ABSTRACT

Mutations in MECP2 cause Rett syndrome, a severe neurological disorder with autism-like features. Duplication of MECP2 also causes severe neuropathology. Both diseases display immunological abnormalities that suggest a role for MECP2 in controlling immune and inflammatory responses. Here, we used mecp2-null zebrafish to study the potential function of MeCP2 as an immunological regulator. Mecp2 deficiency resulted in an increase in neutrophil infiltration and upregulated expression of the pro- and anti-inflammatory cytokines Il1b and Il10 as a secondary response to disturbances in tissue homeostasis. By contrast, expression of the proinflammatory cytokine tumor necrosis factor alpha (Tnfa) was consistently downregulated in mecp2-null animals during development, representing the earliest developmental phenotype described for MECP2 deficiency to date. Expression of tnfα was unresponsive to inflammatory stimulation, and was partially restored by re-expression of functional mecp2. Thus, MeCP2 is required for tnfα expression during zebrafish development and inflammation. Finally, RNA sequencing of mecp2-null embryos revealed dysregulated processes predictive for Rett syndrome phenotypes.

KEY WORDS: Inflammation, mecp2, tnfα, Zebrafish, Rett syndrome

INTRODUCTION

The human X-chromosomal gene methyl-CpG-binding protein 2 (MECP2) was identified as an epigenetic factor capable of binding to methylated DNA (Lewis et al., 1992). Mutations in human MECP2 lead to Rett syndrome (RTT) (Amir et al., 1999), a severe neurological disorder associated with autistic features and motor skill regression after an apparently normal early development (Lyst and Bird, 2015). RTT patients often also display growth retardation (Tarquino et al., 2012), gastrointestinal (GI) and biliary tract disorders (Motil et al., 2012) and oxidative stress (Filosa et al., 2015). Conversely, overexpression of the mouse MECP2 caused by duplication of its genetic locus (Xq28) results in severe mental retardation and progressive neurological symptoms (Van Esch et al., 2005). Although neurological defects are the most striking clinical presentation of RTT and MECP2-duplication syndrome, both diseases display immunological abnormalities that point towards a role for MECP2 in regulating immune and inflammatory responses.

Disturbances in tissue homeostasis are detected by pattern recognition receptors (PRRs), such as the family of Toll-like receptors (TLRs) that recognize pathogen-associated molecular patterns (PAMPs) or damage-associated molecular patterns (DAMPs) (Beg, 2002; Matzinger, 2002; Medzhitov and Janeway, 2000). Activation of TLRs by infection or cellular damage initiates a signaling cascade that leads to the production of proinflammatory cytokines and chemokines (Akira and Takeda, 2004). The primary function of proinflammatory cytokines, including tumor necrosis factor alpha (TNFα) and interleukin 1 beta (IL1B), is to initiate an appropriate cellular or humoral immune response to neutralize the disturbance. Anti-inflammatory cytokines, including interleukin 10 (IL10) and transforming growth factor beta (TGFβ), balance the activity of proinflammatory cytokines by stimulating resolution of inflammation and tissue repair. Alterations in the balance between pro- and anti-inflammatory cytokines are potentially harmful, as prolonged inflammation can be damaging to tissues, while inadequate immune responses leave the body vulnerable to infections.

RTT patients showed a dysregulated cytokine and chemokine profile and displayed subclinical inflammation (Cortelazzo et al., 2014; Pecorelli et al., 2016). Data obtained using a mouse model of RTT demonstrated that MECP2 regulates microglia and macrophage responsiveness to inflammatory stimulation, hypoxia and glucocorticoids (Cronk et al., 2015). Transplantation of wild-type microglia has even been suggested as a therapeutic strategy for RTT patients based on findings obtained using RTT mice (Derecki et al., 2012), but these findings have since been disputed by others in the field (Wang et al., 2015). Although investigations concerning the role of the immune system in the onset of RTT are ongoing, MECP2 duplication syndrome is linked to immunodeficiency with increased susceptibility to infections for reasons that remain to be uncovered (Bauer et al., 2015). An emerging theme is that MECP2 normally regulates the immune response towards inflammatory stimuli and other stress factors.

The zebrafish was originally employed as a model organism to study vertebrate embryogenesis because of its external fertilization and development, genetic tractability, and optical transparency allowing noninvasive intravital imaging (Kimmel et al., 1988). These characteristics have also helped to develop the zebrafish as a useful model for the study of vertebrate immunity (Renshaw and Trede, 2011; van der Vaart et al., 2012). A recently described mecp2-null zebrafish mutant showed altered motor behaviors (Pietri et al., 2013), and mecp2 was found to be required for normal zebrafish brain development (Gao et al., 2015). Zebrafish mecp2 was broadly expressed early in embryonic development, after which it became enriched in the brains of zebrafish larvae (Gao et al.,
2015). This is similar to the distribution of MECP2 in mice, where it is highly expressed in neurons, but also ubiquitously found at lower levels in other cell types (Song et al., 2014).

Here, we studied the potential function of zebrafish Mecp2 as an immunological regulator during development and inflammation. We found that mecp2-null zebrafish display several previously unappreciated phenotypes also present in RTT patients, including growth retardation, GI tract phenotypes and dysregulated expression of cytokines. The gene expression levels of the pro- and anti-inflammatory cytokines illb and ill0 showed a peak during development, but were not hyper-responsive to inflammatory stimulation in mecp2-null larvae. We therefore suggest that the increased expression levels of these inflammatory cytokines during development were a response to a disruption of tissue homeostasis in the absence of Meep2. Remarkably, we found that the expression levels of zebrafish infa were profoundly downregulated during the first hours of development in mecp2-null embryos, preceding the first noticeable disease phenotypes. To the best of our knowledge, this finding represents the earliest developmental phenotype associated with MECP2-deficiency. The lower infa expression levels persisted throughout larval development, and infa was unresponsive to inflammatory stimulation in mecp2-null larvae. Finally, the expression of infa in mecp2-null embryos could be partially restored by enforced expression of wild-type mecp2. However, re-expression of infa in mecp2-null embryos was not sufficient to rescue the observed RTT phenotypes. Based on these findings, we conclude that zebrafish Mecp2 is required for infa expression during development and inflammation. To assess the earliest changes attributable to loss of Mecp2 function, we utilized RNA sequencing to analyze the transcriptome of mecp2-null embryos shortly after initiation of embryonic transcription (Kane and Kimmel, 1993). Strikingly, this revealed disrupted biological processes that are highly predictive of RTT phenotypes that develop much later in human patients. Further exploration of this transcriptome data and its changes over time might generate novel insights into additional developmental functions of MECP2.

RESULTS

mecp2-null zebrafish display growth retardation, GI tract phenotypes and systemic inflammation

To study the function of Mecp2 during zebrafish development, we used a mutant line containing a premature stop codon in the mecp2 gene (mecp2<sup>2063<sup>5</sup>) that truncates the protein before the methyl binding domain (MBD) and transcriptional repression domain (TRD), both of which are vital to its function (Lyst and Bird, 2015; Pietri et al., 2013). Although adult mecp2-null zebrafish are viable and fertile with no discernible difference between wild-type and mecp2-null larvae, but crp levels were significantly elevated in mecp2-null larvae by 4 dpf and 5 dpf (Fig. 1G). This demonstrates that mecp2-null larvae mount an inflammatory response at 4 dpf and 5 dpf that is detectable at a whole-organism level, after an early developmental period with no overt signs of systemic inflammation. Together, these results show that mecp2-null zebrafish display several RTT features during their development, including growth retardation, GI tract phenotypes and systemic inflammation.

Neutrophil numbers and mobilization confirm the presence of inflammation in mecp2-null larvae

To further investigate and characterize the possible inflammatory response in mecp2-null larvae suggested by increased crp levels, we first analyzed neutrophil numbers. Neutrophils are among the first innate immune cells that respond to disturbances in tissue homeostasis; increased tissue infiltration has previously been used to mark inflammation in zebrafish models of wounding, infection and inflammatory bowel disease (Brudal et al., 2014; Brugman et al., 2009; Oehlers et al., 2011; Renshaw et al., 2006). We used Tg(mpex:eGFP) animals (Renshaw et al., 2006), in which neutrophils are fluorescently labeled, to assess the number and distribution of neutrophils in the mecp2-null background over several developmental time points. Correlating with our crp results, we did not find any difference in neutrophil number between wild-type and mecp2-null larvae at 3 dpf, but total neutrophil numbers were significantly increased in mecp2-null larvae at 4 dpf and 5 dpf (Fig. 2A,B). These findings reproduce the neutrophilia observed in Meep2-null mice displaying RTT phenotypes, and underscore the conserved function of Mep2 in lower vertebrates (Cronk et al., 2015).

Neutrophilic granulocytes begin to accumulate in the caudal hematopoietic tissue (CHT) of developing zebrafish embryos following initiation of circulation at 26 hpf (Bertrand et al., 2007; Le Guyader et al., 2008; Stachura and Traver, 2011). A large number of neutrophils continue to reside in the CHT in uninflamed larvae, from which they can be mobilized to migrate towards inflamed tissues when needed (Yoo and Huttenlocher, 2011). We therefore aimed to approximate the source of inflammation in mecp2-null larvae by determining which tissues displayed increased neutrophil infiltration. Although the head region of mecp2-null larvae contained a slightly increased number of neutrophils at 5 dpf, we did not observe any significant infiltration of neutrophils into the brains of mecp2-null animals (Fig. S1A-C). Starting at 2 dpf, we observed increases in neutrophil numbers associated with the GI tract of mecp2-null larvae (Fig. 2C,D), indicating this tissue as a potential source of inflammation. We reproduced this observation by using a previously characterized anti-sense morpholino oligonucleotide approach designed to block initiation of zebrafish Mecp2 protein translation (Fig. S1D) (Gao et al., 2015). These findings are in agreement with our previous observation of GI tract phenotypes during mecp2-null larval development.

Because microglia and macrophages have previously been implicated in RTT-like etiology in mice, and become depleted with disease progression (Cronk et al., 2015), we also assessed their number and localization by using Tg(mpex:eGFP) animals with fluorescently labeled microglia and macrophages (Ellett et al., 2011). At 3 dpf, mpex1-expressing microglia have colonized the brain and are capable of mounting a functional immune response (Herbomel et al., 2001; Svaeh et al., 2013). However, we found no distinguishable difference in microglia or macrophage numbers or localization between mecp2-null and wild-type larvae from 3 to 5 dpf (Fig. 2E-G). In summary, our results indicate that disrupting Mecp2 expression between wild-type and mecp2-null larvae, but crp levels were significantly elevated in mecp2-null larvae by 4 dpf and 5 dpf (Fig. 1G). This demonstrates that mecp2-null larvae mount an inflammatory response at 4 dpf and 5 dpf that is detectable at a whole-organism level, after an early developmental period with no overt signs of systemic inflammation. Together, these results show that mecp2-null zebrafish display several RTT features during their development, including growth retardation, GI tract phenotypes and systemic inflammation.
function during zebrafish development leads to a systemic immune response that appears to originate from the GI tract, based on observed GI tract phenotypes and neutrophil influx into this tissue.

Expression of central pro- and anti-inflammatory cytokines is dysregulated in mec2-null larvae

Because inflammation is mainly controlled by the expression and activity of pro- and anti-inflammatory cytokines and chemokines, we queried whether the expression of these regulatory molecules is affected by Mecp2 deficiency. We used qPCR to analyze the gene expression levels of a panel of zebrafish inflammatory cytokines and chemokines in mec2-null and wild-type larvae during the first 7 days of development. The panel consisted of the proinflammatory cytokines il1b, interleukin 6 (il6) and tnfa; the proinflammatory chemokine interleukin 8 (cxcl8a); and the anti-inflammatory cytokines il10 and tgfb1. At each time point analyzed over the 7-day time course, tnfa was expressed at dramatically lower levels in mec2-null embryos and larvae compared with wild-type embryos and larvae of the same age (Fig. 3A). Even at 6 hpf, the earliest time point with clearly detectable tnfa expression in wild-type embryos, its expression was significantly reduced in mec2-null animals (Fig. 3A). By contrast, we found no significant difference in expression levels of il6, cxcl8a and tgfb1 between mec2-null and wild-type animals over the developmental time course of 7 days (Fig. S2A-C). We did detect a significant increase in whole-organism il1b and il10 expression in mec2-null larvae at 5 dpf, after being expressed at wild-type levels for the first 4 days of development (Fig. 3B,C). While il1b reverted back to wild-type levels over the next 2 days (Fig. 3B), the significantly increased expression of il10 peaked at 6 dpf, after which it also trended downwards (Fig. 3C). The expression levels of il1b and il10 indicate a temporal increase in inflammatory signaling, followed by resolution of inflammation.

We sought to confirm the specific downregulation of tnfa by confocal microscopy imaging of wild-type and mec2-null larvae carrying a Tg(tnfa:eGFP) reporter that expresses eGFP under control...
of *tnfa* regulatory sequences (Fig. S3) (Marjoram et al., 2015). Wild-type larvae of 3 dpf expressed eGFP in brain regions (Fig. 3D,E), posterior gut epithelium (Fig. 3F) and dorsal root ganglion neurons (Fig. 3G). By contrast, 3 dpf *mecp2*-null larvae had no detectable expression of GFP in any of these tissues (Fig. 3H-K). Because the Tg (*tnfa*:eGFP) reporter construct introduced an additional *tnfa* promoter region at a random location in the zebrafish genome (Marjoram et al., 2015), the lack of eGFP expression caused by Mecp2 deficiency appears to be linked to the DNA sequence of the *tnfa* promoter, rather than its chromosomal location. The decreased expression of *tnfa*
Fig. 2. Neutrophil number and distribution confirm the presence of inflammation in mecP2-null larvae. (A) Total numbers of Tg(mppc:eGFP)-positive neutrophils were counted in 3, 4 and 5 dpf wild-type and mecP2-null larvae using stereo fluorescent microscopy (n=12 larvae per condition pooled from two individual experiments; larvae were scored for three consecutive days). (B) Representative stereo microscopy images of 4 dpf Tg(mppc:eGFP) wild-type and mecP2-null larvae. (C) Numbers of Tg(mppc:eGFP)-positive neutrophils associated with the GI tract of 2, 3, 4 and 5 dpf wild-type and mecP2-null larvae were counted (n=12 embryos per condition; data are representative of three individual experiments). (D) Representative confocal micrographs (maximum projection) of the GI tracts of 5 dpf Tg(mppc:eGFP) wild-type and mecP2-null larvae in which the GI tract has been delineated with a white dashed line based on the transmitted light images. (E) Representative confocal micrographs (maximum projection) of the brain region of 3 dpf Tg(mppc:eGFP)-null larvae were counted (n=7 nights each, pooled from two individual experiments). (F) Brain-associated Tg(mppc:eGFP)-positive cells were counted for 3 dpf wild-type, heterozygous and mecP2-null larvae (n=7, n=11, n=6, respectively; one-way ANOVA with Tukey’s post hoc test; ns, not significant; data are representative of two individual experiments). (G) Total numbers of Tg(mppc:eGFP)-positive cells were counted in 3, 4 and 5 dpf wild-type and mecP2-null larvae using stereo fluorescent microscopy (n=11 and n=12 embryos per condition, respectively; data are representative of two individual experiments). A Student’s t-Test was used for all statistical analyses, except for the data analyzed in F, where paired wild-type and mecP2-null numbers per day (**P<0.001; **P<0.01; *P<0.05, ns, not significant).

mecP2-null larvae are unable to activate Tnfalpha expression during an acute inflammatory response

Our finding that Tnfalpha is downregulated in mecP2-null as early as 6 hpi is highly suggestive of a direct effect of Mecp2 on Tnfalpha expression. To test whether the Tnfalpha gene has lost its responsiveness to inflammatory stress signals, we designed an acute inflammation assay by injecting the yeast cell wall particle zymosan, a TLR2 ligand (Underhill et al., 1999), into the brains of 3 dpf zebrafish larvae (Fig. 4A). Fluorescently labeled zymosan injected into the brains of wild-type larvae was rapidly phagocytosed by Tg(mppc1:eGFP)-positive microglia (Fig. 4B), and all zymosan particles were cleared from the brain tissue at 4 h postinjection (hpi) (Fig. 4C). The clearance of zymosan is accompanied by an acute inflammatory response characterized by an initial upregulation of the proinflammatory cytokine genes il1b and Tnfalpha, followed by an upregulation of the anti-inflammatory cytokine genes il10 and tgfbi (Fig. 4D). The gene expression levels of these inflammatory cytokines had returned to baseline levels at 4 hpi of zymosan (Fig. 4D). The inflammatory response to zymosan injected into the brain is strongest in dissected heads of wild-type larvae, but its effects on il1b gene expression can also be detected in whole animal preparations of injected zebrafish larvae (Fig. S4A).

We confirmed that Tg(mppc1:eGFP)-positive cells present in the brain of wild-type and mecP2-null larvae phagocytosed zymosan at comparable rates (Fig. S4B,C). We then used qPCR to compare the gene expression levels of il1b, il10 and Tnfalpha between mecP2-null and wild-type larvae over a 4-h time course after injection of zymosan into the brain. Strikingly, mecP2-null larvae were unable to increase the gene expression level of Tnfalpha in response to zymosan injection, unlike the wild-type control group (Fig. 4E). By comparison, we found no difference in gene expression levels of il1b and il10 between mecP2-null and wild-type larvae during this inflammatory response (Fig. 4E). This demonstrates that the genetic regulation of il1b and il10 in response to a danger signal is not disturbed by Mecp2 deficiency, and suggests that their upregulation during mecP2-null larval development is part of an inflammatory response to disturbances in tissue homeostasis. We conclude that zebrafish Tnfalpha was unresponsive to inflammatory stimulation in the absence of functional Mecp2. These results show that even during an acute stress event, mecP2-null larvae cannot activate Tnfalpha expression, and further suggests that Mecp2 is required for proper expression of Tnfalpha.

Re-expression of mecP2 in mecP2-null zebrafish embryos partially rescues Tnfalpha gene expression

Because mecP2-null larvae were unable to express Tnfalpha at wild-type levels during development or during an acute inflammatory response, we asked whether re-expression of wild-type mecP2 was sufficient to restore Tnfalpha gene expression levels in mecP2 mutants. For this purpose, we injected full-length mecP2 mRNA into mecP2-null or wild-type zygotes. Injection of mecP2 mRNA resulted in a 15- to 20-fold overexpression of mecP2 at 1 dpf (Fig. 5A), or ~50-fold overexpression at twice the dose (Fig. S5). Even at the highest dose tested, we were unable to detect increased mecP2 expression levels at 3 dpf (Fig. S5), suggesting a rapid decay of the injected mecP2 mRNA. We analyzed the effect of mecP2 overexpression on Tnfalpha and il1b gene expression levels by qPCR. We found that overexpression of wild-type mecP2 in mecP2-null could partially rescue Tnfalpha gene expression levels at 1 dpf, but did not affect Tnfalpha gene expression in wild-type embryos (Fig. 5B). Overexpression of wild-type mecP2 mRNA had no noticeable effect on gene expression levels of il1b in either mecP2-null or wild-type embryos (Fig. 5C). The lower Tnfalpha expression throughout embryonic and larval development, combined with the unresponsiveness of Tnfalpha to inflammatory stimulation in mecP2-null larvae, suggested a direct effect of Mecp2 deficiency on Tnfalpha gene expression. Based on the mecP2 mRNA re-expression experiments, we conclude that Mecp2 is required to allow normal expression of Tnfalpha in zebrafish embryos and larvae. However, overexpression of mecP2 mRNA in wild-type embryos did not alter Tnfalpha expression, indicating that Mecp2 alone is not sufficient to induce Tnfalpha expression. This suggests a mechanism in which Mecp2 allows additional transcriptional regulators to be recruited to modulate Tnfalpha gene expression.

Re-expression of Tnfalpha in mecP2-null zebrafish embryos does not rescue RTT phenotypes

We observed that Tnfalpha expression is significantly reduced in mecP2-null zebrafish during embryonic and larval development. The posterior gut epithelium is a prominent source of Tnfalpha expression in wild-type larvae (Fig. 3F), whereas mecP2-null animals had no detectable Tnfalpha expression in this tissue (Fig. 3J). Because dysregulated Tnfalpha expression has previously been implicated in the onset of inflammatory bowel disease in zebrafish larvae (Marjoram et al., 2015), we hypothesized that the lack of Tnfalpha expression might contribute to the development of inflammatory phenotypes in the GI tract of mecP2-null zebrafish. To test for the potential involvement of reduced Tnfalpha expression in the development of RTT phenotypes, we injected a previously described morpholino oligonucleotide targeting Tnfalpha expression into wild-type zygotes (López-Muñoz et al., 2011). We found that knockdown of Tnfalpha resulted in a significant increase in the number of GI tract-associated neutrophils compared to control-injected individuals (Fig. 5D), as well as a significant decrease in total body length (Fig. 5E). Both these phenotypes are also observed in mecP2-null larvae. Next, we attempted to rescue the GI tract neutrophil infiltration and growth reduction observed in mecP2-null larvae by re-expressing Tnfalpha. For this purpose, we injected plasmid encoding full-length Tnfalpha mRNA.
Enforced expression of *tnfa* did not reduce the number of neutrophils associated with the GI tract in mecp2-null larvae (Fig. 5F), nor did it restore the reduced body length of mecp2-null larvae (Fig. 5G). In summary, although knockdown of *tnfa* mimicked the phenotypes observed in mecp2-null larvae, restoring *tnfa* expression was not sufficient to rescue the growth retardation and GI tract inflammatory phenotypes observed in mecp2-null animals.

Fig. 3. Expression of central inflammatory cytokines is dysregulated in mecp2-null larvae. (A,B,C) qPCR was performed to determine the whole-organism expression of *tnfa* from 4 hpf to 7 dpf (A), and *il1b* and *il10* from 1 dpf to 7 dpf (B,C), in wild-type or mecp2-null zebrafish. Gene expression is related to the expression of the housekeeping gene *tbp*, where the fold change relative to gene expression in 1 dpf wild-type embryos is shown (n=3 with 20 embryos or larvae pooled per sample for 1-7 dpf; 30 embryos were pooled per sample for the 4-12 hpf time points; data are representative of two individual experiments). One-way ANOVA with Tukey’s post hoc test was used for all statistical analyses (**P<0.01; *P<0.05; ns, not significant). (D-K) Representative confocal micrographs of 3 dpf Tg(*tnfa:eGFP*) wild-type and mecp2-null larvae showing the eGFP expression pattern in brain regions in a lateral view (D,H), brain regions in a dorsal view (E,I), posterior gut epithelium in a lateral view (F,J) and dorsal root ganglion neurons in a lateral view (G,K).
RNA sequencing reveals early developmental effects of mecp2 deficiency and predicts RTT phenotypes

In this study, we have demonstrated that Mecp2 regulates *tnfa* gene expression levels during early zebrafish embryonic development. Even at 6 hpf, when low levels of *tnfa* expression can first be detected in wild-type embryos, mecp2-null embryos express significantly reduced levels of *tnfa*. At this time point of development, zebrafish embryos are undergoing epiboly and gastrulation, which initiate formation of the basic body plan. Although we were able to detect the effect of mecp2 deficiency at this early developmental stage in zebrafish embryos, RTT patients do not display phenotypes until at least 6 months after birth. Therefore, we reasoned that the zebrafish embryo could be highly informative regarding the earliest effects of disrupted MECP2-function that ultimately result in disease phenotypes. To assess the genes that are disrupted during early development of mecp2-null, we performed RNA sequencing to reveal whole-transcriptome differences between 6 hpf mecp2-null and wild-type embryos. For the mecp2-null group, embryos were derived from homozygous mecp2-null parents to avoid the confounding influence of maternally deposited wild-type mecp2 RNA. The three biological replicates of each condition clustered closely together after DESeq2 analysis (Fig. 6A). At 6 hpf, 3837 transcripts were significantly upregulated in mecp2-null versus wild-type embryos, whereas 4217 transcripts were significantly downregulated (Fig. 6B). Although the raw counts for *tnfa* were lower in mecp2-null compared to wild-type embryos, the average number of raw counts for *tnfa* in wild-type embryos was too low to demonstrate significance (data not shown).

For an unbiased assessment of potentially disrupted biological processes in mecp2-null embryos at 6 hpf, we submitted the subsets of differentially up- or downregulated genes to gene ontology (GO)
analysis. GO analysis revealed that genes associated with a large range of biological processes were significantly enriched in the differentially expressed subsets, illustrating that mecp2 deficiency has a broad effect on transcription. We limited our further analysis to GO terms with at least twofold enrichment, and only included the most specific GO term for groups of hierarchically clustered terms (Fig. 6C,D). This strict GO term analysis revealed significantly enriched biological processes that are linked to known MECP2-functions, such as epigenetic regulation of transcription and mRNA splicing (Lyst and Bird, 2015). Importantly, GO analysis also identified enriched processes at this early developmental stage, which become relevant to RTT phenotypes at later stages, including neurological development, craniofacial development, vascular dysfunction, redox homeostasis, developmental growth, myeloid...
cell differentiation and hepatobiliary system development. Finally, GO analysis identified enriched biological processes that, to the best of our knowledge, have not been previously linked to MECP2-function or RTT, including dorsal/ventral pattern formation; protein folding; and intracellular protein targeting. The analysis of the RNA sequencing data underscores the relevance of the zebrafish model for the study of MECP2 function and RTT, while potentially identifying new biological processes of interest.

At the same time, the unbiased analysis of enriched GO terms appears predictive for the growth retardation, myeloid cell number disruption (neutrophilia) and hepatobiliary dysfunction that occurs later during development. For the GO term ‘developmental growth’, 44 out of a total of 187 genes linked to this biological process were significantly downregulated in 6 hpf mecP2-null versus wild-type embryos. For the GO terms ‘myeloid cell differentiation’ and ‘hepatobiliary system development’, 32 out of a total of 133 or 111 genes linked to this process, respectively, were significantly upregulated in mecP2-null embryos. To investigate the extent of individual gene dysregulation in the absence of Mecp2, we plotted the normalized fold change in all differentially expressed genes linked to these biological processes in a heatmap (Fig. 7A). Mecp2 deficiency affected the expression levels of a large number of genes related to these biological processes; ~75% of these genes were up- or downregulated, at a twofold change or less (Fig. 7B). The same observation was made on a genome-wide scale for all significantly upregulated genes in mecP2-null embryos, or to a lesser degree for...
The graph displays the percentage of significantly differentially expressed change (nFC) for upregulated genes. For all genes, the positive or negative normalized fold change (nFC) for significantly differentially expressed genes. For example, differences in gene expression levels are $bbs4$ and $nos1$ (GO term ‘developmental growth’); $spth$, $smad9$ and $casp3b$ (GO term ‘myeloid cell differentiation’); and $sfrp5$ and $a2ml$ (GO term ‘hepaticobiliary system development’). While the neuron-expressed Nitric oxide synthase 1 (Nos1) protein is well known for its role in neurotransmission, mutations in genes from the Bardet-Biedl syndrome (BBS) family, such as $bbs4$, result in an autosomal recessive disorder characterized by mental retardation and other severe symptoms. The anti-inflammatory adipocytokine Sfrp5 modulates metabolic dysfunction during obesity in mice (Ouchi et al., 2010), and $a2ml$ (Alpha2 macroglobulin-like) was shown to be essential for liver development in zebrafish (Hong and Dawid, 2008). A potential role for $spth$, $smad9$ and $casp3b$ in neutrophilia is not directly clear. For all genes with relatively high differential expression between $mecp2$-null and wild-type embryos at 6 hpf, it will be interesting to investigate whether their dysregulation extends into developmental phases when RTT phenotypes first arise.

**DISCUSSION**

The large body of literature on MECP2 and RTT contains evidence that mutations in MECP2, as well as its overexpression caused by duplication of its genetic locus, result in abnormal functioning of the immune system (Bauer et al., 2015; Cortelazzo et al., 2014; Cronk et al., 2015; Derecki et al., 2012; Leoncini et al., 2015; Pecorelli et al., 2016). Furthermore, because RTT patients acquire disease symptoms after an apparently normal early development, we hypothesized that misregulated responses to external or internal inflammatory stimuli encountered during development could play a key role in the onset of RTT. We therefore set out to test the potential function of zebrafish Mecp2 as an epigenetic regulator of immune and inflammatory responses during development.

Indeed, gene expression levels of the inflammation marker $crp$ and mobilization of neutrophils provided evidence for the presence of inflammation in $mecp2$-null larvae after an inflammation-free early development. Increased gene expression levels of $il1b$ and $il10$ measured at a whole-organism level were found to be involved in this inflammatory response. We hypothesized that, when lacking the epigenetic regulator Mecp2, the zebrafish genes encoding $Il1b$ and $Il10$ were hyper-responsive to inflammatory stimulation. By submitting both wild-type and $mecp2$-null larvae to an acute inflammation assay, we were able to disprove this hypothesis. The expression levels of $il1b$ and $il10$ were regulated in a similar fashion in response to inflammatory stimulation in wild-type and $mecp2$-null larvae. Combined with the fact that $il1b$ and $il10$ were expressed at wild-type levels in $mecp2$-null embryos during early development, we suggest that the peak in expression of these pro- and anti-inflammatory cytokines was a response to a disturbance in tissue homeostasis in the absence of Mecp2.

We observed an increased infiltration of neutrophils into the GI tract of $mecp2$-null larvae, combined with GI tract phenotypes and a potential disturbance of bile production or flow. These observations are relevant, because RTT patients frequently display GI tract phenotypes, including GI dismotility (Baikie et al., 2014). Additionally, cholesterol metabolism is altered in RTT patients (Segatto et al., 2014), and limiting cholesterol biosynthesis alleviated RTT symptoms and increased the survival of $mecp2$-null mice (Buchovecky et al., 2013). While bile acids, a major component of cholesterol, have immunomodulatory effects (Brestoff and Artis, 2013), inflammation can also suppress the expression of bile transporters and thereby reduce the flow of bile (Kosters and Karpen, 2010). With the proven contribution of zebrafish larval and embryonic models to the study of liver diseases and inflammatory bowel diseases (Goessling and Sadler, 2015; Love et al., 2007), the zebrafish $mecp2$-null mutant might be ideally...
suites of cellular systems, it is challenging to reach a unified and evolutionary conserved conclusion on MeCP2 function. Nonetheless, we believe that contributions from each individual model system will ultimately help to understand the function of MECP2 in health and disease. We have used the zebrafish embryonic and larval system to demonstrate that MeCP2 is required for transcription during zebrafish development and inflammation. Besides this, our RNA sequencing results provide insights into the earliest genetic alterations that occur in the absence of MECP2 function, which ultimately could result in RTT phenotypes. Furthermore, zebrafish embryos are amenable to high-throughput screening for drugs with the potential to remedy these phenotypes (Tan and Zon, 2011). We believe that these findings have the potential to instruct future studies in zebrafish and other model systems to increase our understanding of MECP2 function and its role in RTT pathogenesis.

**MATERIALS AND METHODS**

**Zebrafish husbandry and maintenance**

Zebrafish (*Danio rerio*) were maintained and used for experiments according to the guidelines of the UCSD Institutional Animal Care and Use Committee. The following zebrafish lines were used: AB (wild-type strain); *mecp2*^{206*3*} mutants (Pietri et al., 2013); Tg(*mpx:eGFP*)^{i114} (Renschaw et al., 2006); Tg(*mpx:eGFP*)^{i112} (Ellett et al., 2011); Tg(*tnfa:eGFP*) (Marjoram et al., 2015). Genotyping of *mecp2*^{206*3*} mutants occurred as previously described (Pietri et al., 2013). When needed for experimental purposes, zebrafish were anesthetized using Tricaine (200 µg/ml).

**Microscopy**

For stereomicroscopy, embryos and larvae were mounted in E3 medium containing 3% methyl cellulose (Sigma-Aldrich). Brightfield images were acquired using a Leica MZ16 stereomicroscope with a Leica DFC295 camera (Leica Microsystems). Epifluorescence images were acquired using an AxioZoom.V16 stereomicroscope (Zeiss). For confocal microscopy, larvae were mounted in E3 medium containing 0.5% low melting point agarose (Sigma-Aldrich). Confocal micrographs were acquired using a Leica SP5 confocal system (Leica Microsystems). Images were created using Imaris (Bitplane) and ImageJ (https://imagej.nih.gov/ij/) software.

**qPCR**

mRNA was isolated using the RNeasy mini kit according to the manufacturer’s instructions (Qiagen). cDNA was synthesized using the iScript cDNA synthesis kit according to the manufacturer’s instructions (BioRad). qPCR was performed using iQ SYBR Green Supermix (BioRad) and the BioRad CFX96 real-time system according to the manufacturer’s instructions. Gene expression levels were calculated relative to the expression of the housekeeping gene *TATA box binding protein* according to the 2^{−ΔΔCt} method. Primers used for qPCR analysis of gene expression are listed in Table S1.  

RESEARCH ARTICLE

**Disease Models & Mechanisms (2017) 10, 1439-1451 doi:10.1242/dmm.026922**
Microinjection of zymosan particles
Zebrin larvae of 3 dpf were positioned with the dorsal side up to allow injection of 1 nl PBS containing 100-150 Alexa Fluor 594-labeled Zymosan A (S. cerevisiae) BioParticles (Molecular Probes) into the brain. As a control for a potential wounding effect, 1 nl of sterile PBS was injected in a similar manner. The percentage of zymosan phagocytosed by Tg TMPG::GFP-positive cells was determined based on confocal micrographs of the brain.

Microinjection of mRNA, plasmids and antisense oligonucleotide morpholinos
A gBlock (Integrated DNA Technology) containing full-length zebrafish mecpx2 cDNA (ENSDA000000046072) was cloned into a Zero Blunt TOPO PCR vector according to the manufacturer’s instructions (Life Sciences). Zebrafish mecpx2 mRNA was synthesized using the mMessage mMachine SP6 Transcription Kit according to the manufacturer’s instructions (Invitrogen). Then, 50 pg or 100 pg mecpx2 mRNA was injected into the yolk of one-cell stage zebrafish embryos. The antisense oligonucleotide morpholino targeting mecpx2 expression was injected as described by Gao et al. (2015), while the antisense oligonucleotide morpholino targeting tnfa expression was injected as described by López-Muñoz et al. (2011). Control plasmid (pCS2+) and Tnfa plasmid (Roca et al., 2008) (20 pg) were injected into the yolk sac of one-cell stage embryos.

RNA sequencing
mRNA was isolated using the RNeasy mini kit according to the manufacturer’s instructions (Qiagen). Library preparation and sequencing was performed by the Institute for Genomic Medicine Center at the University of California, San Diego. RNA sequencing was performed on an Illumina HiSeq4000 platform using single reads of 50 bases in length. RNA sequencing data were mapped to Diego. RNA sequencing was performed on an Illumina HiSeq4000 platform.

Positive cells was determined based on confocal micrographs of the brain. A suppressor screen in Mecp2 mutant mice implicates cholesterol metabolism in Rett syndrome. Proc. Natl. Acad. Sci. USA 112, 9919-9924.

**Supplementary figure 1: Neutrophil numbers in the head and brain region of wild type and mecp2-null larvae**

(A) Tg(mpx:eGFP)-positive neutrophils were enumerated in the head region of 5 dpf wild type and mecp2-null larvae using stereo fluorescent microscopy (n=12 embryos per condition). (B) Numbers of Tg(mpx:eGFP)-positive neutrophils present in the brain were counted for wild type and mecp2-null larvae at 5 dpf (n=12 embryos per condition). (C) Representative stereo microscopy images of the head region of 5 dpf Tg(mpx:eGFP) wild type and mecp2-null larvae in which the brain tissue has been indicated with a white dotted line. A Mann–Whitney U test was used for statistical analysis (*: p<0.05; ns: not significant). (D) Oligonucleotide morpholino targeting mecp2 expression was injected as previously described by Gao et al. (2015). Numbers of Tg(mpx:eGFP)-positive neutrophils associated with the gastrointestinal tract of 2 dpf control and mecp2 morpholino injected larvae were counted (n≥30 embryos per condition). Student T-test was used for the statistical analyses (***: p<0.001).
Supplementary figure 2: Expression levels of *il6*, *cxcl8a*, and *tgfb1*

Quantitative real-time PCR was performed to determine the whole-organism gene expression level of (A) *il6*, (B) *cxcl8a*, and (C) *tgfb1* in wild type or *mecp2*-null animals. Gene expression is related to the expression of the housekeeping gene *tbp*, while the fold change relative to gene expression in 1 dpf wild type embryos is shown (n=3 with 20 embryos or larvae pooled per sample). A One-way ANOVA with Tukey’s post hoc test was used for all statistical analyses (ns: not significant).
Supplementary figure 3: Confirming the presence of Tg(tnfa:eGFP) in mecp2-null larvae

Since mecp2-null larvae display reduced tnfa gene expression levels and reduced Tg(tnfa:eGFP) encoded GFP expression, the presence of the Tg(tnfa:eGFP) construct in mecp2-null larvae was confirmed by genotyping with the following primers: ACGACGGAACTACAAAGACC (forward) and GTCTCCTGAAGTCGATGC (reverse). The resulting PCR product was detected using gel electrophoresis. The mecp2-null larvae were positive for the Tg(tnfa:eGFP) transgene, which corroborates the residual GFP expression observed in mecp2-null larvae with confocal microscopy (Figure 3).
Supplementary figure 4: Microinjection of zymosan into the brain of zebrafish larvae

(A) Zymosan was injected into the brain of 3 dpf wild type larvae. Quantitative real-time PCR was performed to determine gene expression level of il1b relative to the expression of the housekeeping gene tbp in the dissected heads and bodies of injected larvae. Samples (n=3 with 10 heads or bodies per sample) were taken at 1 hour post injection of zymosan or PBS as a control. The relative fold change of zymosan versus PBS injected samples is shown to account for a possible wounding effect by the injection itself. A One-way ANOVA with Tukey’s post hoc test was used for statistical analysis (*: p<0.05; ns: not significant).

(B) The percentage of zymosan particles phagocytes by Tg(mpeg1:eGFP)-positive cells for wild type and mecp2-null larvae using confocal microscopy of samples fixed 30 minutes after injection (n=5 larvae per condition). A Student T-test was used for statistical analysis (ns: not significant).

(C) Representative confocal micrographs of a wild type and mecp2-null Tg(mpeg1:eGFP) larvae at 30 minutes post injection. An asterix (*) indicates zymosan phagocytosed by Tg(mpeg1:eGFP)-positive cells.
Supplementary figure 5: over-expression of mecp2 in wild type zebrafish embryos

Wild type 1 cell stage embryos were injected with 100 pg of full length mecp2 mRNA. Quantitative real-time PCR was performed to determine the whole-organism gene expression level of (A) mecp2, (B) tnfa, and (C) il1b relative to the expression of the housekeeping gene tbp. Wild type and RNA-injected samples (n=3 with 30 embryos pooled per sample) were taken at 1 and 3 days post fertilization. The relative fold change of each condition versus uninjected wild type controls is shown. A One-way ANOVA with Tukey’s post hoc test was used for all statistical analyses (***, p<0.001; ns: not significant).
**Supplementary table 1: Primers used for quantitative real-time PCR**

| Gene | Accession number | Forward primer | Reverse primer |
|------|------------------|----------------|----------------|

**Supplementary figure 6: over-expression of tnfα in mecp2-null zebrafish embryos**

Wild type (wt) and mecp2-null (mecp2-/-) 1-cell stage embryos were injected with 20 pg of plasmid containing full length mecp2 cDNA (+pCS2+_Tnfa), or an empty plasmid as control (+pCS2+). Plasmid-injected samples (n=10 embryos pooled per sample) were taken at 2 days post fertilization. RNA was isolated from these samples and DNaseI treatment was performed to prevent carryover of plasmid DNA (+ DNaseI). Quantitative real-time PCR was performed to determine the whole-organism gene expression level of tnfα relative to the expression of the housekeeping gene ef1a. Non-reverse transcriptase treated samples (- RT) were taken along as a control to exclude plasmid DNA contamination.
