonicus (Figure 6A). The reason for this difference is not clear. However, it may be relevant to the physiological priority of leaf starch in the photosynthetic assimilates. In other words, it was suggested that GWD has universal importance in the degradation of leaf starch among higher plants.
Recently Weise et al. (2012) reported in maize that RNAi suppression of a GWD gene did not affect the vegetative growth in spite of a high level of starch accumulation in leaves. Thus, together with our results, suggests that vegetative growth of grass species is less dependent on GWD-mediated leaf starch remobilization than the dicot species reported.

Nevertheless, it should be also noted that the grain yield of LSE1 was significantly lower than that of wild-type plants and Nipponbare because of combined suppression of yield components (Table 2). This finding indicates that the impairment of GWD exerted some adverse effect on reproductive growth, although such effects are not apparent in vegetative growth. It is possible that the impairment of GWD in LSE1 slightly affected growth throughout the lifecycle in a manner that was not detectable in the short-term, and the significant reduction in the yield traits might be a manifestation of the cumulative effects. Information on the effect of GWD mutation on the reproductive growth is still limited, although Andriotis et al. (2012) recently reported that mature seeds of Arabidopsis SEX1 mutant have less lipid content than seeds of wild-type plants due to starvation of the carbohydate in the fruit imported from the maternal plant. Here again, mutant plants lacking leaf starch can be a good reference because they share unavailability of leaf starch in common with LSE1. However, the results reported are inconsistent; AGPlane mutants lacking leaf starch, rice apo1 (Röist et al., 2007) and maize agp1-m1 (Slewinski et al., 2010) showed no reduction in productivity under controlled environment whereas the latter mutant did exhibit yield reduction when grown in the field (Schlosser et al., 2012). It may be possible that the adverse effects of the mutation become apparent only in the field where plants routinely experience various environmental stresses unlike in the greenhouse. It may be also assumed that in LSE1 some disorder in starch metabolism in the stem reserve was brought about by the mutation because the stems of rice accumulate starch before heading to meet a large demand of carbohydrate for grain filling and also to buffer unfavorable environmental conditions after heading (see Siewinski, 2012 for a review).

In conclusion, the LSE1 mutation in rice, i.e., disruption of OsGWD1, resulted in a mild phenotypic change at the whole plant level, highlighting the variable physiological priority of leaf starch among plant species. In addition to LSE1, we have isolated additional Tos17 mutant lines exhibiting the LSE phenotype, and some of these LSE mutants appear to exhibit a severe phenotype with respect to growth (Hirose, Aoki, Miyao, Hirochika, unpublished). Analysis of the LSE mutants as well as the identification of the responsible genes would increase our understandings of the molecular mechanism and/or physiological significance of photoassimilate allocation in rice.

ACKNOWLEDGMENTS

We would like to express our gratitude to Ms. Kikko Takatsuo, NARO Agricultural Research Center for the excellent technical assistance; to Drs. Haruto Sasuki, Naoko Uehara, and Tomohito Egami for their help in the analysis of 13C-photoassimilate partitioning, and to the technical staffs of the ISAS, The University of Tokyo for their cultivation management of rice. We measured 13C by means of mass spectrometry at the Asia Natural Environmental Science Center, The University of Tokyo. This work was supported in part by the Japan Society for the Promotion of Science (JSPS), KAKENHI grant number 22380017, to Tatsuro Hirose, Naohiro Aoki, and Ryu Ohashi. Masaki Okamura is a recipient of a fellowship from the JSPS.
