Inelastic neutron scattering measurements on single crystals of superconducting BaFe$_{1.84}$Co$_{0.16}$As$_2$ reveal a magnetic excitation located at wavevectors $(1/2 \ 1/2 \ L)$ in tetragonal notation. On cooling below $T_C$, a clear resonance peak is observed at this wavevector with an energy of 8.6(0.5) meV, corresponding to 4.5(0.3) $k_B T_C$. This is in good agreement with the canonical value of 5 $k_B T_C$ observed in the cuprates. The spectrum shows strong dispersion in the tetragonal plane but very weak dispersion along the c-axis, indicating that the magnetic fluctuations are two-dimensional in nature. This is in sharp contrast to the anisotropic three dimensiona3 spin excitations seen in the undoped parent compounds.

Understanding the physics of superconductivity in high-$T_c$ cuprates and other unconventional superconductors remains a central unresolved problem at the forefront of condensed matter physics. One widespread school of thought maintains that magnetic fluctuations are intimately involved in the pairing mechanism. This view is supported by a growing number of neutron scattering investigations showing the appearance of a magnetic excitation coincident with the onset of superconductivity [1, 2, 3, 4, 5, 6, 7, 8]. The spectrum shows a resonance at a wavevector related to the antiferromagnetic order in the non-superconducting parent compounds. The apparent resonance energy scales with $T_C$ for different cuprate materials exhibiting a wide range of superconducting transition temperatures [9], providing tantalizing evidence for a common mechanism related to magnetic fluctuations.

The discovery of a new family of Fe-based high temperature superconductors with $T_C$ as high as 55 K presents an exciting opportunity to examine the relationship of spin excitations to the superconducting condensate in unconventional superconductors. The new materials are composed of Fe containing planes (FeAs or FeSe). Both theory and experiment indicate that simple electron-phonon coupling cannot describe superconductivity in these materials [10, 11, 12, 13, 14, 15, 16]. Furthermore, the superconducting state exists in close proximity to magnetism as the parent compounds exhibit spin-density wave order [14, 15]. These observations have been put forth as evidence that the superconductivity in the Fe-based materials is unconventional. The presence of the Fe planes suggests quasi-two-dimensionality, as observed in the cuprates. However, neutron scattering investigations of the spin waves in the undoped parent compounds SrFe$_2$As$_2$ [21], BaFe$_2$As$_2$ [22], and CaFe$_2$As$_2$ [23], indicate anisotropic exchange that cannot be classified as two dimensional. Band structure calculations [24, 25] indicate that doping should enhance the two-dimensionality of the Fermi surface, favoring superconductivity [25]. Directly probing the magnetic fluctuations in superconducting Fe-based systems is crucial for further progress.

Recent measurements on a polycrystalline sample of Ba$_{0.6}$K$_{0.4}$Fe$_2$As$_2$ found a spin excitation that appears at the onset of superconductivity [26]. However, it is not possible to unambiguously extract the detailed wavevector dependence of magnetic fluctuations from measurements on polycrystalline samples and, hence, single crystal measurements are essential.

In this letter, we report inelastic neutron scattering measurements on homogeneous single crystals of BaFe$_{1.84}$Co$_{0.16}$As$_2$ (BFCA) with $T_C=22$ K [27]. These measurements indicate a quasi-two-dimensional (2d) magnetic excitation at a wavevector related to the ordering wavevector of the parent compound, BaFe$_2$As$_2$ [28, 29]. The intensity of this excitation is strongly enhanced at the resonance energy upon entering the superconducting state. The resonance energy is found to be 8.6(0.5) meV or 4.5(0.3) $k_B T_C$, similar to the value observed in the cuprates providing a strong indication that the underlying physics is related at a deep level.

Single crystals of BFCA were grown using FeAs flux. The starting materials FeAs and CoAs were prepared by heating the elements to 1060 ºC for several hours in silica ampoules followed by furnace cooling to room temperature. BaFe$_2$As$_2$ was prepared by heating Ba and FeAs in a Ta tube to 1200 ºC for 12 h, and 1000 ºC for 36 h, followed by furnace cooling. Ba metal (99.9 % purity) was handled in a glove box containing less than 1ppm of oxygen and water. All other elements used were better than 99.99 % pure For the crystal growth an alumina crucible
was loaded with 8 g of BaFe$_2$As$_2$, 1.32 g of CoAs, and 6.54 g of FeAs and sealed in a silica ampoule. The ampoule was heated to 1200°C for 24 h and then cooled to 1090°C at 1°C/h and removed from the furnace and spun to remove the excess flux.

The resulting crystals exhibit a tetragonal structure with space group I4/mmm. The tetragonal unit cell of BaFe$_2$As$_2$ contains 2 Fe atoms per plane. The Fe atoms in each plane form a square lattice but the near-neighbor Fe-Fe vector lies along a direction rotated by 45° from the tetragonal a-axis (see Fig. 1(a)). With a tetragonal lattice constant, $a$, the square lattice has a lattice constant of $\sqrt{2}a$. The wavevector of greatest interest is $(1/2 1/2)$ or equivalently $(\pi/a, \pi/a)$ in tetragonal notation, equivalent to $(1/2, 0)$ or $(\pi/\sqrt{2}a, 0)$ in square lattice notation. Electronic structure calculations indicate a Fermi surface nesting instability at this wavevector [24, 25, 30], and indeed the ordering wavevector in the parent compounds [28, 29, 31, 32] is $(1/2 1/2 L)$ (indexed as $(1 0 L)$ in orthorhombic notation). As discussed in Ref. [25] the different notations are mixed in the literature. In this letter we use tetragonal notation exclusively.

For the neutron scattering measurements, three single crystals of BFCA with a total mass of 1.8 g were co-aligned in the (HHL) plane. The data in Fig. 1(b) was collected using the ARCS direct geometry chopper spectrometer at the SNS. The remainder of the data presented here was collected with the HB-3 triple-axis spectrometer (TAS) at the HFIR configured with collimations of 48'-40'-80'-120' with a fixed final energy of 14.7 meV with pyrolitic graphite (PG) monochromator and analyzer crystals.

Fig. 1(b) shows data collected on ARCS with $E_i$ of 60 meV corrected for empty can background. The measured data is energy integrated from 5 to 25 meV and projected onto the (HK0) plane with L integrated from -2.5 to 1.5. This plot shows intensity as a function of Q along (H00) and (0K0). The data shows a sharp excitation centered at $Q=(1/2 1/2)$. This observation is confirmed by constant-E scans ($E=9.5$ meV) along (H00) measured on the HB-3 TAS (Fig 1(c)) which also show a peak centered at the $(1/2 1/2)$ position.

Fig 1(c) shows scans along (HH0) at temperatures above (T=30 K) and below (T=10 K) the superconducting transition temperature indicating an enhancement of inelastic intensity on passing through $T_C$. To explore this excess intensity, Fig. 2(a) shows empty can subtracted

![FIG. 1: (a) Reciprocal space of both the tetragonal unit cell and the square lattice. The gray circles indicate the nuclear zone centers. Labels in black (red) correspond to the tetragonal (square lattice) unit cell. (b) ARCS data collected at T=10 K integrated over the energy range 5 to 25 meV and projected onto the (HK0) plane. Intensity is shown as a color map. (c) HB3 constant-E scan along (HH0) at an energy transfer of 9.5 meV for temperatures of 10 K and 30 K.](image_url)
constant-Q scans with $Q=(1/2 1/2 0)$. For $T > T_C$, the intensity of the constant-Q scan varies only weakly with energy transfer. On cooling through $T_C$, the excitation spectrum develops a gap and there is strongly enhanced intensity above the gap energy peaking at a resonance energy of $\sim 9$ meV. This energy is considerably lower than the 14 meV feature observed in $\text{Ba}_x\text{K}_{0.4}\text{Fe}_2\text{As}_2$ [20] suggesting an energy which scales with $T_C$. It is important to note that the neutron scattering measurements on this Co-doped sample show no evidence for long range antiferromagnetic order, consistent with the published phase diagram [33].

The temperature dependence of the excitation measured at $Q=(1/2 1/2 0)$ and $E=9.5$ meV is shown in Fig. 2(b). The intensity increases on cooling and a power law fit to the data yields $22\pm 1$ K, consistent with bulk $T_C$ of 22 K. Clearly, this excitation is strongly coupled with $T_C$ and the resonance energy, $\sim 9$ meV, corresponds to a value of $4.75\, k_B T_C$ consistent with the canonical value for the cuprates [8] suggesting a remarkable universal behavior between the Fe-based and Cu-based superconductors.

To examine the in-plane dispersion, constant-Q scans were measured near $Q=(1/2 1/2 3)$. The background subtracted data is shown in Fig. 3(a) for energy transfers of 8, 11, and 14 meV. These scans show an increase in width with increasing energy transfer consistent with a steeply dispersive excitation. The best fit to a pair of Gaussians with width constrained to be larger than resolution is represented by the solid lines. The mode appears to disperse linearly with $Q$. To quantify the wavevector dependence, the peak locations were parameterized by a dispersion characterized by a gap together with in-plane and c-axis coupling constants. Using this dispersion, we estimate an in-plane bandwidth of 70 meV with a lower limit of 60 meV. To examine the c-axis dispersion, constant-Q scans were performed at $(1/2 1/2 L)$ with $L=0$, 1/2, and 1 for temperatures of 10 K and 30 K. We observe the same resonance mode at $L=0$ and 1 (Fig. 3(b)). To explore the dispersion of the resonance, Fig. 3(c) shows the difference between the $T=10$ K and $T=30$ K constant-Q scans. The data from all three values of $L$ are within statistical error of one another consistent with very weak or no dispersion. There is, however, a systematic trend as a function of $L$ with the highest peak energy observed at $L=0$ and the lowest at $L=1$ with an average of 8.6(0.5) meV. Our best estimate of the c-axis bandwidth is 0.6 meV with an upper limit of 1.5 meV. The dimensionality of the spin excitations can be quantified by considering the ratio of in-plane to c-axis bandwidths. Our estimate of this ratio is 70/0.6=117 with a lower bound of 60/1.5=40. This result can be directly compared to the spin-wave velocity ratios in the parent compounds where ratios of 2-5 were observed [21, 22, 23]. Thus the bandwidth ratio provides quantitative evidence for strongly enhanced two-dimensionality upon doping.

To examine the origin of the excitations, measurements along $(1/2 1/2 L)$ for $E=9.5$ meV are shown in Fig. 4(a). The scattering due to the empty sample holder and instrumental background has been removed. This data shows no obvious periodicity as a function of $L$. There is, however, a Q dependent background resulting from systematic trend as a function of $L$ with the highest peak energy observed at $L=0$ and the lowest at $L=1$ with an average of 8.6(0.5) meV. Our best estimate of the c-axis bandwidth is 0.6 meV with an upper limit of 1.5 meV. The dimensionality of the spin excitations can be quantified by considering the ratio of in-plane to c-axis bandwidths. Our estimate of this ratio is 70/0.6=117 with a lower bound of 60/1.5=40. This result can be directly compared to the spin-wave velocity ratios in the parent compounds where ratios of 2-5 were observed [21, 22, 23]. Thus the bandwidth ratio provides quantitative evidence for strongly enhanced two-dimensionality upon doping.

The form of $\chi^\prime\prime(Q,\omega)$, measured by neutron scattering, has implications for the pairing symmetry of the super-
These observations are consistent with a strong resonance where the intensity at the resonance responds to $1.38(0.08)\Delta$. The measured superconducting gap, $\Delta$, is 6.25 meV, and exhibits an average energy of about 8.6 meV, which is 4.5 $k_BTc = 1.38 \Delta_0$. The dispersion and $L$ dependence of the excitation spectrum indicates enhanced two-dimensionality in this Co-doped system.
