ABSTRACT

Objective: The purpose of this study was to investigate the effect of low consumption of iron tablets during pregnancy on the risk of low birth weight. This case–control study included 56 women who gave birth to infants weighing <2500 g in RSUD Kota Depok and Bekasi. The control group consisted of 112 mothers who gave birth to infants weighing ≥2500 g.

Methods: This study was performed from September 2015 to December 2015. Data were collected from patient's medical records and via structured interviews with questionnaires.

Results: We found that, among the study participants, 73.2% were aged 20-35 years, 76.2% had a gestational age ≥37 weeks, 61.3% had 1-3 children, parity, time from previous delivery was >2 years in 53.6%, 95.2% did not complete antenatal examinations, 95.8% had a body weight of ≥40 kg before pregnancy, 91.1% showed a ≥5 kg increase in body weight during pregnancy, 45.8% had a high school education, 88.7% were housewives, hemoglobin level was ≥11 g/dl in 63.1%, and 53.0% did not consume heme-containing food daily. Only 53% of the participants consumed an adequate amount of iron, whereas the remaining 47% consumed less than the recommended amount of iron. Bivariate tests revealed that women who consumed an inadequate amount of iron during pregnancy had a 6.08-fold higher risk of low birth weight than women who consumed an adequate amount of iron during pregnancy.

Conclusions: The strongest risk factor for low birth weight was inadequate consumption of iron during pregnancy (odds ratio [OR] = 5.87; 95%, CI: 2.76-12.49) followed by inadequate gestational age (OR = 4.27; 95%, CI: 2.76-12.49).

Keywords: Anemia, Low birth weight, Iron tablets, Pregnancy.
METHODS

This was a retrospective observational study with a case control design.  
1. Cases: Women who delivered low birth weight babies (<2500 g) in RSUD Kota Depok and RSUD Kota Bekasi between September 1, 2015, and December 13, 2015.  
2. Controls: Pregnant women who delivered babies with normal weight (≥2500 g) in RSUD Kota Depok and RSUD Kota Bekasi between September 1, 2015, and December 13, 2015.  

The minimal sample number was calculated to be 56 women per group according to the following formula (Lwanga and Lemeshow, 1991):  
\[ n = \frac{(z_{1-\alpha/2})^2 \times \left[ P(1-P) + P(1-P) \right]}{(P - P)^2} \]

Inclusion criteria were receipt of iron tablets from the government program during pregnancy and delivery in RSUD Kota Depok or RSUD Kota Bekasi between September 1, 2015, and December 13, 2015. The exclusion criteria were delivery of twins, morbidity such as pre-eclampsia, eclampsia, hypertension, heart disease, blood vessel disorder, diabetes mellitus, and infection, delivery of babies with congenital disorders, or denial of consent for inclusion in this study. A questionnaire was used as a reference in the interview. This questionnaire consisted of a combination of closed- and open-ended questions to obtain information about antenatal examination history, compliance with consumption of iron tablets, consumption habits and daily life, and characteristics not included in medical records such as body weight, height, and weight gain during pregnancy.

Data were also collected from the medical records of the participants and their babies. Secondary data collected from participants’ medical records included participants’ identities, characteristics, and hemoglobin levels. Participant’s identities included name, medical records number, address, and phone number. Participant’s characteristics included maternal age, gestational age, and parity; time from the previous delivery, education, and occupation.

Secondary data collected from the medical records of the babies included weight, sex, and the presence or absence of congenital abnormalities.

Data were subjected to univariate, bivariate, and multivariate analysis. Univariate analysis was performed to obtain the frequency distribution of maternal characteristics on nominal or ordinal scales; maternal characteristics analyzed included age, gestational age, parity; time from previous delivery, education, occupation, height, weight before pregnancy, weight gain during pregnancy, hemoglobin level, antenatal examination status (complete or incomplete), and adequacy of iron tablet consumption during pregnancy. Bivariate analysis was performed using the Chi-square test \((\chi^2)\) with \(a = 0.05\) and 95% confidence interval (CI) to determine the correlation between dependent and independent variables and to calculate the risk of each independent variable to a dependent variable using odds ratios (ORs). Multivariate analysis was performed using a logistic regression multivariate test to identify the variable that conferred the highest risk of low birth weight.

\[
\text{OR} = \frac{a/b}{c/d} = \frac{ad}{bc}
\]

OR: Odds ratio (risk of incidence of low birth weight)  
\(a/b\): Ratio of the number of exposed cases to the number of unexposed cases  
\(c/d\): Ratio of the number of exposed cases to the number of unexposed controls  

Interpretation:  
OR <1: Exposure is a protective factor  
OR = 1: Exposure has no effect on case incidence  
OR >1: Exposure is a risk factor

RESULTS AND DISCUSSION

The number of cases and controls in this study was 56 and 112, respectively. Of these, 19 cases and 38 controls were from RSUD Kota Depok, whereas the other 37 cases and 74 controls were from RSUD Kota Bekasi. The characteristics of the study participants are described in Table 1; data regarding the consumption of iron tablets are described in Table 2. CI: LBWB, low birth weight baby. NBWB, normal birth weight baby. OR: As shown in Table 3, the Chi-square test revealed a correlation between iron tablet consumption and the incidence of low birth weight \((p<0.05)\), with an OR of 6.081. This indicates that women who did not consume sufficient iron during their pregnancy had a 6.081-fold higher risk of low birth weight compared to women who consumed a sufficient amount of iron during their pregnancy.

Effects of confounding factors on the incidence of low birth weight in RSUD Kota Depok and RSUD Kota Bekasi

Table 4 summarized the results of bivariate Chi-square test and regression analysis conducted to determine the effect of confounding factors on the incidence of low birth weight. In this study, the correlation between maternal age at delivery and the incidence of low birth weight was not statistically significant \((p=0.414)\). Among women who gave birth to low birth weight babies, the proportion of women with adequate \((≥237\) weeks) gestational age \((57.1\%)\) was higher than that of women with inadequate \((<237\) weeks) gestational age \((42.9\%)\). The correlation between gestational age and low birth weight babies was statistically significant \((p=0.000)\). The incidence rate of low birth weight was higher in mothers with a birth range of 2 years \((51.8\%)\) than in mothers with a birth range of >2 years \((48.2\%)\). The correlation between birth range and low birth weight was not statistically significant \((p=0.325)\). Among women who gave birth to low birth weight babies, the proportion of women with body weight ≥40 kg before pregnancy \((92.9\%)\) was higher than that of women with body weight <40 kg before pregnancy \((71.1\%)\). The correlation between body weight before pregnancy and the incidence of low birth weight was statistically significant \((p=0.172)\). Among women who gave birth to low birth weight babies, the proportion of women with height ≥146 cm was higher \((96.4\%)\) than that of women with height <146 cm \((3.6\%)\).

The correlation between maternal height and the incidence of low birth weight was not statistically significant \((p=0.270)\). Among women who gave birth to low birth weight babies, the proportion of women with ≥5 kg weight gain was higher \((87.5\%)\) than that of women with <5 kg weight gain \((12.5\%)\). The correlation between body weight gain during pregnancy and the incidence of low birth weight was not statistically significant \((p=0.251)\). The proportion of women with high education \((at least a high school education)\) was higher \((55.4\%)\) than that of women with low education \((44.6\%)\). The correlation between maternal education and the incidence of low birth weight was not statistically significant \((p=0.263)\). An equal proportion of women had hemoglobin levels <11 g/dl and 11 g/dl at delivery. The correlation between hemoglobin levels and the incidence of low birth weight was statistically significant \((p=0.013)\). The proportion of women who underwent a complete antenatal examination \((89.5\%)\) was higher than that of women who underwent an incomplete antenatal examination \((10.7\%)\). The correlation between antenatal examination and the incidence of low birth weight was statistically significant \((p=0.010)\).

Maternal age at delivery of <20 years and >35 years is one of the risk factors for low birth weight \([9]\). Maternal age <20 years is associated with immature reproductive organs for pregnancy, whereas maternal age >35 years is associated with decreased fertility of reproductive
also reported a significant relationship between gestational age and the incidence of low birth weight. Inadequate pregnancy age is closely related with immature organs [9]. The risk of low birth weight in women aged <20 years is almost 2-fold greater than that in women aged 20-29 years [10]. Inadequate pregnancy age was one of the factors associated with low birth weight because the mother's condition is still considered to be insufficiently recovered and her nutritional status is suboptimal [9]. Maternal anthropometry such as body weight before pregnancy and height plays an important role in fetal development. Low body weight before pregnancy and weight gain during pregnancy are important predictors of fetal development [10].

Time from previous delivery affects maternal hormonal and nutritional conditions. A short birth range is one of the risk factors for low birth weight because the mother's condition is still considered to be insufficiently recovered and her nutritional status is suboptimal [9]. Maternal anthropometry such as body weight before pregnancy and height plays an important role in fetal development. Low body weight before pregnancy and weight gain during pregnancy are important predictors of fetal development [10].

A high education status is considered to increase access to information and health services that can improve the quality of maternal and infant health. The higher the level of education, the easier it is for mothers to understand the concept of a healthy lifestyle. Restu et al. [8] found a significant correlation between educational level and the incidence of low birth weight. A study by Chimire and Ghimire [12] in Nepal revealed a greater frequency of low birth weight in mothers with anemia (22%) than in non-anemic mothers (9%). Restu et al. [8] reported a significant relationship between gestational age and the incidence of low birth weight.

Table 1: Characteristics of study participants

| Description                                      | LBWB n=56 (%) | NBWB n=112 (%) | Total n=168 (%) |
|--------------------------------------------------|---------------|----------------|----------------|
| Age (years)                                      |               |                |                |
| <20                                               | 7 (12.5)      | 8 (7.1)        | 15 (8.9)       |

found that low maternal hemoglobin (<11 g/dL) was a risk factor for low birth weight (OR = 3.45; 95%, CI: 1.59-7.49). Consistent with this, Sharma et al. [13] found that maternal hemoglobin levels of <11 g/dL were significantly associated with low birth weight (adjusted OR = 0.51; 95%, CI: 0.24-1.07).

Early antenatal examination in pregnancy is enormously beneficial to fetal growth and development, as well as maternal health. Risk factors for low birth weight can be detected during antenatal examination, enabling the implementation of strategies to reduce this risk. A study by Fourn et al. [14] of factors associated with low birth weight found that an adequate antenatal examination was a protective factor against the incidence of low birth weight (OR = 0.85; 95%, CI: 0.69-0.99). Consistent with this, a study conducted by Sistiari [15] at Banyumas Hospital revealed a significant correlation between antenatal examination and the incidence of low birth weight (p = 0.001; OR = 5.85; 95%, CI: 1.9-17.88).

Consumption of heme-containing food can fulfill the nutritional needs of mothers for iron during pregnancy. Poor nutritional intake during pregnancy may cause a deficiency of micronutrients needed for fetal growth and development. Sharma et al. [13] found that lack of nutritious food intake during pregnancy was significantly associated with the incidence of low birth weight (adjusted OR = 1.99; 95%, CI: 1.28-3.10). On the basis of bivariate test results, we included the following variables in logistic regression analysis: Consumption of iron tablets, gestational age, antenatal examination status, body weight before pregnancy, and hemoglobin levels. The results are shown in Table 5.

The results of the logistic regression multivariate tests revealed that inadequate consumption of iron tablets during pregnancy was the strongest risk factor for low birth weight (OR = 5.87; 95%, CI: 2.76-12.48), followed by inadequate gestational age (OR = 4.27; 95%, CI: 2.76-12.49).

CONCLUSION

Women who consumed an inadequate amount of iron had a 6.08-fold higher risk of delivering low birth weight babies than women who consumed an adequate amount of iron during their pregnancies. The strongest risk factors for the incidence of low birth weight were inadequate consumption of iron during pregnancy (OR = 5.87; 95%, CI: 2.76-12.48), followed by inadequate gestational age (OR = 4.27; 95%, CI: 2.76-12.49).
