A STOCHASTIC TARGET APPROACH TO RICCI FLOW ON SURFACES

ROBERT W. NEEL AND IONEL POPESCU

ABSTRACT. We develop a stochastic target representation for Ricci flow and normalized Ricci flow on smooth, compact surfaces, analogous to Soner and Touzi’s representation of mean curvature flow. We prove a verification/uniqueness theorem, and then consider geometric consequences of this stochastic representation.

Based on this stochastic approach we give a proof that, for surfaces of non-positive Euler characteristic, the normalized Ricci flow converges to a constant curvature metric exponentially quickly in every $C^k$-norm. In the case of $C^0$ and $C^1$-convergence, we achieve this by coupling two particles. To get $C^2$-convergence (in particular, convergence of the curvature), we use a coupling of three particles. This triple coupling is developed here only for the case of constant curvature metrics on surfaces, though we suspect that some variants of this idea are applicable in other situations and therefore be of independent interest. Finally, for $k \geq 3$, the $C^k$-convergence follows relatively easily using induction and coupling of two particles.

None of these techniques appear in the Ricci flow literature and thus provide an alternative approach to the field.

1. INTRODUCTION

In [42], Soner and Touzi give a characterization of various extrinsic geometric flows (with ambient space $\mathbb{R}^n$), including mean curvature flow, as stochastic target problems. More specifically, they introduce the relevant target problems and then prove associated verification theorems, namely theorems showing that if the curvature flow has a smooth solution for an interval of time $t \in [0, T)$, then the solution agrees with the solution to the stochastic target problem on this interval. In the first part of this paper, we develop a similar characterization of Ricci flow (and normalized Ricci flow) on compact surfaces, including the relevant verification theorems (see Theorem 3). We then briefly discuss time-dependent bounds on the solution to both normalized and un-normalized Ricci flow and estimates on the blow-ups of solutions to Ricci flow in the cases of non-zero Euler characteristic, all obtained from the stochastic formulation of the flow. In the remainder of the paper, we use this stochastic representation to prove that, for a smooth, compact surface of non-positive Euler characteristic, given that a smooth solution to the normalized Ricci flow exists for all time (which is well-known from the literature), it converges to a constant curvature metric exponentially fast in $C^\infty$ (see Theorem 22 for a precise statement).

Ricci flow on smooth, compact surfaces is essentially completely understood as for instance [14, 15, 23]. Nonetheless, one feature of our approach is that probability often provides an appealing intuition, as in the case of Brownian motion and heat flow. Thus, if Ricci flow is thought of as a kind of “heat equation for curvature,” it is natural to want to extend the analogy to include a diffusion interpretation. For example, it’s nice to see the convergence of a manifold under normalized Ricci flow to a constant curvature limit as the equidistribution of the metric, and as a result of the curvature, from a probabilistic perspective.

More generally, one might ask about the potential merits of developing stochastic techniques for Ricci flow (or other curvature flows). One obvious point to be made here is that one gets a representation of the solution and, at least in the theory of linear second order PDEs, this has turned out to be extremely versatile in extracting properties of the solutions. As we will see, the stochastic tools we employ are good enough to give a different proof of a main result in the theory of Ricci flow on surfaces with the bonus that we see the “averaging property of the curvature” as a consequence of coupling, which is a probabilistic manifestation of ergodicity. Another motivation for such an endeavor is that the stochastic target formulation is fairly insensitive to regularity, and thus potentially useful in formulating notions.
of weak solutions. Indeed, in a second paper, Soner and Touzi [41] show that generalized solutions to various extrinsic curvature flows can also be understood in terms of stochastic target problems. Also stemming from these ideas, we note that stochastic approaches to PDEs can lend themselves to the development of probabilistic numerical schemes (as in [21]), but we do not touch this subject here.

Our framework is not the most general one. We presumably could have worked in a little more generality, but to keep the ideas as appealing and clear as possible, we decided to study surfaces, which are the traditional starting point for studying Ricci flow.

We point out that, as noted in [13], stochastic target problems of certain kind are equivalent to second-order backward stochastic differential equations. As discussed there, second-order backward SDEs are natural stochastic objects to associate with fully non-linear PDEs. Thus, one could presumably recast the results of this paper in those terms. Nonetheless, we have chosen to adopt the stochastic target approach because it seems more geometrically intuitive and visually appealing, and because it puts Ricci flow and mean curvature flow in a similar framework.

There are few papers on stochastic analysis and Ricci flow, for instance [1, 2, 16, 30, 31, 32]. The ones that are somewhat closer to our work are [1] and [16]. These papers investigate the Brownian motion (and the associated parallel transport) with respect to a time changing metric on a manifold of any dimension, not only on surfaces. Using stochastic analysis they also develop a Bismut-like formula to represent the gradient of solutions to heat-type flows with respect to the time-dependent metric. In particular, this leads to gradient estimates for the corresponding solutions.

We use in this paper a different tool, namely couplings. Coupling is a very useful thing and has been successfully used in a variety of situations. There is a large body of research on this and we will point out only some selections without any claim of completeness on the subject. One of the most useful on is the mirror coupling of Brownian motions introduced by Lindval and Rogers in [34] in the Euclidean setting and by Cranston [20] and Kendall in [25] on manifolds. Different types of couplings, as for instance the synchronous coupling appearing in [9, 18, 19] and shy coupling which is treated in [7, 28, 8] or even fixed-distance couplings on manifolds in [36]. There are lots of applications of the coupling in geometric and analytic problems as it can be seen from an excerpt of the literature in [3, 4, 5, 6, 25, 26, 27, 28, 37, 38, 39].

One of the main techniques in the present work is the mirror coupling applied to time changed Brownian motions. It turns out to be an extremely fruitful tool for proving estimates in the context of Ricci flow. Though the coupling and the Bismut formula produce in several cases similar estimates, particularly when it comes to gradient estimates, we do not know how to get a nice and useful version of the Bismut formula for the second-order derivatives. This is one of the reasons we prefer to deal with the coupling techniques which reveals its full power. The idea of dealing with the second-order derivatives comes from [17], where a coupling of three particles is used to estimate second-order derivatives of harmonic functions on Euclidean domains. This triple coupling indicated by Cranston uses a certain symmetry to get a key cancellation in the estimation of the Hessian. This symmetry is not surprising in the flat case. However, there are immediate technical challenges for a similar construction on manifolds, and the way it works in the flat case does not seem to work on arbitrary manifolds for the time changed Brownian motions. Nevertheless, it turns out that we can construct such a triple coupling which has enough good properties in the case of surfaces of constant curvature.

We continue with a few more observations about the present work. We do not prove the existence of solutions to the target problem directly; rather, the verification theorems proceed from the assumption that the Ricci flow admits a smooth solution. In the case of normalized Ricci flow, we have long-time existence as proved in [10] and [23]. However, an immediate consequence of such a verification Theorem is that the solution (to the flow) is unique.

In contrast to the standard proof of the convergence to constant curvature, we deal directly with the metric itself (and its derivatives), rather than introducing an auxiliary PDE satisfied by the curvature. We use uniformization to work with an underlying metric which has constant curvature and is in the same conformal class as the initial metric. One might hope to extend these arguments to more general situations, but for a first paper on this approach uniformization makes the analysis cleaner and reveals the power of the coupling in a nice way.
The outline of the paper is as follows. We first describe the stochastic target problem in Section 2 giving a fair amount of detail, since it is a somewhat non-standard control problem. Then, in Section 3 we prove the verification/uniqueness theorem, namely that, if there is a smooth solution to the Ricci flow (or normalized Ricci flow) on some interval of time, then it agrees with the solution to the stochastic target problem.

Section 4 is a short section showing how one can use the representation to prove that the unnormalized Ricci flow develops singularities (in certain cases) either in finite time or in infinite time. In Section 5, we develop the a priori bounds for the stochastic target problem. As a consequence, we obtain the exponential convergence in the $C^0$-norm of the normalized flow in the case of $\chi(M) < 0$ (as usual, $\chi(M)$ denotes the Euler characteristic of $M$). We also include a short discussion of the blow up of the unnormalized Ricci flow in the cases $\chi(M) > 0$ and $\chi(M) < 0$, which is in tune with the previous section’s findings, although this time assuming uniformization.

Section 6 introduces and proves the main result on mirror coupling for the time changed Brownian motions associated to the target problems. This coupling is well defined for short times, but the main challenge is to show that the coupling extends beyond the cut locus. This is done using the geometric structure of the cut locus on surfaces of Euler characteristic less than or equal to 0. We should also point out that there is a coupling of Brownian motions constructed with respect to time-varying metrics (such as Ricci flow) in [30], but it differs from our situation here.

In Section 7 we start the main analysis of the convergence of normalized Ricci flow. We prove the nontrivial fact that in Euler characteristic zero, the normalized flow converges exponentially fast in the $C^0$-topology. This uses the result from the previous section combined with the comparison of the distance process with a Bessel process in order to estimate the coupling time. This is a fundamentally probabilistic idea. Combining this result with those coming from the a priori estimates proves that, for non-positive Euler characteristic, the flow converges in the $C^0$-topology exponentially fast.

The next task is to prove that the convergence takes place also in $C^1$, or in other words that the gradient of the metric converges exponentially fast. This is done in Section 8, again using coupling. However, the point here is a little different. We use the coupling for particles started close to one another and estimate the coupling time in terms of the gradient of the metric (more precisely the conformal factor of the metric) and the initial distance. This in turn yields a functional inequality satisfied by the $C^0$-norm of the gradient which is contained in Lemma 12. It turns out that this functional inequality is strong enough to produce the exponential convergence.

Going forward, Section 9 is dedicated to the triple coupling used in a crucial way for the Hessian estimates. We exploit in an essential way the constant curvature properties of the underlying metric. We have two mirror coupled particles $x$ and $y$ and another middle particle $z$ which is moving on the geodesic between them which is described by the distance $\rho_1$ from $z$ to $x$, or alternatively, the distance $\rho_2$ from $z$ to $y$. One of the main interests is the symmetry with respect to swapping $\rho_1$ and $\rho_2$. The other thrust of the investigation is as follows. Assuming that $x$ and $y$ are time changed Brownian motions, we study the conditions under which $z$ is a time changed Brownian motion with a drift. This is a key point in the Hessian estimates.

Section 10 covers the Hessian estimates. Here we use the results from the previous sections, for instance, the exponential decay of the flow in the $C^1$-topology and the triple coupling. As in the case of the gradient we end up with a functional inequality for the $C^0$-norm of the Hessian as in Lemma 21. It turns out that this suffices to conclude the exponential convergence.

The last section proves the $C^k$-convergence of the flow. This is done essentially using the Ricci flow equation and induction. It is important to mention here that in the flat case, we still use couplings.

A few words about the sphere case, which requires some finer analysis. There are several obstacles we have to overcome. On one hand, the a priori estimates give bounds which blow up in finite or infinite time. However, these estimates are simply bounds of a stochastic differential equation in terms of the ODE in which the martingale is killed off, and eventually can likely be refined. Further, in the case of non-positive Euler characteristic, there is a unique stationary solution to the normalized Ricci flow with a given volume (in a given conformal class), and thus one has to prove that the flow converges to this uniquely determined solution. In the case of the sphere this is not the case and thus convergence
is harder to establish, because we do not know beforehand toward which stationary solution the flow wants to converge (this is related to the issue of Ricci solitons). Therefore, the strategy we used in this paper for $\chi(M) \leq 0$ needs some refinements if it’s to address the case of positive Euler characteristic.

2. STOCHASTIC TARGET FORMULATION

2.1. Ricci flow. Consider a smooth, compact Riemannian surface $(M, h)$, that is, $M$ is a smooth, compact manifold without boundary of dimension two and $h$ a smooth Riemannian metric on $M$. Any other smooth metric in the same conformal class as $h$ can be written as $g = \pi h$ for some smooth, positive function $\pi$. The Ricci curvature of any metric metric $g$ is given by

\begin{equation}
2\text{Ric}_g = R_g g = 2K_g g,
\end{equation}

where $R_g$ is the scalar curvature and $K_g$ is the Gauss curvature. The Ricci flow is defined as the evolution of the metric $g_t$ according to

\begin{equation}
\frac{\partial}{\partial t} g_{ij} = -2\text{Ric}_{ij}
\end{equation}

where $\text{Ric}$ is the Ricci tensor. From this, it is easy to see that the Ricci flow preserves the conformal class in two dimensions, and thus it becomes an evolution equation for the conformal factor $\pi_t$. In particular, the Ricci flow corresponds to $\pi$ evolving by

\begin{equation}
\frac{\partial}{\partial t} \pi_t = \Delta_h \log \pi_t - 2K_h
\end{equation}

where $K_h$ is the Gauss curvature of $(M, h)$. In passing from (2) to (3), we have already used the fact that if $g = uh$, for two metrics, $g$ and $h$, then (see [15, Exercise 2.8])

\begin{equation}
R_g = \frac{1}{u}(R_h - \Delta_h \log u)
\end{equation}

where the $\Delta_h$ is the Laplacian with respect to the metric $h$. This is a non-linear parabolic equation, and thus the usual probabilistic methods of solution (diffusions, Feynman-Kac, etc.) don’t apply. Instead, we will adopt a stochastic target approach modeled on the approach of [42] to mean curvature flow, as mentioned above.

To be more concrete, we assume that the initial metric on $M$ can be written as $g_0 = \pi_0 h$ for some smooth, positive $\pi$ and some metric $h$. There are two natural choices for $h$. Of course, we can let $h = g_0$ and $\pi_0 \equiv 1$. Alternatively, the uniformization Theorem for instance [35, Chapter 3] implies that there is a metric in the same conformal class as $g_0$ which has constant curvature of $-1$, $0$, or $1$. Then we can take $h$ to be this metric, in which case $\pi_0$ is determined by the condition that $g_0 = \pi_0 h$. We will find the flexibility of this set-up to be useful.

As usual, we also wish to introduce the normalized Ricci flow, which is defined as

\begin{equation}
\frac{\partial}{\partial t} g_{ij} = -2\text{Ric}_{ij} + 2rg_{ij}
\end{equation}

where $r$ is the average of the Gauss curvature on $M$ with respect to the metric $g$. Written in terms of the conformal factor, this is

\begin{equation}
\frac{\partial}{\partial t} \bar{\pi}_t = \Delta_h \log \bar{\pi}_t - 2K_h + 2r_t \bar{\pi}_t.
\end{equation}

Under this flow, the surface is continually rescaled to preserve the area. Indeed, the Gauss-Bonnet Theorem tells us that the integral of the scalar curvature is

\[ \int K_g dA_g = 2\pi \chi(M) \]

where $\chi(M)$ is the Euler characteristic of $M$ and $A_g$ is the area element of the metric $g$. Consequently, if $r_t$ is the average of the Gauss curvature for $g_t$, then

\[ r_t = \frac{2\pi \chi(M)}{\text{area}(M, g_t)} \]
where \( \text{area}(M, g) \) stands for the area of \( M \) with the metric \( g \). From here, a straightforward calculation gives that

\[
\partial_t \text{area}(M, g_t) = \partial_t \int \bar{u}_t dA_h = \int \partial_t \bar{u}_t dA_h = -2 \int K_h dA_h + 2r_t \int \bar{u}_t dA_h = 0,
\]

which shows that the area is preserved under this evolution and, in particular, \( r_t \) does not depend on \( t \).

Therefore the flow (5) preserves the area and

\[
(6) \quad r = \frac{2\pi \chi(M)}{\text{area}(M, g_0)}.
\]

We can now translate (5) into an equation satisfied by the conformal change \( \bar{u}_t \) as (recall that \( g_t = \bar{u}_t h \))

\[
(7) \quad \partial_t \bar{u}_t = \Delta_h \log \bar{u} - 2K_h + 2r \bar{u}_t
\]

with \( r \) the constant from (6).

As is implicit in the above, we see that the set of all smooth metrics (on \( M \)) in a given conformal class corresponds to the set of smooth sections of a one-dimensional bundle over \( M \). More concretely, fixing a "reference metric" \( h \) and writing any other (smooth) metric (in the same conformal class) as \( \bar{u} h \) induces a global coordinate \( u \) on fibers of this bundle making the total space \( E \) diffeomorphic to \( M \times (0, \infty) \). Further, \( \bar{u} \) is given as the composition of the lift from \( M \) to \( E \) (corresponding to the section) with \( u \). This helps to explain the notation: \( u \) is a coordinate on the fibers, and \( \bar{u} \) is the expression of a section in this coordinate. Because our bundle admits natural global coordinates, we will almost always work in these coordinates, and thus we won’t have much occasion to consider sections in a coordinate-free notation.

Viewed in this light, it is natural to introduce a new coordinate on the fibers. Let \( p = (1/2) \log u \). Then any other metric in the same conformal class as \( h \) can be written as \( g = e^{2p} h \) for some smooth function \( p : M \to \mathbb{R} \), which is given by the composition of the lift \( M \to E \) (corresponding to the section) with \( p \). This coordinate makes the bundle into a real line bundle. In particular, the metric \( h \) corresponds to the zero section, and fiberwise addition corresponds to composition of conformal changes. However, we won’t need the vector space structure on fibers in what follows; we really just view the fibers as having a smooth structure. In terms of the coordinate \( p \), the Ricci flow equation becomes

\[
(8) \quad \partial_t \bar{p}_t = e^{-2p_t} (\Delta_h \bar{p}_t - K_h),
\]

and the normalized Ricci flow equation becomes (see also [33, Equation 1.3.1])

\[
(9) \quad \partial_t \bar{p}_t = e^{-2p_t} (\Delta_h \bar{p}_t - K_h) + r.
\]

with \( r \) the constant defined in (6) and thus depending only on the area of \( M \) with respect to the initial metric \( g_0 \).

At this point, we see that there is a one-to-one correspondence between metrics in the same conformal class as \( h \), sections of \( E \) over \( M \), and functions \( p \) (where all of these objects are assumed to be smooth). Further, there is a one-to-one correspondence between smooth sections and smooth hypersurfaces of \( E \) that intersect each fiber once and do so transversely; under composition with \( p \) this is the same as the correspondence between smooth functions on \( M \) and their graphs in \( M \times \mathbb{R} \). Viewing metrics as hypersurfaces in the total space \( E \) provides a framework for studying Ricci flow which is fairly similar to that of mean curvature flow and well-suited for the stochastic target approach. Our next task is to define the appropriate target problem.

2.2. The target problem. Let \( \Gamma(0) \) be the hypersurface corresponding to the initial metric \( g_0 \). In spite of our previous efforts to distinguish between sections over \( M \) from their description in a particular coordinate, in what follows we will fix the global coordinate \( p \) on fibers, thus identifying the fibers with \( \mathbb{R} \), and formulate everything in those terms. In particular, \( \Gamma(0) \) corresponds to the graph of \( p_0 \). The stochastic target problem is, for any time \( t \), the problem of determining the set of points such that the controlled process, starting from such a point, can be made to hit \( \Gamma(0) \) (the “target”) in time \( t \) almost surely. Obviously, this requires specifying the allowed controls and the processes they give rise to. We
will generally explain things for the Ricci flow and then indicate the analogous results for the normalized Ricci flow in situations where there are no additional complications.

We start with the infinitesimal picture in normal coordinates. We choose any point \((q, \tilde{p}) \in M \times \mathbb{R}\) and let \((x_1, x_2)\) be normal coordinates around \(q\). Thus \((x_1, x_2, p)\) are coordinates on a neighborhood of \(\{q\} \times \mathbb{R}\). We assume that the controlled process is currently at \((q, \tilde{p})\), say at time \(\tau\). The \((x_1, x_2)\)-marginal of the controlled process will be (infinitesimally) Brownian motion on \(M\) (with fixed reference metric \(h\)), time-changed by \(2e^{-2\tilde{p}}\). The control consists of choosing a lift of the tangent plane to \(M\) at \(q\) into the tangent space to \(E\) at \((q, \tilde{p})\). The controlled process has its martingale part diffusing (infinitesimally) along this lifted plane in the unique way that gives the right \((x_1, x_2)\)-marginal, and has its drift along the fiber at rate \(2e^{-2p}K_h\) (plus an additional \(-2\pi \chi(M)/\text{area}(M, h)\) for the normalized Ricci flow). More precisely, the control consists of a choice of \((a_1, a_2) \in \mathbb{R}^2\), for which the processes evolves (infinitesimally, assuming the process is at \((q, \tilde{p})\) at time \(\tau\)) according to

\[
\begin{bmatrix}
  dx_{1,\tau} \\
  dx_{2,\tau} \\
  dp_{\tau}
\end{bmatrix} = \begin{bmatrix}
  e^{-\tilde{p}} & 0 & 0 \\
  0 & e^{-\tilde{p}} & 0 \\
  e^{-\tilde{p}a_1} & e^{-\tilde{p}a_2} & 0
\end{bmatrix} \begin{bmatrix}
  \sqrt{2} dW^1_{\tau} \\
  \sqrt{2} dW^2_{\tau}
\end{bmatrix} + \begin{bmatrix}
  0 \\
  0 \\
  e^{-2p}K_h(q)
\end{bmatrix}.
\]

where \(W^1\) and \(W^2\) are one-dimensional Brownian motions. Here we have written \(K_h(q)\) to emphasize that the curvature depends on the point in \(M\). The \(\sqrt{2}\) factors (in front of the Brownian differentials) are needed because the Ricci flow is defined using the Laplacian, instead of half the Laplacian, and rather than use a non-standard normalization for the Ricci flow, we choose to speed up our Brownian motions (this is analogous to the usual discrepancy between the analysts’ and the probabilists’ versions of the heat equation). This is the controlled process, at least infinitesimally, corresponding to the Ricci flow. For the normalized Ricci flow, the set of controls is the same, but the process evolves according to

\[
\begin{bmatrix}
  dx_{1,\tau} \\
  dx_{2,\tau} \\
  dp_{\tau}
\end{bmatrix} = \begin{bmatrix}
  e^{-\tilde{p}} & 0 & 0 \\
  0 & e^{-\tilde{p}} & 0 \\
  e^{-\tilde{p}a_1} & e^{-\tilde{p}a_2} & 0
\end{bmatrix} \begin{bmatrix}
  \sqrt{2} dW^1_{\tau} \\
  \sqrt{2} dW^2_{\tau}
\end{bmatrix} + \begin{bmatrix}
  0 \\
  0 \\
  e^{-2p}K_h(q) - r
\end{bmatrix}.
\]

We point out that, for both the Ricci flow and the normalized Ricci flow, the (infinitesimal) diffusion matrix is

\[
\begin{bmatrix}
  2e^{-2p}r & 0 & 2e^{-2p} a_1 \\
  0 & 2e^{-2p}r & 2e^{-2p} a_2 \\
  2e^{-2p} a_1 & 2e^{-2p} a_2 & 2e^{-2p} (a_1^2 + a_2^2)
\end{bmatrix}
\]

in \((x_1, x_2, p)\) coordinates at \((q, \tilde{p})\), of course.

Having given the infinitesimal picture, we now extend this to a global description. While it is tempting to simply assert that this follows immediately from the local description, we prefer to give a more explicit formulation. There is more than one way to do this, but we choose to use the bundle of orthonormal frames on \((M, h)\). The immediate difficulty with extending the above local picture is that, except in special cases (more on which below), we cannot find coordinates which are normal at more than one point at a time, or even a global orthonormal frame. The solution we have in mind is to use the bundle of orthonormal frames to supply each point along the evolving process with an orthonormal frame and its associated normal coordinates. In particular, let \(\mathcal{O}(M)\) be the bundle of orthonormal frames over \((M, h)\), consisting of points \((q, \mathcal{e}(q))\) where \(q \in M\) and \(\mathcal{e}(q)\) is an orthonormal basis for \(T_qM\) with metric \(h\). We identify \(\mathcal{e}(q)\) with the corresponding linear isometry from \(\mathbb{R}^2\) to \(T_qM\). Let \(e_1\) and \(e_2\) be the standard basis for \(\mathbb{R}^2\) and let \(\mathcal{E}(\mathcal{e}_i)\) be the corresponding canonical vector fields. Further, we let \(\pi : \mathcal{O}(M) \to M\) be the usual projection and \(\pi_* : T\mathcal{O}(M) \to TM\) be the induced push-forward map on tangent spaces.

The connection with the previous infinitesimal picture comes from the following relationship between the canonical vector fields and normal coordinates. Choose a point \(q \in M\) and a frame \(\mathcal{e}(q)\) over \(q\), and let \((x_1, x_2)\) be normal coordinates (for \((M, h)\)) in a neighborhood of \(q\) such that \(\partial_{x_1} = \mathcal{e}(q)(e_1)\) at \(q\). Obviously, \(\pi_* [\mathcal{E}(e_i)|_{\mathcal{e}(q)}] = \partial_{x_i}|_{\mathcal{e}(q)}\). Moreover, let \(s\) be a smooth section of \(\mathcal{O}(M)\) in a neighborhood of \(q\) which is equal to \(\mathcal{e}(q)\) at \(q\) and horizontal at \(q\), meaning that \(\partial_{x_1}s\) are horizontal vectors at \(q\). Then \(\pi_* [\mathcal{E}(e_i) \circ s]\) agrees with \(\partial_{x_1}\) to first-order around \(q\). (Indeed, to show that such a section \(s\) exists, start with normal coordinates and apply the Gram–Schmidt process to \(\{\partial_{x_1}, \partial_{x_2}\}\) at every point in a neighborhood of \(q\).)
We also recall the connection between the bundle of orthonormal frames and Brownian motion on 
\((M, h)\). We have that \((\mathcal{E}(e_1)^2 + \mathcal{E}(e_2)^2)/2\) is Bochner’s Laplacian on \(\mathcal{O}(M)\), and the corresponding martingale problem is well-posed (in the sense of Stroock and Varadhan, namely that there is a unique solution for any initial point). We use \(\tilde{B}_\tau\) to denote such a process. Projecting \(\tilde{B}_\tau\) to \(M\) gives Brownian motion on \(M\), which we denote \(B_\tau\). This is the well-known Eells-Elworthy-Malliavin construction of Brownian motion on \(M\) and we refer the reader to [24] or [43] for a detailed account on the subject. Moreover, the process \(\tilde{B}_\tau\) on \(\mathcal{O}(M)\) should be thought of as the horizontal lift of \(B_\tau\) on \(M\), and thus as giving Brownian motion equipped with parallel transport. In particular, this is how we will typically give Brownian motion on \(M\) endowed with parallel transport. Finally, we note that the solution to the martingale problem for Bochner’s Laplacian can be realized as the (unique) strong solution to the natural SDE driven by a standard Brownian motion on \(\mathbb{R}^2\), or equivalently, two independent, one-dimensional Brownian motions. That is, \(\tilde{B}_\tau\) can be realized as the solution to

\[
d\tilde{B}_\tau = \mathcal{E}(e_1) \circ dW^1_\tau + \mathcal{E}(e_2) \circ dW^2_\tau
\]

where \(\circ dW\) indicates that the differential is to be understood in the Stratonovich sense.

We now have the necessary background to give the global formulation of the stochastic target problem for Ricci flow (and the related target problem for normalized Ricci flow). We write points in \(E\) as \((x, p) \in M \times \mathbb{R}\) and the controlled process (for the Ricci flow) as \(Y_\tau = (x_\tau, p_\tau)\). As suggested above, the \(x\)-marginal \(x_\tau\) will be Brownian motion on \(M\), time-changed by \(p\), and thus we know from the above that we have parallel transport of frames (for \(T_x M\)) along the paths \(x_t\) (note that the frame is always orthonormal relative to the metric \(h\)). In particular, if we choose a frame \(e(x_0)\) at the starting point, then we let \(e(x_\tau)\) denote the parallel transport of this frame along \(x_\tau\). Abstractly, the control consists in choosing a lift of \(T_{x_\tau} M\) to \(T_{(x_\tau, p_\tau)} E\). In terms of our evolving frame, such lifts can be identified with points of \(\mathbb{R}^2\). This is the time to formally introduce the control process. In what follows, \((\Omega, \mathcal{F}, \mathbb{P})\) is a probability space where the Brownian motion \((W^1, W^2)\) is defined and the reference filtration involved here is \(\mathcal{F}_\tau\), the one generated by the Brownian motion.

**Definition 1.** For a fixed time \(t > 0\), an admissible control process \(A\) is a bounded map \(A : [0, t] \times M \times \Omega \to \mathbb{R}^2\) which is continuous in the first two coordinates, and such that for each \((x, \tau) \in M \times [0, t]\), \(A(\tau, x) : \Omega \to \mathbb{R}^2\) is \(\mathcal{F}_\tau\)-measurable. We write this in components \(A = (a_1, a_2)\).

We will explain below in the first remark of this section why we require the control to be bounded.

If we start our process from a point \(Y_0 = (x_0, p_0)\) equipped with a frame \(e(x_0)\) of \(T_{x_0} M\), then it evolves according to the SDE (note that we’re using both Itô and Stratonovich differentials)

\[
\begin{align*}
\mathstrut dx_\tau &= e^{-p_\tau} \left[ \sum_{i=1}^{2} e(x_\tau)(e_i)\sqrt{2} \circ dW^i_\tau \right] \\
dp_\tau &= e^{-p_\tau} \left[ \sum_{i=1}^{2} a_i \sqrt{2} dW^i_\tau \right] + e^{-2p_\tau} K_h(x_\tau) \, d\tau.
\end{align*}
\]

(10)

This equation comes with the following convention.

**Convention.** Whenever we have a bracket \(A[[M \circ dN]]\) the order of operations is that we first write \(M \circ dN = M \, dN + \frac{1}{2} d\langle M, N \rangle\) in Itô form and then multiply everything by \(A\). Thus, we have

\[
A[[M \circ dN]] = (AM) dN + \frac{1}{2} A d\langle M, N \rangle
\]

as opposed to the common writing

\[
A[M \circ dN] = AM \, dN + \frac{1}{2} d\langle AM, N \rangle.
\]

For the standard Itô differentials, the meaning is the standard one, namely

\[
A[MDN] = (AM) dN
\]
Here we see that \( \epsilon(x_\tau)\epsilon_i \) is just the projection onto \( M \) of \( \mathcal{E}(\epsilon_i) \) and to ease the notation we will also use the shortcut \( \epsilon(x_\tau)\epsilon_i = \epsilon_i(x_\tau) \), or even more simply \( \epsilon_i \), if there is no confusion generated by dropping \( x_\tau \). In particular, the horizontal lift of \( x_\tau \), which we write \( \tilde{x}_\tau = (x_\tau, \epsilon(x_\tau)) \) evolves according to

\[
d\tilde{x}_\tau = e^{-p_r} \left[ \sum_{i=1}^{2} \mathcal{E}(\epsilon_i) \sqrt{2} \circ dW^i_\tau \right] \quad \text{on } \mathcal{O}(M),
\]

and the first line of (10) is just the projection of this onto \( M \). We choose to write (10) in this way in order to emphasize that we’re ultimately only interested in the evolution of the surface in \( E \) and not in the frame; the frame is only used as a convenience in order to express the control and the corresponding SDE. We do this despite the fact that (10) requires evolving the frame \( \epsilon(x_\tau) \) as well.

The mixing of Itô and Stratonovich differentials in (10) is a result of the fact that horizontal Brownian motion (or just Brownian motion on \( M \)) is not easily written globally in Itô form. To clarify this, we give the following equivalent characterization, which is just a consequence of Itô’s formula but one of the important properties of the above system. For any smooth function \( \varphi : [0, T] \times M \times \mathbb{R} \to \mathbb{R} \) (assuming that the process \( (x_\tau, p_\tau) \) exists for \( \tau \in [0, T] \)),

\[
d\varphi(\tau, x_\tau, p_\tau) = e^{-p_r} \left[ \sum_{i=1}^{2} \mathcal{E}(\epsilon_i) \varphi + a_i \varphi' \right] \sqrt{2} dW^i_\tau \\
+ \left( \partial_\tau \varphi + e^{-2p_r} K_h(x_\tau) \varphi' + e^{-2p_r} \Delta_h \varphi + e^{-2p_r} \sum_{i=1}^{2} a_i^2 \varphi'' + 2 e^{-2p_r} \sum_{i=1}^{2} a_i \epsilon_i \varphi' \right) d\tau
\]

where all the “inside” functions are evaluated at \( (\tau, x_\tau, p_\tau) \), \( \epsilon_i(x) \varphi \) signifies the derivative (along \( \epsilon_i(x) \)) with respect to the second variable of \( \varphi \), \( \partial_\tau \varphi \) is the derivative with respect to \( \tau \) variable, and the prime is the partial derivative with respect to \( p \). Note that if we let \( (x_1, x_2) \) be appropriate normal coordinates at a point, then applying this to \( x_1, x_2, \) and \( p \) shows that, at that point, this agrees with the infinitesimal picture described above.

We now take a moment to discuss what we mean by asserting the controlled process arises from the control via the SDEs just mentioned. We understand these (systems of) SDEs in the weak sense, that is the choice of driving Brownian motions \( (W_1^\tau, W_2^\tau) \) is part of the solution, not prescribed in advance. Of course, for an arbitrary choice of controls, a solution need not exist, and if it does, it may not be unique in law. We will have more to say about this later, after we introduce the target problem.

Now that we’ve specified the admissible controls \( A_\tau \) and described the evolution of controlled process \( Y_\tau(A) \) that a choice of control gives rise to, it’s time to explain how this gives rise to a subset of \( E \).

**Definition 2.** We define the reachable set at a given time \( t \in [0, \infty) \), denoted \( V(t) \), to be the set of points in \( E \) for which there exists an admissible control such that the controlled process, started at this point and with this control, is in \( \Gamma(0) \) at time \( t \) almost surely.

We follow Soner and Touzi [42] in calling this the reachable set, even though it’s the set of points you can reach a fixed target from, not the set of points you can reach from a fixed starting point. In order for this to be well-defined, we need to show that \( V(t) \) doesn’t depend on the initial choice of frame. Suppose \( A_\tau \) is a control such that \( Y_\tau(A_\tau) \), started from \( y \in E \) with initial frame \( \epsilon(y) \), hits \( \Gamma(0) \) at time \( t \) almost surely (so that \( y \in V(t) \)). If \( \epsilon(y) \) is any other (orthonormal) frame at \( y \), then there is some \( r \in O(2) \) such that \( \epsilon(y) = r \epsilon(y) \). It’s clear that \( A_\tau r \) is such that \( Y_\tau(A_\tau r) \), started from \( y \in E \) with initial frame \( r \epsilon(y) \), hits \( \Gamma(0) \) at time \( t \) almost surely. Thus a point of \( E \) is in the reachable set if not independent of what frame we use to express the controlled process, and so the \( V(t) \) are well-defined.

For a point in the reachable set, we will indicate the control in the definition by \( \hat{A} \), if necessary indicating the point in \( V(t) \) by writing \( \hat{A}(x_0, p_0) \) or \( \hat{A}(Y_0) \), and call it a successful control (this seems linguistically more appropriate than optimal control). In light of the fact that this depends on the initial choice of frame, a successful control should really be thought of as a family of controls indexed by \( O(2) \). However, since the dependence on the initial frame is so simple and not our primary focus, we will generally gloss over this. We will also write \( Y_\tau(A) \) as \( \hat{Y}_\tau \). Thus, the defining property of a point in \( V(t) \) and the
associated successful control is that if we start the process at this point in \( V(t) \), then \( Y_t(\hat{A}) \in \Gamma(0) \) almost surely. This necessarily requires that, for a successful control \( \hat{A} \), there exists a solution to Equation (10) and thus a corresponding process \( Y_\tau(\hat{A}) \) for all time \( \tau \in [0, t] \). In particular, one might imagine that some choice of control gives rise to a solution under which \( p_\tau \) blows up prior to \( t \) \( (x_\tau \text{ can’t blow up since } M \text{ is compact}) \), but such a control cannot be a successful control by definition. The definition does not require that a successful control gives rise to a solution \( Y_\tau(\hat{A}) \) which is unique in law, despite the fact that our notation makes it look as though \( Y_\tau \) is always determined by \( \hat{A} \). (So it is conceivable that a successful control might give rise to another solution \( Y_\tau' \) that doesn’t almost surely hit the target.) Nonetheless, we will see below that, as long as a smooth solution to the Ricci flow exists, there is essentially only one choice of successful control starting from a given point of \( V(t) \), that it is well-behaved, and that this control uniquely determines \( \hat{Y}_\tau \).

Finally, we recall that the stochastic target problem is the determination of the reachable sets \( V(t) \). We note that \( V(0) = \Gamma(0) \); understanding \( V(t) \) for positive \( t \) and its relationship to Ricci flow is the topic of the next section. Looking ahead, what we will prove is that, assuming the Ricci flow has a smooth solution for some interval of time, that solution agrees with the solution to the stochastic target problem in the sense that \( V(t) = \Gamma(t) \) at all times in this interval.

Naturally, we have an analogous set-up which we associate with the normalized Ricci flow. The set of admissible controls remains the same, but now the controlled process, which we denote \( Y^n_\tau(A) \) (the “\( n \)” in the superscript standing for “normalized”) evolves according to

\[
dx_t = e^{-p_\tau} \left[ \sum_{i=1}^2 e(x_\tau)(e_i)\sqrt{2} \circ dW_t^i \right]
\]

(12)

\[
dp_\tau = e^{-p_\tau} \left[ \sum_{i=1}^2 a_i \sqrt{2} dW_t^i \right] + (e^{-2p_\tau} K_h(x_\tau) - r) \, dt.
\]

Note that the only difference from \( Y_\tau \) is that the drift of \( p_\tau \) has an extra term.

We denote the corresponding reachable sets by \( V^n(t) \). We also have the analog of Equation (11) where \( e^{-2p_\tau} K_h \) there is replaced by \( e^{-2p_\tau} K_h - r \):

\[
d\varphi(\tau, x_\tau, p_\tau) = e^{-p_\tau} \sum_{i=1}^2 \left( e_i(x_\tau)\varphi + a_i\varphi' \right) \sqrt{2} dW_t^i
\]

\[+ \left( \partial_t \varphi + (e^{-2p_\tau} K_h(x_\tau) - r) \varphi' + e^{-2p_\tau} \Delta_h \varphi + e^{-2p_\tau} \sum_{i=1}^2 a_i^2 \varphi'' + 2e^{-2p_\tau} \sum_{i=1}^2 a_i(e_i\varphi)\varphi' \right) \, dt.
\]

**Remark.** We want to discuss why we insist that our control \((a_1, a_2)\) is in \( L^\infty \). We begin by describing a simpler situation which illustrates the essential point. Suppose we consider a real-value controlled process given by

\[dx_t = a_t \, dW_t, \quad x_0 = 1,\]

where \( a_t \) is an adapted real-valued function which serves as the control. If we consider the goal to be to make the process \( x_t \) hit 0 in within time 1 (and we stop the process when it hits 0), then we would like to assert that this is impossible, because, for instance, it would violate the martingale property of \( x_t \). However, without some additional restriction on \( a_t \), this will not be the case. For example, consider the following scheme for controlling the process. For \( t \in [0, 1/2] \), we let \( a \) be the constant such that the process has probability 1/2 of hitting 0 by time \( t = 1/2 \). It is clear that this is possible, since letting \( a \) be constant means that \( x_t \) is simply a time-changed Brownian motion, and we know that Brownian motion almost surely hits the origin in finite time, no matter where it is started from. Then at \( t = 1/2 \), the process has hit 0 and been stopped with probability 1/2. If it hasn’t, then \( x_{1/2} \) is some positive value. Again, we can find some constant value for \( a \), depending only on \( x_{1/2} \), such that if we let \( a_t \)

\[
eq \text{constant for } t \in [1/2, 3/4), \text{ then the process hits } 0 \text{ in that interval of time with probability } 1/2. \text{ Thus, by time } t = 3/4, \text{ the process has hit } 0 \text{ with probability } 3/4. \text{ Now we can iterate this procedure, at each step using up half of the remaining time, in order to get } x_t \text{ to hit } 0 \text{ with probability } 1 \text{ by time } t = 1. \text{ If we do this, the resulting process } x_t \text{ will no longer be a martingale on the interval } t \in [0, 1] \text{ but instead merely a local martingale. Part of the point is that this is a simple trick. We can think of } a_t \text{ as determining a time-change so that } x_t \text{ is a time-changed}
Brownian motion, and since we know Brownian motion hits the origin in finite time, if we’re allowed to speed up time as much as we’d like we can simply compress the entire lifetime of the Brownian motion prior to the first time it hits the origin into a finite interval.

We now return to the target problem we associate to Ricci flow. In light of the above, if we assumed only that \((a_1, a_2)\) was adapted, we could imagine a similar procedure of choosing the control to be very large so that, from any starting point, we could cause it to hit \(\overline{p}_{t-r}\) (this is a moving target, but it varies in a smooth fashion and stays bounded) by time \(t\). Once it hits \(\overline{p}_{t-r}\), we could then “switch” to the successful control described in the next section in order to hit \(\overline{p}_0\) as time \(t\). The result would be that every point would be in \(V(t)\), which is obviously not what we want. Of course, what we’ve just described uses a discontinuous control, but one can imagine smoothing it to get a continuous analogue. At any rate, the underlying logic of this “bad” control justifies our wish to avoid unbounded controls.

Requiring that \((a_1, a_2)\) be bounded prevents this kind of easy trick and forces a successful control to respect the geometry of the situation. Of course, one might imagine that there might be other, less restrictive, ways to achieve this, such as requiring the controls to be in some \(L^p\)-space for finite \(p\) or requiring some natural coordinate to be a martingale, as opposed to merely a local martingale. Indeed, if one were to extend this stochastic target formulation to include, say, non-compact surfaces, it seems like some weaker assumption on the control would be appropriate. However, for the present paper, we have no need to speculate on what other conditions one might want in other circumstances.

**Remark.** We close this section by noting that, in the case when \((M, h)\) is flat (and thus either a torus or a Klein bottle), the orthonormal frame bundle is unnecessary. In particular, uniformization implies that \((M, h)\) is isometric to \(\mathbb{R}^2\) modulo the action of the group of Deck transformations \(\Lambda\). If we let \(x_1\) and \(x_2\) be the usual Euclidean coordinates on \(\mathbb{R}^2\), then \(h = dx_1^2 + dx_2^2\) (after identifying \(M\) with \(\mathbb{R}^2/\Lambda\)). Further, \((W^1, W^2)\) is Brownian motion on \((M, h)\), once we take it modulo \(\Lambda\). In this case, the set of controls are adapted, time-continuous, bounded maps into \(\{(a_1, a_2): a_i \in \mathbb{R}\}\), and the controlled process simplifies, so that it is given, for both Ricci and normalized Ricci flow, by the SDE

\[
\begin{pmatrix}
  dx_{1,r} \\
  dx_{2,r} \\
  dp_r
\end{pmatrix} =
\begin{pmatrix}
  e^{-p_{r}} & 0 \\
  0 & e^{-p_{r}} \\
  e^{-p_{r}a_1} & e^{-p_{r}a_2}
\end{pmatrix}
\begin{pmatrix}
  \sqrt{2} \, dW_1^r \\
  \sqrt{2} \, dW_2^r
\end{pmatrix}.
\]

**Convention.** Throughout this paper very often we will have a fixed time \(t > 0\) so that the stochastic target problem is defined on \([0, t]\) or the (normalized) Ricci flow is defined up to time \(t\). Since the process time is always going to be in \([0, t]\), all the stopping times involved will always be minimized with \(t\) so that the stopped process is well defined.

Also, the constants involved in the main estimates may change from line to line in such a way that they do not depend on time \(t\).

3. **Verification and the connection with Ricci flow**

At this point, we’ve described a pair of closely related stochastic target problems, namely the determination of \(V(t)\) and \(V^n(t)\), which we associate with Ricci flow and normalized Ricci flow, respectively. However, we’ve given no justification for these associations. In the present section, we prove that, under the assumption that a solution to the Ricci flow exists, the solution is given by the reachable sets. This justifies the introduction of these particular stochastic target problems in the context of Ricci flow.

Continuing with the notation of the previous section, we suppose that there is a smooth solution \(\overline{p}_t\) to the Ricci flow, that is, to Equation (8), with initial condition \(\overline{p}_0\) on the interval \(t \in [0, T]\) (where we allow the possibility that \(T = \infty\)). At each time \(t\), we can associate the solution with a section of \(E\) over \(M\) and thus with a submanifold of the total space \(E\), which is smooth and intersects each fiber once, transversely. We call the resulting submanifolds \(\Gamma(t)\) and note that this extends our earlier definition of \(\Gamma(0)\). Of course, knowing the \(\Gamma(t)\) for \(t \in [0, T]\) is equivalent to knowing \(\overline{p}_t\). Similarly, suppose there is a smooth solution \(\overline{p}_t^n\) to the normalized Ricci flow, that is, to Equation (9), with initial condition \(\overline{p}_0^n = \overline{p}_0\) on the interval \(t \in [0, T^n]\) (where, for the same manifold \((M, h)\) with the same initial metric \(g_0\), it is not necessarily true that \(T\) and \(T^n\) are equal). Then we have the associated submanifolds \(\Gamma^n(t)\) of \(E\). The connection between the Ricci flow and normalized Ricci flow (viewed in this way) and the stochastic target problems introduced above is given by the following Theorem. Note that both this sort of result and the method of proof mirror that of [42]. The main additional complication, besides the geometric
formalism needed for the general statement of the target problem, is that the controls are not restricted to a compact set.

**Theorem 3.** Let \((M, h)\) be a smooth, compact Riemannian surface with initial metric \(g_0 = e^{2\eta_0} h\), as above. Suppose that the Ricci flow has a smooth solution \(p_t\) on \(t \in [0, T]\). Then \(\Gamma(t) = V(t)\) for all \(t \in [0, T]\). Similarly, if the normalized Ricci flow has a smooth solution \(\bar{p}_t\) on \(t \in [0, T^n]\), then \(\Gamma^n(t) = V^n(t)\) for all \(t \in [0, T^n]\).

**Proof.** We start with the Ricci flow. We fix some \(t \in (0, T)\) and let \(\tau\) be the time parameter for the controlled process \(Y_\tau(A), \tau \in [0, t]\) (as usual in probabilistic approaches to PDEs, process time runs “backward” compared to PDE time). We consider the square of the vertical distance between the controlled process \(Y_\tau\) and \(\Gamma(t - \tau)\). That is, we consider \(\eta(x, p, \tau) = (p - \bar{p}_{t-\tau}(x))^2\) along the paths of \(Y_\tau\), so that \(\eta_\tau = (p_t - \bar{p}_{t-\tau}(x))^2\).

Actually, we begin by considering a slightly more general quantity. Let \(\xi(x, p, \tau) = p - \bar{p}_{t-\tau}(x)\), and for the moment let \(\varphi : \mathbb{R} \to [0, \infty)\) be any smooth function. We wish to consider \(\varphi(\xi(x, p, \tau))\); clearly \(\eta_\tau\) is just the special case \(\varphi(z) = z^2\).

We now apply Itô’s formula (11) to \(\varphi(\xi)_\tau\). In the following, \(\bar{p}\) is always evaluated at time \(t - \tau\) and position \(x_\tau\), we write \(\varepsilon_i\) for \(\varepsilon_i(x_\tau(x_\tau))\), and we suppress other arguments (such as for the controls \(a_i\)) as desired to make things more readable. Then we have

\[
d(\varphi(\xi)) = \sqrt{2} \varphi' e^{-p_\tau} \left[ (a_1 - \varepsilon_1 \bar{p}) dW^1_\tau + (a_2 - \varepsilon_2 \bar{p}) dW^2_\tau \right] + \sum_{i=1}^{2} e^{-2\eta_\tau} \left[ \varphi'' (-\varepsilon_i \bar{p})^2 + \varphi' (-\varepsilon_i^2 \bar{p}) \right] d\tau + \varphi' \partial_\bar{p} d\tau
\]

\[+ e^{-2\eta_\tau} \left[ \varphi' K_\tau + \varphi'' (a_1^2 + a_2^2) \right] d\tau + 2 e^{-2\eta_\tau} \varphi'' \left[ -a_1 \varepsilon_1 \bar{p} - a_2 \varepsilon_2 \bar{p} \right] d\tau.
\]

Recall that \(\varepsilon_1^2 + \varepsilon_2^2\) is just \(\Delta h\). Then a little algebra and the fact that \(\bar{p}\) satisfies Equation (8) allows us to simplify this, yielding

\[
d(\varphi(\xi)) = \sqrt{2} \varphi' e^{-p_\tau} \left[ (a_1 - \varepsilon_1 \bar{p}) dW^1_\tau + (a_2 - \varepsilon_2 \bar{p}) dW^2_\tau \right] + \left\{ e^{-2\eta_\tau} \varphi'' \left[ (a_1 - \varepsilon_1 \bar{p})^2 + (a_2 - \varepsilon_2 \bar{p})^2 \right] + \varphi' \left( e^{-2\eta_\tau} - e^{-2\eta_\tau} \right) \left( \Delta h \bar{p} - K_\tau \right) \right\} d\tau.
\]

We now return to considering \(\eta_\tau\). In this case, this equation specializes to

\[
d\eta_\tau = 2 \sqrt{2} (p_\tau - \bar{p}) e^{-p_\tau} \left[ (a_1 - \varepsilon_1 \bar{p}) dW^1_\tau + (a_2 - \varepsilon_2 \bar{p}) dW^2_\tau \right] + 2 e^{-2\eta_\tau} \left[ (a_1 - \varepsilon_1 \bar{p})^2 + (a_2 - \varepsilon_2 \bar{p})^2 \right] d\tau + 2 (p_\tau - \bar{p}) \left( e^{-2\eta_\tau} - e^{-2\eta_\tau} \right) \left( \Delta h \bar{p} - K_\tau \right) d\tau.
\]

First we show that any point \((x, p_t(x))\) in \(\Gamma(t)\) is in \(V(t)\). Obviously, this is true for \(t = 0\). Now choose \(t > 0\). We choose our controls \(a_1\) and \(a_2\) as follows: For \(\tau \in [0, t]\), we let \(a_1 = \varepsilon_1 \bar{p}_{t-\tau}(x)\) and \(a_2 = \varepsilon_2 \bar{p}_{t-\tau}(x)\). Thus, our controls are Markov with respect to the process’ position and the time (and the “current” frame, although this is largely just a convention, as discussed above). Intuitively, all we are doing is trying to cause the process to be tangent to the evolving solution given by \(\bar{p}\). Our controls are not only Markov in space and time, but they are given by evaluating smooth functions of space and time (and the lift of “space” into the orthonormal frame bundle) along the controlled process, and thus we know that the system of SDEs for \(Y_\tau\) has a unique strong solution. In particular, \(Y_\tau\) is uniquely determined by these controls. Using these controls, Equation (16) simplifies to

\[
d\eta_\tau = 2 (p_\tau - \bar{p}) \left( e^{-2\eta_\tau} - e^{-2\eta_\tau} \right) \left( \Delta h \bar{p} - K_\tau \right) d\tau.
\]

Because \(\bar{p}\) is smooth on \(M \times [0, T]\) and \(M\) is compact, we know that both \(\bar{p}_{t-\tau}(x)\) and \(\Delta h \bar{p}_{t-\tau}(x) - K_\tau\) are bounded on \((x, \tau) \in M \times [0, t]\). Now choose any \(\delta > 0\) and let \(\theta_\delta = \inf\{\tau: \eta_\tau \geq \delta\}\) be the first hitting time of \(\delta\). Also observe that both the controlled process \(Y_\tau = (x_\tau, p_\tau)\) and \(\eta_\tau\) have continuous paths. If we stop our process at \(\theta_\delta\), then \(p_\tau\) is also bounded (this follows from the fact that \(\bar{p}\) is bounded and the definition of \(\eta\)). Combining the boundedness of both \(\bar{p}\) and \(p_\tau\) with an easy estimate for the exponential function, we see that \(e^{-2\eta_\tau} - e^{-2\eta_\tau}\) is bounded above and below by a constant multiple of \(\pm (p_\tau - \bar{p})\), respectively. It follows that (for \(\tau \leq \theta_\delta\), we have \(d\eta_\tau \leq C\eta_\tau d\tau\), for some positive constant \(C\) depending
on \( t, \delta, \) and the bounds mentioned above. Recalling that \( \eta_0 = 0, \) because we start our controlled process on \( \Gamma(t), \) and integrating gives

\[
\eta_{\tau \wedge \theta_5} \leq C \int_0^{\tau \wedge \theta_5} \eta_s \, ds \quad \text{for } \tau \in [0, t].
\]

Then Gronwall’s lemma implies that \( \eta_{\tau \wedge \theta_5} = 0 \) for all \( \tau \in [0, t]. \) Because \( \eta_{\tau} \) has continuous paths, this means that \( \theta_5 > t, \) and thus we have that \( \eta_{\tau} = 0 \) for all \( \tau \in [0, t]. \) In particular, \( \eta_t = 0, \) and so \( Y_t \in \Gamma(0). \) Thus we’ve shown that \( \Gamma(t) \subset V(t). \)

Next, we need to show the opposite inclusion, \( V(t) \subset \Gamma(t). \) Again, this is clear for \( t = 0, \) so we fix some \( t \in (0, T). \) We have some starting point \( (\alpha, \beta) \in M \times \mathbb{R}, \) and we assume that there exists a control \( (a_1, a_2) \) such that \( Y_{\tau}(a_1, a_2) \) almost surely hits \( \Gamma(0) \) at time \( \tau = t. \)

At this point, we produce a mollified version of \( \eta \) by a judicious choice of \( \varphi. \) In particular, we now let \( \varphi : \mathbb{R} \to [0, \infty) \) be a smooth, symmetric function satisfying the following additional properties: \( \varphi \) is non-decreasing on \( [0, \infty), \varphi(z) = z^2 \) in some neighborhood of 0, and \( \varphi \) is constant on \( [A, \infty) \) for an appropriately chosen constant \( A. \) It follows that the value of \( \varphi \) on \( [A, \infty) \) is positive, \( \varphi \) is 0 only at 0, and all derivatives of \( \varphi \) are bounded. If we now let \( \hat{\eta}(x, p, \tau) = \varphi(\xi(x, p, \tau)), \) then \( \hat{\eta} \) is a mollified version of \( \eta, \) in the sense that they agree for small values of \( \eta \) but \( \hat{\eta} \) is bounded, along with all of its derivatives.

Let \( D(\tau) = E[\hat{\eta}_{\tau}]. \) Then Equation (15) shows that

\[
D(\tau) = D(0) + \int_0^\tau E \left[ e^{-2p_s} \varphi'' \left( (a_1 - \epsilon_1 \bar{p})^2 + (a_2 - \epsilon_2 \bar{p})^2 \right) + \varphi' \left( e^{-2p_s} - e^{-2p_0} \right) (\Delta h \bar{p} - K_h) \right] \, ds.
\]

Here, of course, the derivatives of \( \varphi \) are evaluated at \( \xi(x_s, p_s, s), \) Note that \( \epsilon_1 \bar{p}, \epsilon_2 \bar{p} \) and \( \Delta h \bar{p} - K_h \) are all bounded. Also, for small \( \xi \) we have that \( \varphi'' = 2 \) and \( \varphi' = 2(p_s - \bar{p}), \) and both of these derivatives are bounded for all \( \xi. \) Moreover, both \( e^{-2p_s} \varphi'' \) and \( \varphi' (e^{-2p} - e^{-2p_0}) \) are bounded because the derivatives of \( \varphi \) are identically zero for \( \xi > A. \)

If we now let \( C_1, C_2 \geq 0, \) there is another constant \( C_3 > 0 \) such that for any \( \xi \in \mathbb{R},
\[
C_1 \varphi''(\xi) - C_2 \varphi'(\xi) \xi \geq -C_3 \varphi(\xi)
\]

Combining all of these with the fact that \( a_1 \) and \( a_2 \) are bounded, we see that there is some positive constant \( C \) (different from the one above) depending on the bounds just mentioned, but not on \( \tau, \) such that

\[
D(\tau) = D(0) + (-C) \int_0^\tau (D(s)) \, ds \quad \text{for all } \tau \in [0, t].
\]

This is trivially equivalent to

\[
-D(\tau) \leq -D(0) + (-C) \int_0^\tau (-D(s)) \, ds \quad \text{for all } \tau \in [0, t].
\]

Now we apply standard Gronwall type arguments to deduce that

\[
-D(\tau) \leq (-D(0)) e^{-Ct} \quad \text{for all } \tau \in [0, t].
\]

Indeed, if \( E(\tau) = -\left( \int_0^\tau D(s) \, ds \right) e^{-C\tau}, \) we obtain first that \( E(\tau) \geq -D(0)(1 - e^{-C\tau})/C \) and from this the claimed inequality. In particular, letting \( \tau = t \) and multiplying by \(-1\) gives \( D(0) e^{-Ct} \leq D(t). \) By assumption, the controlled process hits \( \Gamma(0) \) at time \( t \) a.s., and thus \( D(t) = 0. \) Since \( D \) is always non-negative (because \( \varphi \) was chosen to be non-negative) and \( e^{-Ct} \) is positive, we conclude that \( D(0) = 0. \) This is equivalent to saying that our initial point \( (\alpha, \beta) \) is in \( \Gamma(t). \) Thus we have proven that \( V(t) \subset \Gamma(t). \)

The proof for the normalized Ricci flow is almost identical. With the appropriate quantities, \( \hat{p}, p_r, x_r \) and so on, equation (14) becomes

\[
d(\varphi(\xi))_r = \sqrt{2} \varphi' e^{-p_0} \left[ (a_1 - \epsilon_1 \bar{p}) \, dW^1_r + (a_2 - \epsilon_2 \bar{p}) \, dW^2_r \right] + \sum_{i=1}^2 e^{-2p_0} \left[ \varphi'' (-\epsilon_i \bar{p})^2 + \varphi' (-\epsilon_i^2 \bar{p}) \right] \, d\tau + \varphi' \partial_r \bar{p} \, d\tau
\]

\[
+ e^{-2p_0} \left[ \varphi' K_h - \tau e^{2p_r} + \varphi'' \left( a_1 + a_2 \right) \right] \, d\tau + 2e^{-2p_0} \varphi'' \left[ a_1 \epsilon_1 \bar{p} - a_2 \epsilon_2 \bar{p} \right] \, d\tau.
\]

and then from (9), we get exactly the same equation from (15), thus the rest of the proof is identical. \( \square \)
From the point of view of control theory, the above result is a verification theorem. From the point of view of PDE theory, this can also be thought of as a uniqueness theorem. In particular, it shows that smooth solutions to the Ricci flow are unique and we state this in the following.

**Corollary 4.** If there is a (smooth) solution to (normalized) Ricci flow on the time interval \([0, T]\), then it is unique.

It bears repeating that the above relies on already knowing that the Ricci flow has a smooth solution on some interval; in other words, it sheds no light on the existence of a solution (to either the Ricci flow or the control problem). On the other hand, this existence is well known in the present case. Cao [10] and Hamilton [23] show that, for a smooth, compact initial surface, the Ricci flow always has a smooth solution on some (non-trivial) interval of time, and the normalized Ricci flow has a smooth solution for all time. (Of course, much more can be said, including the relationship between the normalized and un-normalized flows, but again, this is well-known and can be found in any book on the subject.) For an accessible overview we refer to [14, Chapter 5], which treats the (normalized) Ricci flow on surfaces.

One additional feature of the successfully controlled process is that it provides Brownian motion on \(M\) under the backward Ricci flow (or backward normalized Ricci flow, of course), as we now explain. If we put a smooth family of metrics \(g_t\) on a smooth manifold \(M\), then a process \(B_t\) is a Brownian motion on \((M, g_t)\) if it solves the martingale problem for the time-inhomogeneous operator \(\Delta_{g_t}\). Suppose we have a smooth solution to the Ricci flow, as above, for \(t \in [0, T]\), and let \(g_t\) be the metric on \(M\) corresponding to this solution. Then if we choose a time \(t\) (in \((0, T)\)) and point \(x_0 \in M\), there is a unique point \((x_0, \tilde{p}_t)\) over \(x_0\) (where, of course, we use our standard fiber coordinate \(p\)) in \(\Gamma(t) = V(t)\). If we now run our successfully controlled process \(Y_t = (x_t, p_t)\) starting from this point, we know that it is on \(\Gamma(t - \tau)\) for all \(\tau \in [0, t]\), or equivalently that \(p_{\tau} = \tilde{p}_{t-\tau}(x_\tau)\), for all \(\tau \in [0, t]\) almost surely. Then looking at \(x_\tau\) (which is just the \(M\)-marginal) and recalling that \(g_\tau = e^{2p_t}h\), a little thought shows that \(x_\tau\) is a Brownian motion on \((M, g_{t-\tau})\) for \(\tau \in [0, t]\). That “process time” runs backward compared to “PDE” time, which manifests itself in the \((t - \tau)\) parameter (with \(t\) fixed and \(\tau\) increasing) for the metric \(g_t\), explains why we get Brownian motion on \(M\) under backward Ricci flow, as opposed to just Ricci flow.

For clarity, let us temporarily denote \(x_\tau\) under the successful control as \(\tilde{x}_\tau\). Then recognizing it as Brownian motion under backward Ricci flow gives a way of representing the solution to the Ricci flow (or normalized Ricci flow) that looks more like the usual representations for parabolic (linear) PDEs. In the special case when \(h\) is flat, normalized and un-normalized Ricci flow are the same, and we see that \(p_\tau\) is a martingale. Further, we have that

\[
(21) \quad \tilde{p}_t(x_0) = E^{x_0,t}[\tilde{p}_0(\tilde{x}_t)]
\]

where the expectation is taken with respect to the successfully controlled process started from \((x_0, \tilde{p}_t(x_0))\) and run until \(\tau = t\). This is analogous to solving the heat equation with some initial condition by running Brownian motion and then using it to average the initial condition. The difference is that, for the heat equation, we can construct Brownian motion (or more analytically, the heat kernel) without already having a solution to the heat equation with our initial data. This is because Brownian motion (or the heat kernel) doesn’t depend on the initial data, and so we can use it to solve the heat equation in the first place. All of this is a manifestation of the linearity of the heat equation. In the case of Ricci flow, we need to know \(\tilde{p}_t\) in order to determine \(\tilde{x}_\tau\) (or more accurately, these two are intertwined by the system of SDEs they solve), so we can’t first determine \(\tilde{x}_\tau\) and then use it in the above to solve the Ricci flow.

Also, we can now say a bit more about the recent work of [16] and [1]. They give a lift of Brownian motion on a manifold with time-dependent metric to the frame bundle which gives the parallel transport along the Brownian paths. They then introduce a notion of damped parallel transport which, under the Ricci flow (but not the normalized flow), becomes an isometry as well. This damped parallel transport can be used to produce martingales from solutions to heat problems under the Ricci flow. In our notation, \(x_\tau\) is the Brownian motion with respect to a time-dependent metric (with an additional factor of \(\sqrt{2}\) to get the normalization right, of course), and \(\{e^{-p_t}e(x_\tau)(e_1), e^{-p_t}e(x_\tau)(e_2)\}\) (which is an orthonormal frame for the time-varying metric) gives the parallel transport along the Brownian path \(x_\tau\).
4. THE BLOW UPS OF THE RICCI FLOW FOR THE CASE OF POSITIVE OR NEGATIVE EULER CHARACTERISTIC

This section is dedicated to showing that in the case of the (unnormalized) Ricci flow, there are blow ups either in finite or infinite time if the curvature of the reference metric $K_h$, is either always positive or always negative.

Assume now that the Ricci flow has a smooth solution defined on the time interval $[0, T)$. Then, from Theorem 3, we learn that for any fixed time $t \in [0, T)$, $p_t = \overline{p}_{t-\tau}(x_\tau)$ where $(x_\tau, p_\tau)$ is the solution to (10) with the initial conditions $(x, \overline{p}_0(x))$. On the other hand, taking a smooth function $\varphi : [0, t] \times \mathbb{R} \to \mathbb{R}$ in (11), we obtain that

$$d\varphi(\tau, p_\tau) = e^{-2\varphi}(p_\tau) \sum_{i=1}^{2} a_i \sqrt{2} dW_i^\tau + \left[ \partial_\tau \varphi(\tau, p_\tau) + e^{-2\varphi}(p_\tau) K_h(x_\tau) + \varphi''(\tau, p_\tau) \sum_{i=1}^{2} a_i^2 \right] d\tau.$$

Since the successful control is given by $a_i = e_i \overline{p}_{t-\tau}$, we get

$$\sum_{i=1}^{2} a_i^2 = |\nabla \overline{p}_{t-\tau}(x_\tau)|^2,$$

and this means that

$$\varphi(\tau, p_\tau) - \int_{0}^{\tau} \left[ \partial_\tau \varphi(\sigma, p_\sigma) + e^{-2\varphi(\sigma, p_\sigma)} \left( \varphi'(\sigma, p_\sigma) K_h(x_\sigma) + \varphi''(\sigma, p_\sigma) |\nabla \overline{p}_{t-\sigma}(x_\sigma)|^2 \right) \right] d\sigma$$

is a martingale. In particular, taking expectation at times $\tau = 0$ and $\tau = t$ and using $p_\tau = \overline{p}_{t-\tau}(x_\tau)$, yields

$$\varphi(0, \overline{p}_t(x)) = \mathbb{E}^{(x,t)}[\varphi(t, \overline{p}_0(x_0))]$$

$$(22)$$

$$- \int_{0}^{t} \mathbb{E}^{(x,t)} \left[ \partial_t \varphi(\sigma, p_\sigma) + e^{-2\varphi(\sigma, p_\sigma)} \left( \varphi'(\sigma, p_\sigma) K_h(x_\sigma) + \varphi''(\sigma, p_\sigma) |\nabla \overline{p}_{t-\sigma}(x_\sigma)|^2 \right) \right] d\sigma.$$

There are two obvious obstructions stemming from this formula. The first one is that if $K_h(x) > 0$ for all $x \in M$, then taking $\varphi(\tau, p) = e^{2p}$, the above formula (22) implies

$$e^{2\overline{p}_t(x)} = \mathbb{E}^{(x,t)}[e^{2\overline{p}_0(x_0)}] - 2 \int_{0}^{t} \mathbb{E}^{(x,t)} \left[ K_h(x_\sigma) + 2 |\nabla \overline{p}_{t-\sigma}(x_\sigma)|^2 \right] d\sigma \leq \mathbb{E}^{(x,t)}[e^{2\overline{p}_0(x_0)}] - 2 \int_{0}^{t} \mathbb{E}^{(x,t)}[K_h(x_\sigma)] d\sigma$$

and thus, upon denoting the uniform norm by $| \cdot |_u$ and taking $K_0 = \inf_{x \in M} K_h(x)$,

$$e^{2\overline{p}_t(x)} \leq e^{2|\overline{p}_0|_u} - 2tK_0.$$

As this is true for any $t \in [0, T)$, the extinction time of the Ricci flow is finite and is certainly at most $e^{2|\overline{p}_0|_u} / (2K_0)$. Therefore, in the case of positive curvature the flow develops singularities in finite time.

On the other hand if the curvature is negative ($K_h < 0$ on $M$) then there are some constants $C_1, C_2 > 0$ such that

$$\overline{p}_t(x) \geq \log(C_1 t + 1) - C_2$$

for all $x \in M$ and $t \geq 0$.

To see this, take $K_0 = \inf_{x \in M} -K_h(x) > 0$, then $K_h(x) \leq -K_0 < 0$ and then consider $\varphi(\tau, p) = p$ in (22) to deduce that

$$\overline{p}_t(x) = \mathbb{E}^{(x,t)}[\overline{p}_0(x_0)] - \int_{0}^{t} \mathbb{E}^{(x,t)}[e^{2\varphi(\sigma, p_\sigma, K_h(x_\sigma))}] d\sigma \geq \inf_{x \in M} \overline{p}_0$$

which means that $\overline{p}_t(x)$ is bounded below uniformly in $t \geq 0$ and $x \in M$. Now consider the test function $\varphi(\tau, p) = \exp \left( \alpha(t - \frac{1}{2K_0 e^{2p}}) \right)$. Since $\overline{p}_t(x)$ is bounded below, this implies that for large enough $\alpha$, $\varphi''(\sigma, p_\sigma) \geq 0$. On the other hand, $\partial_\tau \varphi(\sigma, p) - K_0 e^{-2p} \varphi'(\sigma, p) = 0$, and this combined with the preceding and the fact that $\varphi'$ is negative leads to

$$\varphi(0, \overline{p}_t(x)) \leq \mathbb{E}^{(x,t)}[\varphi(t, \overline{p}_0(x_0))] \leq 1,$$

which means that $\overline{p}_t(x) \geq \frac{1}{2} \log(2K_0 t)$ for any $t > 0$ for which $\overline{p}_t$ exists. In particular this shows that either the flow ceases to exist after a finite time, or, if it does exist for all times, $\overline{p}_t(x)$ goes to infinity.
uniformly over \( x \in M \). The moral is that we can not expect the Ricci flow to converge as the time approaches either the extinction time or infinity.

For the flat case, since the curvature is 0, the normalized and the unnormalized Ricci flows are the same and thus we will treat this case as the normalized Ricci flow.

**Remark.** The blow up in the negative case does not take place in finite time but this requires more arguments which we do not provide here.

5. Time-dependent a priori bounds for Ricci flow

We now turn our attention to using the stochastic target representation for the normalized Ricci flow to derive (more accurately, of course, to re-derive) geometric facts about the flow. We will always work with the case where the reference metric \( h \) has constant curvature. By uniformization, this is no loss of generality, and it simplifies the analysis considerably. After a preliminary rescaling, we can assume that this constant curvature is either 1, 0, or \(-1\). Further, we can rescale the initial metric \( g_0 \) so that it has the same area as \( h \). Thus, without loss of generality, we are in one of three cases (by the Gauss-Bonnet theorem). First, if the Euler characteristic of \( M \) is positive, we have that \( K_h \equiv r \equiv 1 \). If the Euler characteristic of \( M \) is zero, we have that \( K_h \equiv r \equiv 0 \). Finally, when the Euler characteristic of \( M \) is negative we have that \( K_h \equiv r \equiv -1 \). The bounds we have in mind are similar in all three cases, although the differences in sign of \( K_h \) result in important differences.

We call these bounds “a priori” because they don’t depend on the structure of the reachable set. We elaborate on this after Theorem 6.

We have one more comment about notations before we begin. Because we will be concerned with the normalized Ricci flow for the rest of the paper, we drop the “n” superscripts. Thus, for instance, we let \( p_t \) denote a solution to the normalized Ricci flow, unless otherwise indicated.

The interesting feature of choosing \( h \) to be a metric of constant curvature is that the drift of the SDE satisfied by \( p_t \) doesn’t depend on \( x \) (although the target always does, except in trivial cases). In particular, we have the following three cases:

\[
\begin{align*}
    r &= 1 : \quad dp_t = e^{-pr} \left[ \sum_{i=1}^{2} a_i \sqrt{2} dW^i_t \right] + \left( e^{-2pr} - 1 \right) d\tau \\
    r &= 0 : \quad dp_t = e^{-pr} \left[ \sum_{i=1}^{2} a_i \sqrt{2} dW^i_t \right] \\
    r &= -1 : \quad dp_t = e^{-pr} \left[ \sum_{i=1}^{2} a_i \sqrt{2} dW^i_t \right] + \left( 1 - e^{-2pr} \right) d\tau
\end{align*}
\]

(23)

In general, the stochastic target problem for the normalized Ricci flow (and also the Ricci flow itself) gives an equation of the form

\[
dp_t = e^{-pr} \left[ \sum_{i=1}^{2} a_i dW^i_t \right] + U_t(p_t)d\tau,
\]

where the controls \( a_i, i = 1, 2 \) are bounded and chosen such that \( p_t \) is almost surely on \( M_0 \), the section corresponding to \( p_0 \) in the bundle \( M \times \mathbb{R} \). In the case at hand we assume that \( U_t(p) \) is a function \( U : [0, t] \times \mathbb{R} \rightarrow \mathbb{R} \) which is uniformly locally Lipschitz in the second variable, i.e. for any \( L > 0 \) there is a constant \( C_L \) with \( |U_t(p) - U_t(q)| \leq C_L|p - q| \) for all \( \tau \in [0, t] \) and \( p, q \in [-L, L] \).

The basic point is that there are natural barriers for \( p_t \) given in terms of Equation (24) where the martingale part is set to be equal to 0. To be precise, we define a barrier as a solution \( q_t \) to the ODE

\[
dq_t = U_t(q_t)d\tau.
\]

(25)

In this framework we have a general result as follows.

**Lemma 5.** Assume that \( p_t \) and \( q_t \) are solutions to (24) and (25) respectively for \( \tau \in [0, t] \) with \( U \) a uniformly locally Lipschitz function in the second variable on \( [0, t] \times \mathbb{R} \).
If at any time \( \tau_1 \in [0, t) \), \( p_{\tau_1} < q_{\tau_1} \) with positive probability, then at any later time \( \tau_2 \in (\tau_1, t] \), \( p_{\tau_2} < q_{\tau_2} \) with positive probability.

Similarly, if at any time \( \tau_1 \in [0, t) \), \( p_{\tau_1} > q_{\tau_1} \) with positive probability, then at any later time \( \tau_2 \in (\tau_1, t] \), \( p_{\tau_2} > q_{\tau_2} \) with positive probability.

**Proof.** The proof is a basic application of stopping time and Gronwall type argument. We will prove only the first part, the second one being similar.

So, assume that \( q_{\tau_1} > p_{\tau_1} \) with positive probability, and therefore we can choose a constant \( L > 0 \) such that \( L \geq q_{\tau_1} - p_{\tau_1} > 1/L \) with positive probability. We further take \( L \) large enough so that \( |q_{\tau}| \leq L \) for all \( \tau \in [0, t] \).

Now, for any smooth function \( \eta : \mathbb{R} \to \mathbb{R} \), we have

\[
\eta(q_t - p_t) = \eta(q_{\tau_1} - p_{\tau_1}) + M_\tau + \int_{\tau_1}^{\tau} (e^{-2p_{\tau_2}^q}(q_s - p_s)(a_1^2(s) + a_2^2(s)) + \eta'(q_{s} - p_{s})(U_s(q_{s}) - U_s(p_{s}))) \, ds
\]

where \( M_\tau \) is a martingale with \( M(\tau_1) = 0 \). Further, we choose the function \( \eta(\xi) \) such that it is non-decreasing, equal to 0 for \( \xi \leq 0 \), equal to 1 for \( \xi \geq 2L \) and \( \eta(\xi) = \xi^2 \) for small \( \xi \geq 0 \).

Next, we define the stopping time \( \sigma = \inf\{u \geq \tau_1 : p_u \geq q_u \} \wedge t \). With this setup, we will denote for simplicity \( \eta_t = \eta(q_t - p_t), \eta_t' = \eta'(q_t - p_t) \) and \( \eta_t'' = \eta''(q_t - p_t) \). Furthermore, from (26),

\[
\mathbb{E}[\eta_{\tau_\wedge \sigma}] = \mathbb{E}[\eta_{\tau_1}] + \int_{\tau_1}^{\tau} \mathbb{E}[1_{[\tau_1, \sigma]}(s)(e^{-2p_{\tau_2}^q}(a_1^2(s) + a_2^2(s)) + \eta'(U_s(q_{s}) - U_s(p_{s})))] \, ds.
\]

Since \( q_s \) remains bounded on \( [\tau_1, \tau_2] \) and \( \eta' \) has compact support, combined with the property that \( U_\tau \) is uniformly Lipschitz in the second variable on compact intervals, we can find a constant \( C > 0 \), such that

\[
\eta'_t(U_s(q_{s}) - U_s(p_{s})) \geq -C \eta'_t(q_s - p_s).
\]

This, the choice of our function \( \eta_t \), the fact that the controls \( a_i, i = 1, 2 \) are bounded, and that \( q_s \) is bounded, yield, in the first place, that \( e^{-2p_s^q} \eta'_t \) is bounded, and also that for some constant \( C > 0 \),

\[
(e^{-2p_s^q} \eta''_t(a_1^2(s) + a_2^2(s)) + \eta'_t(U_s(q_{s}) - U_s(p_{s}))) \geq -C \eta_s.
\]

To check this, one can reason as follows. For \( q_s \leq p_s \), both sides are 0. For \( \epsilon > q_s - p_s > 0 \) with small \( \epsilon \), the first term is non-negative and the second one is bounded below by \( -C(q_s - p_s)^2 \) which is again a constant times \( \eta_s \). For \( q_s - p_s > \epsilon \), the inequality follows easily as the left hand side is bounded below by some negative constant and \( \eta_s \) is certainly bounded below by \( \epsilon^2 \).

Summing up the findings we get that

\[
\mathbb{E}[\eta_{\tau_\wedge \sigma}] \geq \mathbb{E}[\eta_{\tau_1}] - C \int_{\tau_1}^{\tau} \mathbb{E}[1_{[\tau_1, \sigma]}(s) \eta_s] \, ds
\]

Since \( \sigma \) is the first time \( p_s = q_s \), it follows that, \( \mathbb{E}[1_{[\tau_1, \sigma]}(s) \eta_s = \eta_{s \wedge \sigma} \), consequently, for some \( C > 0 \),

\[
\mathbb{E}[\eta_{\tau_\wedge \sigma}] \geq \mathbb{E}[\eta_{\tau_1}] - C \int_{\tau_1}^{\tau} \mathbb{E}[\eta_{s \wedge \sigma}] \, ds \text{ for } \tau \in [\tau_1, \tau_2].
\]

At this point, a Gronwall type argument similar to the passage from (18) to (19) results with

\[
\mathbb{E}[\eta_{\tau_\wedge \sigma}] e^{C(\tau - \tau_1)} \geq \mathbb{E}[\eta_{\tau_1}] > 0,
\]

where the hypothesis \( q_{\tau_1} > p_{\tau_1} \) with positive probability is translated into the last inequality. For \( \tau = \tau_2 \) we obtain \( \mathbb{E}[\eta_{\tau_2 \wedge \sigma}] = \mathbb{E}[\eta_{\tau_2}, \sigma > \tau_2] > 0 \) and therefore we conclude that \( \{ \sigma > \tau_2 \} \) has positive probability; stated otherwise, the probability that \( q_{\tau_2} > p_{\tau_2} \) is positive.

One technical word is in place here. Namely, the definition from (24) is in the sense of local martingales, but during the proof we look at \( \eta(q_t - p_t) \) and this is actually a semi-martingale in the sense that is a sum of martingale and a bounded variation process, not merely a sum of local martingale and locally bounded variation. This is indeed due to the boundedness and continuity of the quantities involved, namely \( e^{-p_s \eta'_t}, e^{-2p_s \eta''_t} \) and the controls \( a_i, i = 1, 2 \).

\[ \square \]
Next, we solve equation (25) for each of the three cases described in equation (23) (this is straightforward, as the resulting ODEs are separable). For ease of reference, we will label the resulting equations as $B_c^{\pm}(\tau)$ with super- and sub-scripts indicating relevant parameters. In the case $r = 1$, we have that

$$B_c^1(\tau) = \frac{1}{2} \log \left( 1 - ce^{-2\tau} \right) \quad \text{for some constant } c \in (-\infty, 1).$$

The choice of $c$ allows any initial condition. Note that $c = 0$ gives the constant solution $B_c^1(\tau) \equiv 0$. For any $c$, as $\tau \to \infty$, we see that $B_c^1(\tau) \to 0$. The case $r = 0$ gives

$$B_c^0(\tau) = c \quad \text{for some constant } c \in \mathbb{R}.$$

Obviously, the choice of $c$ allows any initial condition. (This is perhaps a bit pedantic, but we include it for the sake of completeness.) Finally, $r = -1$ gives

$$B_c^{-1}(\tau) = \frac{1}{2} \log \left( 1 - ce^{2\tau} \right) \quad \text{for some constant } c \in (-\infty, 1).$$

Again, the choice of $c$ allows any initial condition, and $c = 0$ gives the constant solution $B_c^{-1}(\tau) \equiv 0$. This time, though, if $c \neq 0$, then the solution heads to $\pm \infty$ as $\tau$ increases (in finite time for negative initial condition, and as $\tau \to \infty$ for positive initial condition).

Continuing, we want to use the previous Lemma and a judicious choice of the parameter $c$ to bound the reachable set at time $t$. Recall that $\overline{p}_0$ gives the initial barrier $g_0$ and serves as the target in the target problem (and which as a section we write as $\Gamma(0)$). The assumption that $g_0$ and $h$ have the same area implies that $\max_{x \in M} \overline{p}_0(x) = \alpha \geq 0$ and that $\min_{x \in M} \overline{p}_0(x) = \beta \leq 0$. Further, if either $\alpha$ or $\beta$ is zero then both are, meaning that $\overline{p}_0 \equiv 0$ and $g_0$ is just $h$.

The logic of the proof of the following Theorem explains why solutions $q_r$ of equation (25) are called barriers, in this context.

**Theorem 6.** Consider the target problem (for the normalized Ricci flow) where $h$ corresponds to one of the three constant curvature cases as discussed above (and with $\alpha$ and $\beta$ as just described). For any $t \geq 0$, we have that

$$\sup_{(x,p) \in V(t)} p \geq \begin{cases} \frac{1}{2} \log \left( 1 - e^{-2t} \left( 1 - e^{2\alpha} \right) \right) & \text{if } r = -1, \\ \alpha & \text{if } r = 0, \\ \frac{1}{2} \log \left( 1 - e^{-2t} \left( 1 - e^{2\alpha} \right) \right) & \text{if } r = 1, \end{cases}$$

and

$$\inf_{(x,p) \in V(t)} p \geq \begin{cases} \frac{1}{2} \log \left( 1 - e^{-2t} \left( 1 - e^{2\beta} \right) \right) & \text{if } r = -1, \\ \beta & \text{if } r = 0, \\ \frac{1}{2} \log \left( 1 - e^{-2t} \left( 1 - e^{2\beta} \right) \right) & \text{if } r = 1 \text{ and } t < -\frac{1}{2} \log \left( 1 - e^{2\beta} \right). \end{cases}$$

(If $\beta = 0$, we set $-\frac{1}{2} \log \left( 1 - e^{2\beta} \right) = \infty$.)

**Proof.** We start with the upper bound in the $r = -1$ case. We consider some fixed but arbitrary $t \geq 0$. Let $c' = e^{-2t} \left( 1 - e^{2\alpha} \right)$. Then

$$B_{c'}^{-1}(t) = \alpha \quad \text{and} \quad B_{c'}^{-1}(0) = \frac{1}{2} \log \left( 1 - e^{-2t} \left( 1 - e^{2\alpha} \right) \right).$$

Thus, by the previous Lemma, if we start from a point $(x_0, \overline{p}_0)$ with $\overline{p}_0 > B_{c'}^{-1}(0)$, we have that $p_t > B_{c'}^{-1}(t) = \alpha$ with positive probability (for any controls). By the definition of $\alpha$, this means that $p_t$ is not in the target with positive probability. Since this holds for any controls, it follows that $(x_0, \overline{p}_0)$ is not in the reachable set at time $t$, which we recall we denote $V(t)$. This implies the upper bound on $\sup_{(x,p) \in V(t)} p$ given in the Theorem.

For the lower bound in the $r = -1$ case, consider $c' = e^{-2t} \left( 1 - e^{2\beta} \right)$. Then

$$B_{c'}^{-1}(t) = \beta \quad \text{and} \quad B_{c'}^{-1}(0) = \frac{1}{2} \log \left( 1 - e^{-2t} \left( 1 - e^{2\beta} \right) \right).$$

Analogously, to the argument for the upper bound, the previous Lemma implies that no point $(x_0, \overline{p}_0)$ with $\overline{p}_0 < B_{c'}^{-1}(0)$ can be in $V(t)$. This implies the desired lower bound.
For the \( r = 0 \) case, analogous arguments apply, using \( c' = \alpha \) for the upper bound and \( c' = \beta \) for the lower bound.

Finally, we consider the \( r = 1 \) case. The upper bound is proven just as in the \( K = -1 \) case, using \( c' = e^{2t} (1 - e^{2\alpha}) \). The proof of the lower bound is similar, except that if \( t \geq -\frac{1}{2} \log (1 - e^{2\beta}) \), we have that \( B^1_c(t) > \beta \) for any choice of \( c \in (-\infty, 1) \). Thus, these arguments do not produce any lower bound for \( \inf_{(x,p) \in V(t)} \beta \) in this case. On the other hand, if \( t < -\frac{1}{2} \log (1 - e^{2\beta}) \), we can let \( c' = e^{2t} (1 - e^{2\beta}) \) and argue just as before. \( \square \)

In light of the verification theorem, these conclusions can be restated in terms of \( \overline{p}_t \). Namely, we can replace \( \sup_{(x,p) \in V(t)} \beta \) in the above theorem with \( \max_{x \in M} \overline{p}_t(x) \) and \( \inf_{(x,p) \in V(t)} \beta \) with \( \min_{x \in M} \overline{p}_t(x) \). Nonetheless, there is a reason to state the theorem as above. Suppose we consider the same target problem (or problems, since there are three cases), except that now we allow the target to be any (non-empty) closed set \( \Gamma \) such that \( \max_{\Gamma} \beta \geq 0 \) and \( \max_{\Gamma} \alpha \leq 0 \), rather than just a smooth section corresponding to a metric \( g_0 \) on \( M \). Then we can still ask about the reachable set at time \( t \geq 0 \). Assuming that it is non-empty, the bounds in the above theorem still hold (with the same proofs). This shows that these bounds don’t depend on the verification theorem and the resulting connection with PDEs, or on the structure of the reachable set, such as its smoothness or whether it’s a section. (Moreover, similar methods could be employed even if \( \alpha \) and \( \beta \) weren’t assumed to be non-negative and non-positive, respectively.) It is this sense in which we refer to them as “a priori bounds.” Of course, it is likely that these bounds are only interesting in light of their connection to the Ricci flow, as given by the verification Theorem.

We close this section with some easy observations about this theorem. First of all, if \( \alpha = 0 \), then \( \sup_{(x,p) \in V(t)} \beta = 0 \) for all \( t \geq 0 \), and this holds in all three cases. Similarly, if \( \beta = 0 \), then \( \inf_{(x,p) \in V(t)} \beta = 0 \) for all \( t \geq 0 \), in all three cases. Since one of \( \alpha \) or \( \beta \) being zero implies that both are, we conclude that if either \( \alpha \) or \( \beta \) is zero, the reachable set only contains points with \( p = 0 \). On the other hand, every point with \( p = 0 \) will clearly be in the reachable set (just let the controls be identically zero). Thus we will have \( V(t) = \{ p \equiv 0 \} \) for all \( t \geq 0 \). This corresponds to the basic fact that if \( g_0 \) is already a metric of constant curvature, then it is stationary under the normalized Ricci flow.

In the case when \( \alpha \) and \( \beta \) are not zero, we see much different behavior for the cases of the three different curvatures. For \( r = -1 \), the bounds improve as \( t \) increases, which we will see makes this the easiest case to deal with. For \( r = 0 \), the bounds are constant. Finally, for \( r = 1 \), the bounds get worse as \( t \) increases, and the lower bound even ceases to exist in finite time. This corresponds to the well-known observation that the case of the sphere (or projective space) is the hardest case to handle for Ricci flow on compact surfaces.

**Remark.** It’s worth point out that the above argument from Theorem 6 is overkill in the \( r = 0 \) case, since then the result follows directly from the fact that \( p_c \) is a martingale and martingales have constant expectation.

We finish this discussion with the following useful Corollary which plays an important role later on.

**Corollary 7.** For the case of \( r = -1 \), or equivalently, the case \( \chi(M) < 0 \), the solution \( p_t \) of the normalized Ricci flow converges to 0 uniformly in the \( C^0 \)-norm exponentially fast as \( t \to \infty \).

The same arguments work in the case of unnormalized Ricci flow. We record this here as follows.

**Theorem 8.** For the unnormalized Ricci flow, as long as the stochastic target is well defined up to time \( t \),

\[
\sup_{(x,p) \in V(t)} p \leq \begin{cases} 
\frac{1}{2} \log (e^{2\alpha} + t) & \text{if } r = -1, \\
\frac{1}{2} \log (e^{2\alpha} - t) & \text{if } r = 1, \text{ and } t < e^{2\alpha}.
\end{cases}
\]

and

\[
\inf_{(x,p) \in V(t)} p \geq \begin{cases} 
\frac{1}{2} \log (e^{2\beta} + t) & \text{if } r = -1, \\
\frac{1}{2} \log (e^{2\beta} - t) & \text{if } r = 1, \text{ and } t < e^{2\beta}.
\end{cases}
\]

The only thing we should point out here is that there is a blow-up in finite time for the case of \( r = 1 \) and there is also a blow up in finite or infinite time for the case of \( r = -1 \). This recovers the blow-up results in the previous section, only this time we used uniformization.
Remark. This theorem shows that for the unnormalized Ricci flow, in the negative curvature case, the flow does not blow up in finite time, at least in the $C^0$ topology. This is already a good indication that the solution is defined for all times and corroborated with the above Theorem shows that the flow blows up at infinity. Thus, this result is probably a better result (in the case of negative constant curvature case) as the one obtained in Section 4.

6. Mirror Coupling

For the remainder of the paper, we assume that we have a smooth initial metric and a smooth solution to the normalized Ricci flow for all time (which we do since the initial conditions are smooth on a compact surface). We are interested in studying the convergence to the constant curvature limit according to the stochastic framework we have been developing.

We consider the cases of zero Euler characteristic and of negative Euler characteristic, and we work relative to the underlying metric of constant curvature, as in the previous section. The positive Euler characteristic case (the sphere or projective plane) is well-known to be more difficult. This is largely due to the fact that there are many constant curvature metrics in any given conformal class, so that it’s not clear in advance which one will be the limiting metric under normalized Ricci flow (this is related to the issue of solitons). As a result, we don’t pursue this case.

We are assuming that we have a smooth solution to the normalized Ricci flow for all time. This means that the reachable set is always a smooth hypersurface transverse to the vertical fibers. From now on, we’re only interested in the successfully controlled process, so for notational simplicity we will let $(x_\tau, p_\tau)$ always denote that process (that is, what we previously denoted $\hat{Y}_\tau = Y_\tau(A)$). Moreover, if $\bar{p}$ is the smooth solution, we see that $p_\tau = \bar{p}_{t-\tau}(x_\tau)$. One consequence of this is that we can generally restrict our attention to the $x_\tau$ process. In particular, if we wish to couple two copies of the successfully controlled process (so that they meet as quickly as possible), it is enough to couple the $x_\tau$ marginals, since if the processes meet on the manifold, then they also meet on the fiber. In this sense, what we are doing is equivalent to just considering Brownian motion on the underlying time-varying manifold, and so we see again that running a Brownian motion along the solution flow (and employing the stochastic techniques that apply in that situation) is subsumed by the more general construction of the stochastic target problem.

A significant part of our results on the long-time convergence of the normalized Ricci flow is based on coupling two copies of the marginal process on $M$, which we denote by $x_\tau$ and $y_\tau$. Recall that $x_\tau$ will be time-changed Brownian motion on $(M, h)$, with the time change given by integrating $a = 2e^{-2b}$ along the paths, and analogously for $y_\tau$, where we let $b$ denote the instantaneous time-dilation (this is one significant advantage to working relative to this fixed metric). Note that we’ve incorporated the $\sqrt{2}$ normalization factor into the time-change, so that we really do have Brownian motion with respect to $h$ as the underlying object. This makes the stochastic analysis look a bit more standard.

We wish to implement the mirror coupling for $x_\tau$ and $y_\tau$, where the mirror map is with respect to the fixed $h$ metric. Viewed in this way, this is a fairly straight-forward variant of the mirror coupling for two Brownian motions on a smooth (non-varying) Riemannian manifold. We simply generalize to allow our processes to be Brownian motions up to a random but smooth (in terms of the particle’s position in space-time) time-change. References for the standard (non-time changed) construction are [24] and [20], and we proceed by modifying this as necessary and by not belaboring the aspects which carry over without modification.

Note that, since we’re working only in the cases of non-positive Euler characteristic, $a$ (and thus also $b$) is bounded above and below by positive constants (depending only on the initial metric) for all time, by the results of the previous section.

First, let $C_M$ be the subset of $M \times M$ consisting of points $(x, y)$ such that $y \in \text{Cut}(x)$ (which is equivalent to $x \in \text{Cut}(y)$), and let $D_M$ be the diagonal subset of $M \times M$. Then let $E_M$ be $M \times M$ minus $C_M$ and $D_M$. Note that the distance function $\text{dist}(x, y)$ is smooth on $E_M$, and that the direction of the (unique) minimal geodesic from $x$ to $y$ is smooth on $E_M$. Let $(x, y) \in E_M$; then the mirror map is the isometry from $T_xM$ to $T_yM$ given by reflection along the minimal geodesic connecting $x$ and $y$. We see that the mirror map is smooth (on $E_M$, which is where it is defined). As a result, there is no problem in running the mirror coupling as long as the joint process is in $E_M$. That is, for one-dimensional independent
Brownian motions $W^1_\tau$ and $W^2_\tau$, consider the system of SDEs

$$
\begin{align*}
&dx_\tau = a_\tau \left[ \sum_{i=1}^{2} \xi_i(x_\tau) \circ dW^i_\tau \right] \\
&dy_\tau = b_\tau \left[ \sum_{i=1}^{2} \Psi_\tau \left[ \xi_i(y_\tau) \right] \circ dW^i_\tau \right],
\end{align*}
$$

where $\Psi_\tau = \Psi(x_\tau, y_\tau) = m_{x_\tau, y_\tau} e(x_\tau) e(y_\tau)^{-1}$ with $m_{x, y}$ being the mirror map, namely parallel transport followed by reflection with respect to the perpendicular to the geodesic from $x$ to $y$. Then the coefficients are smooth in both space and time, so the system admits a unique strong solution, up until the first time the process leaves $E_M$.

The point of the coupling is to get the particles to meet, so we turn our attention to this issue next. First note that the marginals $x_\tau$ and $y_\tau$ are time-changed Brownian motions as desired, so we’re coupling the right processes. The natural object of study is the distance between the particles, with respect to the fixed metric $b$. We denote this distance by $\rho$. It is a (continuous, non-negative) semi-martingale, so we derive the SDE that it satisfies by Ito’s formula. This is the standard computation with the factors of $a$ and $b$ included, so we’ll be brief. For more on this, see [24, Section 6.5].

The martingale part is easily seen to be $(a + b) \, dW_\tau$ for some Brownian motion $\hat{W}_\tau$, whether we’re in the $r = 0$ or $r = -1$ case. (In what follows, we use $W_\tau$ to denote some Brownian motion, which may change from appearance to appearance, in order to more conveniently describe the SDE satisfied by a given process.) As for the drift, the only contribution comes from the second derivative of the distance with respect to the diffusions perpendicular to the geodesic from $x$ to $y$, which is computed in terms of the index of the appropriate Jacobi field along the geodesic from $x$ to $y$. We now summarize the computation.

Let $\gamma$ be the unique minimal geodesic from $x$ to $y$ (parametrized by arclength), and let $E$ be a unit vector field along $\gamma$, perpendicular to $\gamma$ (this determines $v$ uniquely up to sign, and either of choice of sign is fine). Then we want the Jacobi field $w(s) E(\gamma(s))$ where $w : [0, \rho] \to \mathbb{R}$ satisfies

$$
\ddot{w} + rw = 0, \quad w(0) = a, \quad w(\rho) = b.
$$

When $r \equiv 0$, the solution space to this differential equation is spanned by $1$ and $s$. Taking the boundary conditions into account, we see that the solution is

$$
w(s) = a + \frac{b - a}{\rho} s.
$$

Similarly, when $r \equiv -1$, the solution space is spanned by $\cosh s$ and $\sinh s$, and the boundary conditions give

$$
w(s) = \frac{a \sinh(\rho - s) + b \sinh s}{\sinh \rho}.
$$

The index of each of these Jacobi fields is given by

$$
\int_{\gamma} \left( \ddot{w}^2 - rw^2 \right) \, ds = w(\rho) \dot{w}(\rho) - w(0) \dot{w}(0),
$$

where the right-hand side is obtained from the left via integration by parts and the differential equation satisfied by $w$. Thus for $r \equiv 0$, the index is

$$
b \left( \frac{b - a}{\rho} \right) - a \left( \frac{b - a}{\rho} \right) = \frac{(a - b)^2}{\rho},
$$

and for $r \equiv -1$, the index is

$$
b \left[ a \sinh \rho + (b - a \cosh \rho) \frac{\cosh \rho}{\sinh \rho} \right] - a \left[ b - a \cosh \rho \frac{\cosh \rho}{\sinh \rho} \right] = (a^2 + b^2) \coth \rho - 2ab \frac{1}{\sinh \rho}
\begin{align*}
&= (a - b)^2 \coth \rho + 2ab \tanh \frac{\rho}{2}.
\end{align*}$$
Putting this together, we see that
\[
    d\rho_r = \begin{cases}
        (a+b)\,d\hat{W}_r + \frac{1}{2} \left[ \frac{(a-b)^2}{\rho} \right] \,d\tau & \text{for } r = 0, \\
        (a+b)\,d\hat{W}_r + \frac{1}{2} \left[ \frac{(a-b)^2}{\coth \rho + 2ab\tanh \frac{\rho}{2}} \right] \,d\tau & \text{for } r = -1.
    \end{cases}
\]

As mentioned, this holds until the first exit time from \(E_M\). Following the reasoning in [24, Section 6.6], one can show that \(\hat{W}_r = -\sum_{i=1}^2 \langle \epsilon_i(x_r), \dot{\gamma}_r(0) \rangle dW^i_r\) where \(\gamma_r\) is the minimal geodesic joining \(x_r\) and \(y_r\) starting at \(x_r\) and running at unit speed.

When the particles meet, we’ve achieved our goal, and we can either stop the process, or allow it to continue to run as \(x_r = y_r\). Either way, there’s no problem caused by the process hitting the diagonal. On the other hand, we do need to find a way to continue the process past the first hitting time of the cut locus. Showing that this is possible constitutes the content of the remaining of this section.

**Theorem 9.** Let \(M = (M, h)\) be a compact surface of constant curvature 0 or \(-1\), and let \(a = a(x, \tau)\) and \(b = b(y, \tau)\) be as above. Then there exists a process \((x_r, y_r)\) on \(M \times M\), started from any \((x_0, y_0) \not\in D_M\) and run until the first time of hitting \(D_M\), such that

1. The marginals \(x_r\) and \(y_r\) are time-changed Brownian motions, with times changes given by \(a\) and \(b\), respectively.
2. The distance (relative to \(h\)) between \(x_r\) and \(y_r\), denoted \(\rho_r\), satisfies the SDE

\[
    d\rho_r = \begin{cases}
        (a+b)\,d\hat{W}_r + \frac{1}{2} \left[ \frac{(a-b)^2}{\rho} \right] \,d\tau - L_r & \text{for } r \equiv 0, \\
        (a+b)\,d\hat{W}_r + \frac{1}{2} \left[ \frac{(a-b)^2}{\coth \rho + 2ab\tanh \frac{\rho}{2}} \right] \,d\tau - L_r & \text{for } r \equiv -1,
    \end{cases}
\]

where \(L_r\) is a non-decreasing process which increases only when \((x_r,y_r) \in C_M\) (and the set of \(\tau\) for which \((x_r,y_r) \in C_M\) has measure zero almost surely).

**Proof.** As mentioned, the only issue is extending the construction mentioned above past the first hitting time of \(C_M\). As usual, we proceed by approximation.

Choose small, positive \(\delta\). Until \(y_r\) is within distance \(\delta\) of \(\text{Cut}(x_r)\), we run the mirror coupling as above. When \(y_r\) hits distance \(\delta\) from \(\text{Cut}(x_r)\), at time \(\tau_1\), we start to run \(x_r\) and \(y_r\) as independent (time-changed) Brownian motions. This continues until \(y_r\) is distance \(2\delta\) from \(\text{Cut}(x_r)\), at time \(\tau_2\), when we again run them under the mirror coupling. We continue this procedure, so that we have a joint process \((x^\delta_r, y^\delta_r)\) which evolves under the mirror coupling on intervals of time \([\tau^\delta_{2n-1}, \tau^\delta_{2n+1})\) and as independent processes on intervals of time \([\tau^\delta_{2n-1}, \tau^\delta_{2n+1})\), for non-negative integers \(n\), where the \(\tau_n\) are the alternating hitting times of the \(\delta\) and \(2\delta\) level sets of the \(\delta\) and \(2\delta\) from \(y_r\) to \(\text{Cut}(x_r)\). (This is less symmetric than switching when the joint process is distance \(\delta\) or \(2\delta\) from \(C_M\), in the product metric on \(M \times M\), but it is more convenient to compute with and works in essentially the same way. In particular, the condition \(\text{dist}(y_r, \text{Cut}(x_r)) < \delta\) determines an open neighborhood of \(C_M\) in \(M \times M\), and these neighborhoods converge to \(C_M\) as \(\delta \to 0\) )

It’s clear that \(x_r^\delta\) and \(y_r^\delta\) are time-changed Brownian motions as desired, and that the \(\rho^\delta\) satisfies the desired SDE when \((x_r^\delta, y_r^\delta)\) is distance more than \(2\delta\) from \(C_M\). It’s also clear that when \(x_r^\delta\) and \(y_r^\delta\) are being run independently, \(\rho^\delta\) satisfies an SDE of the form

\[
    d\rho^\delta_r = u \,dW_r + v \,d\tau - \hat{L}_r,
\]

where \(u\) and \(v\) are bounded (with bound depending only on \(M\) and the bounds on \(a\) and \(b\)) and \(\hat{L}_r\) is a non-decreasing process which increases only when \((x_r^\delta, y_r^\delta) \in C_M\) (again, see the references mentioned above).

Suppose we show that, for any \(t > 0\) and any \(\varepsilon > 0\), the expected amount of time on the interval \([0, t]\) that \(y_r^\delta\) spends within distance \(\varepsilon\) of \(\text{Cut}(x_r^\delta)\) goes to zero with \(\varepsilon\) at a rate independent of \(\delta\). Then the amount of time on \([0, t]\) that \(y_r^\delta\) spends within distance \(2\delta\) of \(\text{Cut}(x_r^\delta)\) goes to zero with \(\delta\) (just let \(\varepsilon = 2\delta\)), and thus the amount of time the particles spend being run independently goes to zero almost surely as \(\delta \searrow 0\). (The point is that the total amount of time spent in the union of all intervals of the form \([\tau^\delta_{2n-1}, \tau^\delta_{2n+1}) \cap [0, t]\) goes to zero uniformly, even though the number of such intervals that are non-empty
might increase without bound as \( \delta \) goes to zero.\) So letting \( \delta \) go to zero, we know there is at least one subsequence along which the process \( (x^\delta, y^\delta) \) converges to a limiting process \( (x_\tau, y_\tau) \) (by compactness). That this limiting process satisfies the first property in the theorem is immediate, since \( x^\delta \) and \( y^\delta \) do for all \( \delta > 0 \). For the second property, note that the contributions from the \( u \mathcal{d} \tilde{W}_\tau \) term and the \( v \mathcal{d} \tau \) term go to zero by the boundedness of \( u \) and \( v \) and the fact that the expected length of time over which these terms are integrated goes to zero. It follows that the martingale part and the “regular” part of the drift come entirely from the SDE for \( \rho \) induced by the (mirror) coupling, and that the time spent at \( C_M \) (equivalently, the time spent with \( y_\tau \in \text{Cut}(x_\tau) \)) has measure zero. Finally, the \( \tilde{L}_\tau \) contribution converges to a term \( L_\tau \) as indicated.

Thus, to complete the proof, we need only show that the expected amount of time on the interval \([0, t] \) that \( y^\delta_\tau \) spends within distance \( \varepsilon \) of \( \text{Cut}(x^\delta_\tau) \) goes to zero with \( \varepsilon \) at a rate independent of \( \delta \). Here we will take advantage of the specific geometry with which we are dealing much more so than in the general approximation procedure just described. Because the argument is somewhat lengthy, we divide it into four steps. Moreover, at the end of the first step, we highlight as a “key fact” the most important aspect of the geometry for our purposes.

**Step 1:** Here, we describe the structure of the cut locus, which is also summarized in Figure 1 below.

In particular, note that, because we deal with surfaces of non-negative curvature, there are no conjugate geodesics, and a point \( z \) is in \( \text{Cut}(x) \) exactly when there is more than one minimal geodesic from \( x \) to \( z \).

In this case, there are necessarily only finitely many such geodesics, and the exponential map at \( x \) is a local diffeomorphism near (the tangent vector corresponding to) each of these geodesics.

More concretely, if we let \( M \) be the universal cover of \( M \) (with the metric induced by \( M \)) and we let \( \tilde{x} \) denote a distinguished lift of \( x \) to \( \tilde{M} \), then all other lifts of \( x \) can be written as \( g(\tilde{x}) \) for \( g \in G \), the group of Deck transformations. Then one can construct an open fundamental polygon \( P \) (also called a Voronoi region or Dirichlet region) around \( \tilde{x} \) by taking all points of \( \tilde{M} \) that are closer to \( \tilde{x} \) than to any other lift of \( x \). Note that \( P \) is convex. The boundary of this fundamental polygon \( \partial P \) has each side given by (a portion of) the curve of points equidistant from \( \tilde{x} \) and \( g(\tilde{x}) \) for some \( g \). Moreover, let \( \tilde{q} : \tilde{M} \to M \) be the covering map (and local isometry) given by quotienting by the action of \( G \). Then if \( z \) is a point on a side (but not a corner) of \( \partial P \), \( \gamma_0 \) is the minimal geodesic from \( \tilde{x} \) to \( z \), and \( \gamma_1 \) is the minimal geodesic from (the appropriate) \( g(\tilde{x}) \) to \( z \), we see that \( q(\gamma_0) = \text{Cut}(x) \) and that \( q(\gamma_0) \) and \( q(\gamma_1) \) are the two minimal geodesics from \( x \) to \( q(z) \) (in \( M \)). Each corner of \( \partial P \) corresponds to a point \( z \) where there are at least two (but only finitely many) lifts of \( x \), say \( g_1(\tilde{x}), \ldots, g_k(\tilde{x}) \), such that \( z \) is equidistant from \( \tilde{x} \) and each of these other lifts, with corresponding minimal geodesics \( \gamma_1, \ldots, \gamma_k \), and we obtain the minimal geodesics from \( x \) to \( q(z) \in \text{Cut}(x) \) as \( q(\gamma_0), q(\gamma_1), \ldots, q(\gamma_k) \). More globally, \( q(P) = M \setminus \text{Cut}(x) \) and \( q(\partial P) = \text{Cut}(x) \).

The purpose of the above is that it gives us a way to understand how \( \text{Cut}(x_\tau) \) evolves as \( x_\tau \) evolves. Indeed, in our situation, it would be possible to give a fairly precise description, since we deal with surfaces of constant curvature. If \( r = 0 \), \( M \) is \( \mathbb{R}^2 \) with the Euclidean metric, and the group of Deck transformations consists of translations by a lattice, if \( M \) is orientable and thus a torus, or is generated by such translations plus a reflection, if \( M \) is non-orientable and hence a Klein bottle. Similarly, if \( r = -1 \), \( M \) is the hyperbolic space \( \mathbb{H}^2 \), and the group of Deck transformations consists of a Fuchsian group, if \( M \) is orientable, or is generated by such a group plus a reflection, if \( M \) is non-orientable, and these can be realized fairly concretely using the upper half-space model of the hyperbolic plane. Nonetheless, such an argument by cases is tedious and provides more than we need here. Instead, we give a more general argument.

We choose some \( \varepsilon_0 > 0 \), with the intent of studying the distance to the cut locus in, roughly, an \( \varepsilon_0 \)-neighborhood of the cut locus, and we will assume \( \varepsilon_0 \) is small enough to satisfy various conditions as we go. Recall that the fundamental polygon \( P(x) \) (where we now allow the possibility of making the dependence on the point \( x \) from above explicit) has a finite number of smooth sides (which we think of as closed segments by including the corners), which means that \( \text{Cut}(x) \) is given by the union of a finite number of smooth (closed) arcs, which vary smoothly with \( x \) (this smooth dependence follows from the fact that \( \tilde{x} \) and all of the \( g(\tilde{x}) \) in \( \tilde{M} \) vary smoothly with \( x \), and thus so do the curves of points equidistant between them); denote these arcs by \( \tilde{a}_1(x), \ldots, \tilde{a}_K(x) \), for some positive integer \( K \) as are shown in Figure.
1 below. (For clarity in the figures, we label the vertices of $P$ by $P_i$, with $a_i$ being the side between $P_i$ and $P_{i+1}$, with indices understood modulo $K$.)

![Diagram of the fundamental domain for a negatively curved surface as a subset of the universal cover, which is the hyperbolic plane.](image)

**Figure 1.** The fundamental domain for a negatively curved surface as a subset of the universal cover, which is the hyperbolic plane. The pre-image of $x$ on the universal cover is $\{\hat{x}, g_1(\hat{x}), g_2(\hat{x}), \ldots\}$, with $g_1, g_2, \ldots$ in the Deck group. The arc $\hat{a}_i(x)$ is equidistant from $\hat{x}$ and $g_i(\hat{x})$. For instance, the vertex $\hat{P}_3$ is equidistant to $\hat{x}$, $g_2(\hat{x})$, and $g_3(\hat{x})$. Here $\xi_i$ is the distance from $y$ to $a_i$, placed by the geodesic that realizes this distance. Notice that the closest point to $y$ on $a_3(x)$ falls outside the arc $\hat{a}_3(x)$, which is one of the reasons for introducing a tubular neighborhood around each arc later in the proof.

Further, we let $a_i(x)$ be a (closed) arc which smoothly extends $\hat{a}_i(x)$ some small amount in each direction. We can accomplish this by extending each side of the fundamental polygon a small amount past the two adjacent corners; indeed, in the constant curvature case, the $\hat{a}_i(x)$ are geodesics segments, and thus we can extend them to slightly longer geodesic segments. (This is the general case when $a_i$ is a segment with two endpoints. It is possible for $a_i$ to be a closed geodesic loop, in which case $a_i$ is just $\hat{a}_i$.)

Next, consider a tubular (open) neighborhood around $a_i(x)$ consisting of all points that lie on a geodesic perpendicular to the interior of $a_i(x)$ at distance less than $\varepsilon_0$, and denote this neighborhood by $Q_i(x)$. Note that $Q_i(x)$ also varies smoothly with $x$. We now assume that $\varepsilon_0$ is small enough so that there is always only one such minimal geodesic from $a_i(x)$ to any point in $Q_i(x)$. Because $Q_i(x)$ varies smoothly, $M$ is compact, and there are only finitely many sets $Q_i(x)$, it is indeed possible to choose such $\varepsilon_0 > 0$ for all $x \in M$ and $i \in \{1, 2, \ldots, K\}$; see Figure 2. (Again for clarity in the figures, we let $P_i$ and $P_{i+1}$ be the endpoints of the extended arc $a_i$.)

Now let $\xi_i(y)$ be the distance of $y$ from $a_i(x)$. Of course $\xi_i = \xi_i(y)$ also depends on $x$, through its dependence on $a_i(x)$. We see that $\xi_i$ is Lipschitz on all of $M \times M$ (in fact, $\xi_i$ is locally given by the minimum or maximum of a finite number of smooth functions), smooth in both $x$ and $y$ on $Q_i(x) \setminus a_i(x)$, and convex at $a_i(x)$ (indeed, the signed distance is smooth in a neighborhood of any point in the interior of $a_i(x)$, and $\xi_i$ is just the absolute value of this signed distance). We also let $S_i(x; \varepsilon)$ be the (closed) set
consisting of all points that lie on a geodesic perpendicular to \( \hat{a}_i(x) \) at a distance no more than \( \varepsilon \), for any \( 0 < \varepsilon < \varepsilon_0/2 \). See picture Figure 2 below for an illustration of the relevant elements.

\[
\{ y : \text{dist}(y, \text{Cut}(x)) \leq \varepsilon \} \subset \bigcup_{i=1}^{K} S_i(x; \varepsilon).
\]

So, in order to control the expected amount of time on the interval \([0,t]\) that \( y^i_t \) spends within distance \( \varepsilon \) of \( \text{Cut}(x^i) \), it’s enough to control the expected amount of time on the interval \([0,t]\) that \( y^i_t \) spends in \( S_i(x^i_t; \varepsilon) \), for each \( i \).

Before we move on to the next step, we make an important point, which will be in fact the backbone of the argument, and comes from the fact that on negatively curved manifolds there are no conjugate points. Let \( \varphi \) be the angle between the minimal geodesic joining \( x \) to \( y \) and the minimal geodesic from \( y \) to \( a_i \), as shown in Figures 2 and 3. Then we claim that \( |\varphi| \) is bounded away from \( \pi/2 \) on \( Q_i \), with the bound depending only on \( M \) and \( \varepsilon_0 \). To see this, first note that, any geodesic from \( x \) to \( a_i \) cannot be tangent to \( a_i \), since for surfaces of non-positive curvature the geodesics from \( x \) are transverse to \( \text{Cut}_x \) and thus also transverse to \( a_i \), assuming that \( a_i \) is not extended too much beyond \( \hat{a}_i \) (this is clear by looking at the fundamental polygon in \( \tilde{M} \) as above). Thus, if we let \( y \) approach a point of \( a_i \), the corresponding limit of \( |\varphi| \) is strictly less than \( \pi/2 \). By compactness (and continuity of \( \varphi \)), all such limiting values of \( |\varphi| \) are bounded away from \( \pi/2 \), with bound depending only on the geometry of \( M \). Thus, by assuming that \( \varepsilon_0 \) is small enough, we see (again by continuity and compactness) that \(|\varphi|\) is bounded away from \( \pi/2 \) on \( Q_i \), with the bound only depending on \( M \) and \( \varepsilon_0 \). Equivalently, \( \cos \varphi \) is bounded from below by a positive constant depending on \( M \) and \( \varepsilon_0 \) under the same conditions. Because this one of the key geometric facts underlying our argument, we highlight it separately here.
Key Fact. There is a constant $\varphi_0 < \pi/2$ such that for small enough $\epsilon_0$, and any $y \in Q_i(x)$,

$$|\varphi| \leq \varphi_0 < \pi/2$$

From now on, we assume that $\epsilon_0$ is small enough so that this holds.

(We note that if we consider a high-dimensional compact manifold of non-positive sectional curvature, the analogous fact holds relative to the hypersurface components of the cut locus. For this and related reasons, the present argument extends naturally to higher dimensions. However, if we allow positive curvature, the structure of the cut locus can change significantly, and new ideas would be required to extend this method of proving the existence of the mirror coupling.)

Step 2: Here we study the evolution of $\xi_i$ under the process by controlling the SDE it satisfies, both when the particles are running independently and when they are running under the mirror coupling. We also (and much more briefly) derive an SDE which governs how quickly $y^\delta_\tau$ can move from the complement of $Q_i(x^\delta_\tau)$ to $S_i(x^\delta_\tau; \epsilon_0/2)$.

Let $\xi_{i,\tau}$ be, as usual, the process $\xi_i(y^\delta_\tau) = \text{dist}(y^\delta_\tau, a_i(x^\delta_\tau))$. From the convexity properties of $\xi_i$ and the Itô-Tanaka formula, we see that $\xi_{i,\tau}$ is a semi-martingale. Next, suppose that $y^\delta_\tau \in Q_i(x^\delta_\tau)$. There are two cases to consider, the one when the particles are running independently, and the one when they are running under the mirror coupling. Since we will be assuming either one or the other of these cases in what follows, we will drop the superscript $\delta$’s in the notation, making it less cumbersome.

We begin with some observations that apply in either case. Referring to Figure 3, we run the processes $x_\tau$ and $y_\tau$ as indicated, without yet assuming that $(W^1, W^2)$ and $(W^3, W^4)$ are either independent or identical. Then, since the distance function $\xi_i$ is smooth away from 0 and convex at 0, we can use Itô-Tanaka formula to get that

$$d\xi_{i,\tau} = -b \cos \varphi \, dW^1_\tau - b \sin \varphi \, dW^2_\tau + r_i \, dW^3_\tau + s_i \, dW^4_\tau + v_i \, d\tau + dL_i$$

where $|r_i|, |s_i|, |v_i|$ are bounded by some constants depending only on $M, \epsilon_0$ and the bounds on $a$ and $b$, and where $L_i$ is a non-decreasing process increasing only when $\xi_i$ is 0. Notice the minus sign in the first term on the left-hand side above equation, which is due to the fact that $\xi_i$ decreases as $y$ approaches $a_i$ because the gradient of $\xi_i$ points opposite of the minimal geodesic from $y_i$ to $a_i$. Notice also that the first two terms of the martingale part are obtained by fixing the point $x$ and taking the derivative with respect to $y$, while the last two terms of the martingale part come from fixing $y$ and taking the derivative with respect to $x$ (in this case the arc $a_i$ changes with $x$).
The martingale part of Equation (29) is controlled by its quadratic variation process; equivalently, the martingale part is a time-changed (one-dimensional) Brownian motion and thus controlled by the time change. Clearly the precise behavior of the quadratic variation is different in our two cases (the independent case and the mirror-coupled case). But in either case, our goal now is to show that the martingale part is of the form $u_i \, d\hat{W}_\tau$, where $\hat{W}_\tau$ is a Brownian motion and $u_i$ a process such that $0 < \alpha \leq u_i \leq \beta$ with $\alpha$ and $\beta$ two constants independent of $\varepsilon$ and $\delta$. The purpose is that, if this is true, standard methods of stochastic analysis will allow us to estimate the amount of time that $y_\tau$ spends near $a_i(x_\tau)$, which is our overall task. In particular, the upper bound by some $\beta$ already follows from Equation (29), in both cases. Thus, the real work is in obtaining the lower bound, and for this we treat the two cases separately.

If the particles $x_\tau$ and $y_\tau$ evolve independently, then $W^1$, $W^2$, $W^3$, and $W^4$ in Equation (29) are independent, and thus the martingale part can be written as $\sqrt{b^2 \cos^2 \varphi + b^2 \sin^2 \varphi + r_\tau^2 + s_\tau^2} \, d\hat{W}_\tau = \sqrt{\varphi^2 + \hat{b}^2 + \hat{s}^2} \, d\hat{W}_\tau$. Because $b$ is bounded from below by a positive constant, this proves that, in the case the particles run independently, for $y_\tau \in Q_i(x_\tau)$, $\xi_{i,\tau}$ satisfies the SDE

$$d\xi_{i,\tau} = u_{I,i} \, d\hat{W}_\tau + v_{I,i} \, d\tau + dL_{I,i},$$

where $u_{I,i}$ and $|v_{I,i}|$ are bounded and $u_{I,i}$ is bounded from below by a positive constant, with all of these bounds depending only on $M$, $\varepsilon_0$, and the bounds on $a$ and $b$, and where $L_{I,i}$ is a non-decreasing process that increases only when $\xi_{i,\tau} = 0$. (Here the subscript $I$ is meant to denote that these are the coefficients for the SDE induced by running the particles independently.)

Now we wish to perform a similar analysis when the particles are being run under the mirror coupling. The issue now is that, in this case, the Brownian motions in Equation (29) are correlated by $W_3 = W^1$ and $W_4 = W^2$. Therefore the martingale part is of the form $\sqrt{(-b \cos \varphi + r_\tau)^2 + (-b \sin \varphi + s_\tau)^2} \, d\hat{W}_\tau$. To show that the coefficient is bounded from below by a positive constant, it is enough to show that at least one of the squares under the square root stays bounded from below. Recall now that $|\varphi|$ is bounded away from $\pi/2$, which we noted as our “key fact” earlier, and therefore $b \cos \varphi$ is bounded away from 0. Our strategy in what follows is to show that the term $r_\tau$ does not spoil this property (that is, we want to make sure that the contribution to the quadratic variation coming from moving $y_\tau$ by $dW^1_\tau$ is not cancelled by the movement of $x_\tau$ by $dW^2_\tau = dW^4_\tau$). More precisely we are going to show that $r_\tau$ is actually negative and this proves that $-b \cos \varphi + r_\tau$ stays away from 0, which is enough to get the desired conclusion.

In this case, we write the evolution for $\xi_{i,\tau}$ in the form

$$d\xi_{i,\tau} = u_{C,i} \, d\hat{W}_\tau + v_{C,i} \, d\tau + dL_{C,i},$$

where $u_{C,i} = \sqrt{(-b \cos \varphi + r_\tau)^2 + (-b \sin \varphi + s_\tau)^2}$. (Here the subscript $C$ denotes that the coefficients for the SDE are induced by running the particles independently.) Also, recall that the particles never run under the mirror coupling when $y_\tau$ hits $\text{Cut}(x_\tau)$ (for any $\delta$). Thus, when considering the present case, we have that the geodesic between $x_\tau$ and $y_\tau$ along which we perform the mirror coupling evolves continuously. That is, essentially, Figure 3 evolves continuously, and in particular, the vectors along which the diffusions $W^1$, $W^2$, $W^3$, and $W^4$ occur and the angle $\varphi$ evolve continuously.

Since the martingale part of $d\xi_{i,\tau}$ depends only on the first order structure at a point, we see that we can consider the contribution of $x_\tau$ with $y$ fixed and the contribution of $y_\tau$ with $x$ fixed separately (the “complete” martingale part is just given by the sum of these two contributions). We’ve already seen that when $x$ is fixed, the arc $a_i$ is also fixed, and the contribution coming from the evolution of $y_\tau$ is $-b \cos \varphi \, dW^1_\tau - b \sin \varphi \, dW^2_\tau$.

The other contribution to the martingale part of $d\xi_{i,\tau}$ comes from letting $x_\tau$ evolve while keeping $y$ fixed (namely the $r_i$ and $s_i$ terms in Equation (29)). To provide a good picture for what follows, we put all the relevant elements in Figure 4 below. The point is that when $x_\tau$ moves, $a_i(x_\tau)$ moves as well. In order to make the exposition clearer, we will assume for the moment that $\xi_{i,\tau} \neq 0$ (and thus $\text{dist}(y, a_i(x_\tau)) > 0$), so that $\xi_i$ is smooth in a neighborhood of the present point. We now use $x$ to denote the starting point of $x_\tau$, before we let it move to first order (stochastically). Thus the closest point to $y$ on $a_i(x)$, which we denote $z$, and which we now also fix, is in the interior of $a_i$, by the definition of $Q_i$. Let $d_0(\cdot, \cdot)$ be
the distance from a neighborhood of $x$ to a neighborhood of $y$ along geodesics which are close (in the exponential map) to the minimal geodesics from $x$ to $\tilde{a}_i(x)$ that lie on the same side of $a_i(x)$ as $y$. Let $d_1(\cdot, \cdot)$ be the distance from a neighborhood of $x$ to a neighborhood of $y$ along minimal geodesics from $x$ to $\tilde{a}_i(x)$ that lie on the opposite side of $a_i(x)$ as $y$. In other words, if we think about the universal cover, $d_0$ corresponds to minimal geodesics (in $\tilde{M}$) starting from a neighborhood $\tilde{x}$, and $d_1$ corresponds to minimal geodesics starting from a neighborhood $g(\tilde{x})$, where $g$ is such that $g(\tilde{x})$ is the point “on the other side” of the lift of $a_i(x)$. Both $d_0$ and $d_1$ are smooth in both arguments. We can assume $z$ is in both neighborhoods of $y$, so that $d_0(x, z) = d_1(x, z)$, and moreover, $a_i(x)$ is given by the equation $d_0(x, \cdot) = d_1(x, \cdot)$ near $z$. Also $d_0(x, y) < d_1(x, y)$, and it is this inequality which shows “which side” of $a_i(x)$ $y$ is on.

![Figure 4](image_url)

**Figure 4.** Here $\tilde{x}$ moves away from $y$ at unit speed along the dashed line, motion which we parametrize as $\tilde{x}_\sigma$. The distance $d_1(\tilde{x}, y)$ is obtained as the distance between $g_i(\tilde{x})$ and $y$ (on the universal cover), and as $\tilde{x}$ moves, $g_i(\tilde{x})$ moves along the dashed line as $g_i(\tilde{x}_\sigma)$. The derivative of $d_1(x, y)$ is thus given by $\cos(\theta)$, where $\theta$ is the angle between the arcs $g_i(\tilde{x})g_i(y)$ and $g_i(\tilde{x})y$. Notice that for small enough $\varepsilon_0$ and $y \in Q_i(\tilde{x})$ the angle $\theta$ is positive (and we assume that $\varepsilon_0$ satisfies this condition). Indeed, $g_i(y)$ cannot be on the geodesic $g_i(\tilde{x})y$ because $y$ and $g_i(y)$ must be some distance apart (given by the shortest non-contractible loop on the manifold $M$). The dashed line $P_i(\tilde{x}_\sigma)P_{i+1}(\tilde{x}_\sigma)$ is the arc $a_i(\tilde{x}_\sigma)$, corresponding to moving $\tilde{x}$ to $\tilde{x}_\sigma$.

Now suppose $x_\sigma$ moves away from $y$ along the minimal geodesic connecting them, at unit speed. (We imagine $x_\sigma$ moves smoothly in order to estimate the relevant gradients, and then we use Itô’s rule to determine the stochastic analogue.) Referring to Figure 4 and (29), our next goal is to show that $r = \frac{\partial d_0(x, y)}{\partial \sigma}|_{\sigma=0} \leq 0$. On one hand, we have $\frac{d}{d\sigma}d_0(x_\sigma, y) = 1$. Again referring to Figure 4, by the first variational formula and the fact that the angle $\theta$ is not $0$, $\frac{d}{d\sigma}d_1(x_\sigma, y) = \cos \theta \leq 1 - \lambda$, for some small,
positive $\lambda$. Hence $\frac{d}{d\sigma}(d_1 - d_0)(x,\sigma, y) < -\lambda < 0$. Because $d_1 - d_0$ is smooth, if $y$ is close enough to $z$, we must have that $\frac{d}{d\sigma}(d_1 - d_0)(x,\sigma, z) < 0$. Further, by compactness and continuity, we can make $\varepsilon_0$ small enough so that this holds whenever $y \in Q_i \setminus a_i$. The point is that as $x_\sigma$ moves away from $y$ in this way, $d_1(x_\sigma, z)$ immediately becomes smaller than $d_0(x_\sigma, z)$, putting $z$ on the “opposite side” of $\hat{a}_i(x_\sigma)$ from $y$. Since $a_i(x_\sigma)$ moves smoothly, this means that it immediately intersects the minimal geodesic from $y$ to $z$ between $y$ and $z$, or in other words, that $\xi_i(x_\sigma, y)$ decreases to first order, and thus $r$ is negative. In fact, an even softer argument gives that the distance between $y$ and $a_i(x_\sigma)$ is smaller that $\xi_i$, as is obvious from Figure 4, which implies $r \leq 0$. As pointed out earlier, this is enough to conclude that $u_{C,i}$ in Equation (30) is bounded from below by $b \cos \varphi$, and thus is bounded from below by a positive constant depending only on $M, \varepsilon_0$, and the bounds on $a$ and $b$.

To extend this to the case when we allow $\xi_{i,\tau} = 0$, which means $y_{\tau} \in a_i(x_{\tau}) \setminus \hat{a}_i(x_{\tau})$, let $\tilde{\xi}_i$ be the signed distance from $y_{\tau}$ to $a_i$ in some neighborhood of $y_{\tau}$, as shown in Figure 5 below (here we take our sign so that $\tilde{\xi}_i < 0$ when $y$ is on the opposite side of $a_i(x)$ from $x$). Then $\tilde{\xi}_i$ is smooth on this neighborhood and, as noted above, the minimal geodesic from $x_{\tau}$ to $y_{\tau}$ is evolving continuously (so there’s no problem with the definition of the mirror coupling). Then the above arguments apply to $\tilde{\xi}_i$ as well, by continuity. To be more precise, we can think about the analogue of Equation (29) for the signed distance $\xi$. On the region where $\tilde{\xi}_i \geq 0$, the same arguments as above apply (since here $\tilde{\xi}_i = \xi_i$, and now we can include points with $\tilde{\xi}_i = 0$ because they’re now smooth points). On the region where $\tilde{\xi}_i < 0$, the gradient of $\tilde{\xi}_i$ is minus the gradient of $\xi_i$. Thus the first term in Equation (29) is still $-b \cos \varphi \, dW^1_i$. Now the arc $a_i(\hat{x}_{\tau})$ is moving away from $y_{\tau}$, however, because the gradient has the opposite sign, the above reasoning again shows that $r \leq 0$. This is illustrated in Figure 5, which should make the underlying geometry clear. Thus, in taking the quadratic variation, we still have that $(-b \cos \varphi + r_{\tau})^2$ is bounded from below by a positive constant, which is what we wanted.

Because $\xi_i = |\tilde{\xi}_i|$, we use the Itô-Tanaka formula to see that, for $y_{\tau} \in Q_i(x_{\tau})$, we have

\begin{equation}
    d\xi_{\tau} = u_C \, d\tilde{W}_{\tau} + v_C \, d\tau + dL_C,
\end{equation}

where $u_C$ and $|v_C|$ are bounded and $u_C$ is bounded from below by a positive constant, with all of these bounds depending only on $M, \varepsilon_0$, and the bounds on $a$ and $b$, and where $L_C$ is a non-decreasing process that increases only when $\xi_{i,\tau} = 0$ (assuming the process is being run under the mirror coupling, of course).

**Figure 5.** The case when particle $y$ moves in the region $\{\tilde{\xi}_i < 0\}$ (corresponding to $y$ being on the opposite side of $a_i(x)$ from $x$), which is denoted by the gray boxes. Here we see $a_i(\hat{x}_\sigma)$ moving away from $y$, but this still corresponds to $\tilde{\xi}_i$ decreasing, because of our choice of sign.
Now we see that the SDE satisfied by $\xi_{i,\tau}$ switches between these two possibilities, running under independence or running under the mirror coupling, at the stopping times $\tau_i^n$. In particular,
\[
d\xi_{i,\tau} = u_i \, dW_{\tau} + v_i \, d\tau + dL_i \quad \text{for } y^\delta_{\tau_i} \in Q_i(x^\delta_{\tau_i}),
\]
where $u = \begin{cases} u_{I,i} & \text{for } \tau \in \left[\tau_1, \tau_2 - 1\right], \\ u_{C,i} & \text{for } \tau \in \left[\tau_2, \tau_3\right], \end{cases}$ and $v = \begin{cases} v_{I,i} & \text{for } \tau \in \left[\tau_2 - 1, \tau_3\right], \\ v_{C,i} & \text{for } \tau \in \left[\tau_3, \tau_4\right]. \end{cases}$

and where $L$ is a non-decreasing process that increases only when $\xi_{i,\tau} = 0$. The previously discussed bounds on $u_{I,i}, u_{C,i}, v_{I,i},$ and $v_{C,i}$ imply that there exist positive constants $\alpha, \beta,$ and $\gamma,$ depending only on $M, \varepsilon_0,$ and the bounds on $a$ and $b,$ such that $\alpha \leq u_i \leq \beta$ and $|v_i| \leq \gamma,$ for any $\delta > 0$ and any $i \in \{1, \ldots, K\}$. (That is, these bounds hold for both $u_{I,i}$ and $u_{C,i}$ and both $v_{I,i}$ and $v_{C,i},$ and thus they hold for $u_i$ and $v_i$ regardless of whether the process is being run under independence or under the mirror coupling, and thus they hold independent of $\delta.$ Also, because there are only finitely many $i,$ these bounds can be made independent of $i.$)

Our final task, in this step, is to introduce a semi-martingale that will allow us to control how the joint process transitions from having $y \in Q_i(x),$ independent of $\delta,$ to having $y \not\in Q_i(x).$ Indeed, this control is the other reason for introducing the neighborhood $Q_i(x).$ Note that $S_i(x; \varepsilon_0/2)$ and the complement of $Q_i(x)$ are a positive distance apart, for any $x$, so we can take $\eta_i$ to be a smooth function taking values in $[0, 1],$ such that $\eta_i$ is identically equal to 0 on $S_i(x; \varepsilon_0/2)$ and identically equal to 1 on the complement of $Q_i(x).$ Further, we can let $\eta_i$ vary smoothly in $x.$ As usual, we let $\eta_{i,\tau}$ be the semi-martingale arising from composing $\eta_i$ with the process $(x_{\tau}, y_{\tau}),$ where the particles can be running independently or under the mirror coupling (and thus switching at the $\tau_i^n$ for any $\delta > 0$). Then, by smoothness and compactness, we see that $\eta_{i,\tau}$ satisfies the SDE
\[
d\eta_{i,\tau} = U_i \, dW_{\tau} + V_i \, d\tau,
\]
everywhere on $M \times M,$ where $U_i$ and $|V_i|$ are bounded, with bounds depending only on $M, \varepsilon_0,$ and the bounds on $a$ and $b.$ More precisely, there are positive constants $\tilde{\beta}$ and $\tilde{\gamma},$ depending only on $M, \varepsilon_0,$ and the bounds on $a$ and $b,$ such that $0 \leq U_i \leq \tilde{\beta}$ and $|V_i| \leq \tilde{\gamma},$ for any $\delta > 0$ and any $i \in \{1, \ldots, K\}.$ (Because we are dealing only with coarse bounds, it seems unnecessary to consider the cases of independence and mirror coupling separately, as we did for $\xi_{i,\tau}$)

Step 3: Here, we give the basic estimate on the amount of time spent near each piece of the cut locus; that is, the amount of time $y^\delta_{\tau}$ spends in $S_i(x^\delta_{\tau}; \varepsilon).$ The argument is essentially an exercise in stochastic calculus, which uses only the bounds on the SDEs satisfied by $\xi_{i,\tau}$ and $\eta_{i,\tau}$ that we just derived.

For $0 < \varepsilon < \varepsilon_0/2,$ consider the function
\[
 f(x) = \begin{cases} -2\varepsilon x - \varepsilon^2 & \text{for } x < -\varepsilon \\
 x^2 & \text{for } -\varepsilon \leq x \leq \varepsilon \\
 2\varepsilon x - \varepsilon^2 & \text{for } x > \varepsilon. \end{cases}
\]

Then $f$ is $C^1$ with $|f'(x)| \leq 2\varepsilon,$ and $f''$ exists in the weak sense.

For now, we fix some $i,$ and just write $\xi$ for $\xi_{i,\tau}$ and $Q$ for $Q_i,$ etc.

We first suppose that $y_0 \not\in Q(x_0).$ Then the Itô-Tanaka formula shows that, at least until the first time $y_{\tau}$ exits $Q(x_{\tau}),$ $f(\xi_{\tau})$ satisfies the SDE
\[
df(\xi_{\tau}) = f'(\xi_{\tau})u_{\tau} \, dW_{\tau} + f'(\xi_{\tau})v_{\tau} \, d\tau + u_{\tau}^2 1_{(-\varepsilon, \varepsilon)}(\xi_{\tau}) \, d\tau + f'(\xi_{\tau})dL_{\tau}. \tag{32}
\]

Notice here that $\int_0^\tau f'(x_{\tau})dL_{\tau}$ is a non-decreasing process due to the conditions on $L.$

Next, consider the sequence of stopping times defined inductively as follows:
\[
\sigma_0 = 0, \quad \text{and} \quad \zeta_0 = \inf\{s \geq 0 : y_s \notin Q(x_s)\}
\]
and for $n \geq 1$
\[
\sigma_n = \inf\{s \geq \zeta_{n-1} : y_s \in S(x_s; \varepsilon_0/2)\} \quad \text{and} \quad \zeta_n = \inf\{s \geq \sigma_n : y_s \notin Q(x_s)\}.
\]
It is clear now, from the geometry of these sets, that

\[
\int_0^t 1_{S(x; \varepsilon)}(y_\tau) \, d\tau \leq \sum_{n \geq 0} \int_{\sigma_n \wedge t}^{\zeta_n \wedge t} 1_{(-\varepsilon, \varepsilon)}(\xi_\tau) \, d\tau
\]

and thus

\[
E \left[ \int_0^t 1_{S(x; \varepsilon)}(y_\tau) \, d\tau \right] \leq \sum_{n \geq 0} E \left[ \int_{\sigma_n \wedge t}^{\zeta_n \wedge t} 1_{(-\varepsilon, \varepsilon)}(\xi_\tau) \, d\tau \right].
\]

On each time interval \([\sigma_n \wedge t, \zeta_n \wedge t]\), we use (32) combined with the fact that

\[
E \left[ \int_{\sigma_n \wedge t}^{\zeta_n \wedge t} f'(\xi_\tau) u_\tau dW_\tau \right] = 0
\]

and \(|f'(x)| \leq 2\varepsilon| to first justify that (recall that \(f' dL_u\) is non-decreasing)

\[
E \left[ \int_{\sigma_n \wedge t}^{\zeta_n \wedge t} u_\tau^2 1_{(-\varepsilon, \varepsilon)}(\xi_\tau) \, d\tau \right] + E \left[ \int_{t \wedge \sigma_n}^{t \wedge \zeta_n} f'(\xi_\tau) v_\tau d\tau \right] \leq E[f(\xi_{t \wedge \zeta_n}) - f(\xi_{t \wedge \sigma_n})] \leq 2\varepsilon \varepsilon_0 E[t \wedge \zeta_n - t \wedge \sigma_n].
\]

Complement this with the fact that \(v_\tau f'(\xi_\tau) \geq -2\varepsilon \gamma\) and \(u_\tau \geq \alpha\) to arrive at

\[
E \left[ \int_{\sigma_n \wedge t}^{\zeta_n \wedge t} 1_{(-\varepsilon, \varepsilon)}(\xi_\tau) \, d\tau \right] \leq \frac{2\varepsilon(\varepsilon_0 + \gamma)}{\alpha^2} E[t \wedge \zeta_n - t \wedge \sigma_n].
\]

Consequently, since \(\sum_{n \geq 0} (t \wedge \zeta_n - t \wedge \sigma_n) \leq t\) this results in the main estimate

\[
E \left[ \int_0^t 1_{S(x; \varepsilon)}(y_\tau) \, d\tau \right] \leq \frac{2t \varepsilon(\varepsilon_0 + \gamma)}{\alpha^2} (1 + E[D_t])
\]

where \(D_t\) is the number of “downcrossings” of \(y_\tau\) from the complement of \(Q(x_\tau)\) to \(S(x_\tau; \varepsilon_0/2)\), inside the interval \([0, t]\). That is, \(D_t\) is supremum of \(n\) such that \(\sigma_n \leq t\).

This basic estimate leaves us with the task of getting an upper bound on the number of downcrossings, as just described. First note that \(\eta_{\zeta_n} = 1\) and \(\eta_{\sigma_n} = 0\), assuming these stopping times are less than or equal to \(t\). Also, we have that

\[
E[\eta_{t \wedge \sigma_n} - \eta_{t \wedge \zeta_n}] = E \left[ \int_{t \wedge \sigma_n}^{t \wedge \zeta_n} U_i \, dW_u \right] + E \left[ \int_{t \wedge \sigma_n}^{t \wedge \zeta_n} V_i \, du \right]
\]

\[
= \sum_{n=0}^{N} E \left[ \int_{t \wedge \sigma_n}^{t \wedge \zeta_n} V_i \, du \right] \leq \tilde{c} E[t \wedge \sigma_n - t \wedge \zeta_n],
\]

where we used the boundedness of \(U_i\) to see that the martingale part is actually integrable. For any \(N \geq 1\), we have that

\[
\sum_{n=0}^{N} E[\eta_{t \wedge \sigma_n} - \eta_{t \wedge \zeta_n}] \leq \tilde{c} \sum_{n=0}^{N} E[t \wedge \sigma_n - t \wedge \zeta_n] \leq \tilde{c} t.
\]

Since we always have \(0 \leq \eta_{\tau} \leq 1\), we let \(N \to \infty\) to see that

\[
1 + E[D_t] \leq \sum_{n=0}^{N} E[\eta_{t \wedge \sigma_n} - \eta_{t \wedge \zeta_n}] \leq \tilde{c} t.
\]

This, in turn, implies that

\[
E \left[ \int_0^t 1_{S(x; \varepsilon)}(y_\tau) \, d\tau \right] \leq \frac{2t \tilde{c}(\varepsilon_0 + \gamma)}{\alpha^2} \varepsilon.
\]

In the case we start with \(y_0 \notin Q(x_0)\), we run the process until it hits \(S(x_\tau; \varepsilon_0/2)\), and once this happens use the same argument as above.

Step 4: From here, the proof is easy to finish. We just put everything together.
For any $0 < \varepsilon < \varepsilon_0/2$, the expected amount of time on the interval $[0, t]$ that $y_\delta^\varepsilon$ spends within distance $\varepsilon$ of \text{Cut}(x_\delta^\varepsilon)$ satisfies
\[
\mathbb{E} \left[ \int_0^t 1_{\{ \text{dist}(\cdot, \text{Cut}(x_\delta^\varepsilon)) \leq \varepsilon \}} \left( y_\tau^\varepsilon \right) d\tau \right] \leq \sum_{i=1}^K \mathbb{E} \left[ \int_0^t 1_{S_i(x_\delta^\varepsilon; \varepsilon)} \left( y_\tau^\varepsilon \right) d\tau \right] \leq K \frac{2t^2\gamma(\varepsilon_0 + \gamma)}{\alpha^2} \varepsilon = C \varepsilon,
\]
where $C > 0$ (defined by the above equality) is a constant depending only on $t$, $M$, $\varepsilon_0$, and the bounds on $a$ and $b$ (in particular, $C$ does not depend on $\delta$). As noted just before Step 1, this is exactly the estimate we need to finish the proof. \hfill \Box

7. Convergence of first order to constant curvature in the case $\chi(M) = 0$

Now that we have our uniqueness/verification theorem and the general coupling procedure, we begin exploring some of the consequences. As usual, for simplicity, we assume that we have a smooth solution $\bar{\pi}_t$ for all time $t \geq 0$ on the manifold $M$. We take here a flat metric $h$, which is possible under the assumption that $\chi(M) = 0$.

The main result of this section is the following.

**Theorem 10.** For $M$, $h$, and $\bar{\pi}_0$ as above, suppose that we have a smooth solution $\bar{\pi}_t$ to Equation (9) for all $t \in [0, \infty)$. Then there exist constants, $c, C > 0$ which depend only on the metrics $g_0$ and $h$ such that
\[
\text{sup}_{x \in M} |\bar{\pi}_t(x)| \leq ce^{-Ct}.
\]

**Proof.** Fix a time $t > 0$, a time $s \in [0, t)$ and a point $x \in M$ so that the Ricci flow has a solution on $[0, t]$. The first thing to notice is that $p_t = \bar{\pi}_{t-\tau}(x_\tau)$ is a martingale. Thus we have the following stochastic representation
\[
\bar{\pi}_t(x) = \mathbb{E} \left[ \bar{\pi}_{t-\sigma}(x_\sigma) \right]
\]
valid for any stopping time $\sigma$ with $0 \leq \sigma \leq t$. In particular, setting $\sigma = t$ shows that $\bar{\pi}_t(x)$ is a weighted average of the values of $\bar{\pi}_0$. Thus
\[
\min_M \bar{\pi}_0 \leq \min_M \bar{\pi}_t \leq \max_M \bar{\pi}_t \leq \max_M \bar{\pi}_0
\]
for any $t$. The main idea for getting (33) is to prove that for some $c, C > 0$,
\[
\text{osc \ \bar{\pi}_t} \leq ce^{-Ct}.
\]
Indeed, if this is true, then combining this with the fact that the integral of $e^{2\tilde{\rho}_t}$ with respect to the volume induced by $h$ is 1, we deduce that there is at least one point $\tilde{x}$ for which $\tilde{\rho}_t(\tilde{x}) = 0$ and from here it is clear that we get (33).

We now choose any two starting points $x$ and $y$ for the processes $x_\tau$ and $y_\tau$. Over each of these points, there’s exactly one point ($\bar{\pi}_t(x)$ and $\bar{\pi}_t(y)$) in the fiber which is in the reachable set $\Gamma_t$. We wish to run the controlled process starting from both $(x, \bar{\pi}_t(x))$ and $(y, \bar{\pi}_t(y))$, and couple them so that they meet as quickly as possible. Our reachable sets have the semigroup property, i.e. the process $(x_\tau, p_\tau)$ at time $\tau \in [0, t]$ is on $\Gamma_{t-\tau}$, and since we know that we have a solution until time $t$, we know that after running the controlled processes for time $\tau \leq t$ they will be on the solution section corresponding to the Ricci flow at time $t - \tau$. This means that if the particles couple on $M$, they couple in the total space as well, that is, $x_\tau = y_\tau$ implies that $\bar{\pi}_{t-\tau}(x_\tau) = \bar{\pi}_{t-\tau}(y_\tau)$ as well.

In light of this, if $\sigma$ is the coupling time of $x_\sigma$ and $y_\sigma$, the martingale property gives that
\[
\bar{\pi}_t(x) - \bar{\pi}_t(y) = \mathbb{E} \left[ \bar{\pi}_{t-\sigma\wedge s}(x_{\sigma\wedge s}) \right] - \mathbb{E} \left[ \bar{\pi}_{t-\sigma\wedge s}(y_{\sigma\wedge s}) \right]
\]
\[
= \mathbb{E} \left[ \bar{\pi}_{t-\sigma}(x_{\sigma}) - \bar{\pi}_{t-\sigma}(y_{\sigma}), \sigma \leq s \right] + \mathbb{E} \left[ \bar{\pi}_{t-s}(x_s) - \bar{\pi}_{t-s}(y_s), s < \sigma \right]
\]
\[
= \mathbb{E} \left[ \bar{\pi}_{t-s}(x_s) - \bar{\pi}_{t-s}(y_s), s < \sigma \right].
\]

The outcome of this is that
\[
\text{osc \ \bar{\pi}_t} \leq \mathbb{P}(s < \sigma) \text{osc \ \bar{\pi}_{t-s}}.
\]
What remains to be controlled here is $\mathbb{P}(s < \sigma)$. While the above is true for any coupling of $x_\tau$ and $y_\tau$, we wish to use the mirror coupling, as was introduced in the previous section. The main property of this coupling, for us, is contained in (27) which gives the equation satisfied by the distance function $\rho_\tau = d(x_\tau, y_\tau)$, namely

$$d\rho_\tau = (a + b) d\tilde{W}_\tau + \frac{1}{2\rho_\tau} (a - b)^2 d\tau - L_\tau$$

with $a_\tau = e^{-\tilde{p}_\tau(x_\tau)}$, $b_\tau = e^{-\tilde{p}_\tau(y_\tau)}$ and $\tilde{W}$ being a one dimensional Brownian motion on the time interval $[0, t]$. Obviously the time $\tau$ runs up to $\sigma$ (the hitting time of 0) or $t$, whichever comes first and the term $L_\tau$ is non-negative. We are interested in estimating the probability this hitting time $\sigma$ occurs after time $s$. To this end, the first thing which will be used here is the fact that from (35) we know that $a$ and $b$ are all bounded from above as well from below. So we have two constants $A, B > 0$ which are depending only on $p_0$, or otherwise the starting metric $g_0$, with the property that

$$A \leq a, b \leq B.$$  

To move on, we let

$$\lambda(u) = \int_0^u \frac{1}{(a_v + b_v)^2} dv$$

be the time-change making the martingale part of $\rho_\tau$ from (39) into a Brownian motion. Then with the notation $\tilde{\rho}_u = \rho_{\lambda(u)}$,

$$d\tilde{\rho}_u = d\tilde{W}_u + \frac{1}{2\tilde{\rho}_u} (a - b)^2 du - dL_u$$

where $a$ and $b$ are evaluated at time $\lambda(u)$ and the above equation is valid for $u \in [0, t \land \lambda^{-1}(t))$, where $\lambda^{-1}(t)$ is the first value of $u$ corresponding to $\lambda(u) = t$. Obviously $cu \leq \lambda(u) \leq Cu$ for some constants $c, C > 0$ and also because of (40),

$$\frac{a - b}{a + b} \leq \frac{B - A}{B + A} = 1 - \epsilon < 1.$$  

Ignoring the $L$ term in (41) and then using standard comparison for ordinary stochastic differential equations, we learn that the process $\tilde{\rho}$ is bounded above by a Bessel process of dimension $\delta < 2$ and starting at some value $\tilde{\rho}_0$ bounded by the diameter (with respect to the metric $h$) of the manifold $M$. Thus, invoking [22, Equation (15)] which gives the distribution of the hitting time $\tilde{\sigma}$ of 0 for a Bessel process of dimension $\delta < 2$ starting at $\tilde{\rho}_0$, we obtain

$$\mathbb{P}(s < \tilde{\sigma}) = \frac{1}{\Gamma(1 - \delta/2)} \int_0^{\tilde{\rho}_0/(2s)} y^{-\delta/2} e^{-y} dy.$$  

Finally, since $cu \leq \lambda(u) \leq Cu$ and the diameter of the manifold $M$ is finite, we arrive at

$$\mathbb{P}(s < \sigma) \leq \frac{1}{\Gamma(1 - \delta/2)} \int_0^{D/s} y^{-\delta/2} e^{-y} dy =: \Lambda(s)$$

where $D$ is a constant which depends only on the initial metric $g_0$ and some geometry of the underlying metric $h$ (more precisely the diameter of $M$ with respect to $h$). Hence it turns out that the function $\Lambda$ is determined by the metrics $h$ and $g_0$.

To summarize, from (38) and the preceding we now have that

$$\operatorname{osc} \tilde{\rho}_t \leq \Lambda(s) \operatorname{osc} \tilde{\rho}_{t-s}.$$  

Using this, it is easy to get (36) as follows. For $t \in [0, 1]$, we know from (35), that $\operatorname{osc} \tilde{\rho}_t \leq \operatorname{osc} \tilde{\rho}_0$. Now for each $t \in [n, n + 1]$, $n \geq 1$, using repeatedly the above inequality, we arrive at

$$\operatorname{osc} \tilde{\rho}_t \leq \Lambda(1)^n \operatorname{osc} \tilde{\rho}_{t-n} \leq \Lambda(1)^n \operatorname{osc} \tilde{\rho}_0 / \Lambda(1)$$

which is exactly the exponential decay of (36) since $0 < \Lambda(1) < 1$. □
Remark. It is interesting to point out that we can prove the same exponential decay as in Theorem 10 for the case of $\chi(M) < 0$ using the coupling argument. This decay is, however, already taken care of by the a priori estimates of Corollary 7. Nonetheless, this coupling argument is the one we will employ for the gradient estimates in the following section.

8. Estimates on the Gradient Decay of the Normalized Ricci Flow in the Case $\chi(M) \leq 0$

We continue under the same assumptions that $M$ is a compact surface with reference metric $h$ of constant curvature $0$ or $-1$ (so $M$ has non-positive Euler characteristic by the Gauss-Bonnet theorem) and $g_0$ is a smooth initial metric in the same conformal class and with the same area as $h$, so that the normalized Ricci flow has a smooth solution for all time which is given by $\bar{p}_t$. Now, $\bar{p}_t$ converges in the $C^0$-norm exponentially fast to $0$ as shown in Corollary 7 for the case $\chi(M) < 0$ and Theorem 10 for the case $\chi(M) = 0$. So we have that for some constants $c, C > 0$,

$$\sup_{x \in M} |\bar{p}_t(x)| \leq ce^{-Ct}. \quad (42)$$

Let

$$G(t) = \sup_{x \in M} |\nabla \bar{p}_t(x)|. \quad (43)$$

The idea is to start with

$$\langle \nabla \bar{p}_t(x), \xi \rangle = \lim_{h \rightarrow 0} \frac{\bar{p}_t(\gamma_h(x)) - \bar{p}_t(x)}{h}$$

where $\xi$ is a unit vector in the tangent space at $x$ and $\gamma(t)$ is any curve started at $x$ with initial speed $\xi$. Then we use the coupling to estimate $\bar{p}_t(x) - \bar{p}_t(y)$ for $x$ and $y$ close to one another. Due to the non-linearity of the flow, the estimates coming from the above will still contain the gradient bounds, but in the end, letting $x$ and $y$ come close to one another leads to a functional inequality on $G(t)$, from which we are able to derive the desired estimate.

Theorem 11. If $\chi(M) \leq 0$ then $G(t)$ goes to $0$ exponentially fast. As a consequence, $\bar{p}_t$ converges to $0$ exponentially fast in $C^1$.

Proof. Pick two sufficiently close points $x, y \in M$ and some $t > 0$, and let $\rho_\tau = d(x, y)$ for $0 \leq \tau \leq t$ be the distance (measured with respect to the time independent metric $h$) between the processes $x_\tau$ and $y_\tau$ started at $x$ and $y$ respectively. We are going to use mirror coupling for the processes $x$ and $y$. Recall that the coupling equations satisfied by $(x_\tau, p_\tau)$ and $(y_\tau, q_\tau)$ are given by

$$\begin{align*}
dx_\tau &= e^{-p_\tau} \left[ \sum_{i=1}^{2} \xi_i(x_\tau) \sqrt{2} \circ dW^i_\tau \right] \\
dy_\tau &= e^{-q_\tau} \left[ \sum_{i=1}^{2} \xi_i(y_\tau) \sqrt{2} \circ d\tilde{W}^i_\tau \right] \\
dp_\tau &= e^{-p_\tau} \left[ \sum_{i=1}^{2} a_i \sqrt{2} d\tilde{W}^i_\tau \right] + r(e^{-2p_\tau} - 1) d\tau \\
dq_\tau &= e^{-q_\tau} \left[ \sum_{i=1}^{2} a_i' \sqrt{2} d\tilde{W}^i_\tau \right] + r(e^{-2q_\tau} - 1) d\tau,
\end{align*}$$

where $r = 0$ or $-1$ and $\tilde{W}$ is the Brownian motion given by the mirror coupling.

We consider $\sigma$, the coupling time of $x$ and $y$. From the fact that $p_\tau + \int_0^\tau (1 - e^{-2p_u}) du$ is a martingale and $p_\tau = \bar{p}_{t-\tau}(x_\tau)$, we write,

$$\bar{p}_t(x) - \bar{p}_t(y) = \mathbb{E}[p_{t \wedge \tau} - q_{t \wedge \tau}] - r \mathbb{E} \left[ \int_0^{t \wedge \tau} (e^{-2p_u} - e^{-2q_u}) du \right] \quad (44)$$

for any stopping time $\tau$. The useful estimates we are interested in are estimates from above of $\bar{p}_t(x) - \bar{p}_t(y)$, and this is good if we assume that $\bar{p}_t(x) - \bar{p}_t(y) > 0$. This is always possible unless $\bar{p}_t$ is constant.
in which case the gradient is 0, so there is nothing to prove then. Thus, assume that \( \tilde{p}_t(x) - \tilde{p}_t(y) \geq 0 \) for some points \( x \) and \( y \) (which is the same as \( p_0 > q_0 \)) and take \( \alpha \) to be the first time \( u \) for which \( p_u = q_u \). With this choice of the stopping time, for any \( u \in [0, \alpha] \) we know that \( p_u \geq q_u \), which thus means \( e^{-2p_u} - e^{-2q_u} \leq 0 \). This combined with the fact that \( r \leq 0 \) and the exponential decay of \( \tilde{p}_t \), implies that for any \( s \in [0, t \wedge 1] \),

\[
\tilde{p}_t(x) - \tilde{p}_t(y) \leq \mathbb{E}[p_\alpha - q_\alpha, \alpha \leq s] + \mathbb{E}[p_s - q_s, s < \alpha] \leq c e^{-C t} \mathbb{P}(s < \alpha).
\]

The point is that if \( \sigma \) is the first coupling time, of the processes \( x \) and \( y \), it is obvious that \( \alpha \leq \sigma \) and thus

\[
\mathbb{P}(s < \alpha) \leq \mathbb{P}(s < \sigma) \text{ for any } s \in [0, t \wedge 1],
\]

which in turn yields

\[ \tilde{p}_t(x) - \tilde{p}_t(y) \leq c e^{-C t} \mathbb{P}(s < \sigma) \text{ for any } s \in [0, t \wedge 1]. \]

With this equation our next task becomes the estimate of \( \mathbb{P}(s < \sigma) \).

From Theorem 9 we learn that the distance process \( \rho \) satisfies

\[ d\rho \leq (e^{-pr} + e^{-qr}) dB_t + \frac{(e^{-pr} - e^{-qr})^2}{2\rho} d\tau \]

in the case \( r = 0 \) and

\[ d\rho \leq (e^{-pr} + e^{-qr}) dB_t + \frac{1}{2} \left[ (e^{-pr} - e^{-qr})^2 \coth \rho + 2e^{-pr} \tanh \frac{\rho}{2} \right] d\tau \]

in the case \( r = -1 \). Here \( B_t \) is a one dimensional Brownian motion run in the time interval \([0, t]\).

So far, we have used this strategy of coupling in the proof of Theorem 10, in which, due to the singularity in the drift of the equations (46) and (47), we compared the distance function \( \rho \) with a Bessel process. For the gradient estimates, we are going to remove the singularity based on the observation that

\[ p_r = \tilde{p}_{t-r}(x_r) \text{ and similarly } q_r = \tilde{p}_{t-r}(y_r). \]

The upshot of this is that the term \( e^{-pr} - e^{-qr} \) is in fact of order \( \rho \). More precisely, due to the boundedness of \( \tilde{p}_r \),

\[
|e^{-pr} - e^{-qr}| = |e^{-\tilde{p}_{t-r}(x_r)} - e^{-\tilde{p}_{t-r}(y_r)}| \leq Cd(x_r, y_r) \sup_{x \in M} |\nabla \tilde{p}_{t-r}(x)| = CG(t - \tau) \rho_r.
\]

Since \( \rho_r \leq D \), where \( D \) is the diameter of \( M \), it is straightforward to show that either (46) or (47) implies

\[ d\rho \leq (e^{-pr} + e^{-qr}) dB_t + C(1 + G^2(t - \tau)) \rho_r d\tau. \]

To go further from here, consider \( \tilde{\rho}_r \) the solution to

\[ d\tilde{\rho}_r = (e^{-pr} + e^{-qr}) dB_t + C(1 + G^2(t - \tau)) \rho_r d\tau. \]

with the same initial condition \( \rho_0 = d(x, y) \) as \( \rho \). Standard arguments (in fact a simple application of Gronwall’s Lemma) give that

\[ \rho_r \leq \tilde{\rho}_r \]

which results in the fact that the first hitting time of 0 for \( \rho \) is less then or equal to the first hitting time of 0 for \( \tilde{\rho} \). Now if \( \tilde{\sigma} \) denotes the hitting time of 0 for the process \( \tilde{\rho}_I \)

\[ \mathbb{P}(s < \sigma) \leq \mathbb{P}(s < \tilde{\sigma}) \text{ for all } s \in [0, t \wedge 1]. \]

Therefore the task now is to estimate the latter, and to do this we solve for \( \rho \) as

\[ \tilde{\rho}_r = \left( \rho_0 + \int_0^T (e^{-p_\nu} + e^{-q_\nu}) e^{-\int_0^\nu f(z) dz} dB_\nu \right) e^{\int_0^T f(z) dz}. \]
with the notation \( f(\tau) = C(1 + G^2(t - \tau)) \), for \( 0 \leq \tau \leq t \). Consequently the first hitting time of 0 for \( \tilde{\rho} \) is the first hitting time of \( -\rho_0 \) for the time-changed Brownian motion \( \int_0^t (e^{-pv} + e^{-qv}) e^{-\tilde{f}(z)} dB_z \). In law, this is the same as the first hitting time of \( -\rho_0 \) of \( B_{c(\tau)} \), with the time change

\[
c(\tau) = \int_0^{\tau} (e^{-pv} + e^{-qv})^2 e^{-2\tilde{f}(z)} dv.
\]

Once again using the boundedness of \( \tilde{\rho} \), we can find a constant \( C > 0 \) such that

\[
c(\tau) \geq \tilde{c}(\tau) := C \int_0^{\tau} e^{-2\tilde{f}(z)} dv \text{ for } \tau \in [0, t].
\]

Now, if \( \sigma_{-\rho_0} \) is the first hitting time of \( -\rho_0 \) for the Brownian motion, then the hitting time of \( -\rho_0 \) for \( B_{c(\tau)} \) is given by \( c^{-1}(\sigma_{-\rho_0} \land c(t)) \). This combined with (48) yields that

\[
\mathbb{P}(s < t \land \tilde{\sigma}) = \mathbb{P}(s < c^{-1}(\sigma_{-\rho_0} \land c(t))) \leq \mathbb{P}(c(s) \leq \sigma_{-\rho_0}) \leq \mathbb{P}(\tilde{c}(s) < \sigma_{-\rho_0}).
\]

The distribution of \( \sigma_{-\rho_0} \) is actually well understood (see for instance the Remark after [40, Proposition 3.7 of Chapter III]), and its density is given by \( \frac{\rho_0}{\sqrt{2\pi}x^3} e^{-\rho_0^2/(2x^2)} \) on the positive axis, which results with

\[
\mathbb{P}(\tilde{c}(s) < \sigma_{-\rho_0}) = \int_{\tilde{c}(s)}^{\infty} \frac{\rho_0}{\sqrt{2\pi}x^3} e^{-\rho_0^2/(2x^2)} dx = \frac{2}{\sqrt{2\pi}} \int_0^{\sqrt{\tilde{c}(s)}} e^{-r^2/2} dr.
\]

Going back to (45) and using the preceding, we conclude that for \( s \in [0, t] \),

\[
\tilde{p}_t(x) - \tilde{p}_t(y) \leq c e^{-C(t-s)} \int_0^{\sqrt{\tilde{c}(s)}} e^{-r^2/2} dr,
\]

from which, using the fact that \( d(x, y) = \rho_0 \) and letting \( \rho_0 \) go to 0, we fairly easily deduce that

\[
G(t) \leq c \frac{e^{-Ct}}{\sqrt{c(s)}},
\]

which we rearrange as

\[
A(t) \int_0^s e^{-\tilde{f}(z)} A(t-u) du d\tau \leq ce^{-Ct} \text{ for all } s \in [0, t \land 1] \text{ with } A(\tau) = CG^2(\tau).
\]

From here the exponential decay of \( A(t) \) is taken care of by the following Lemma. \( \square \)

**Lemma 12.** Suppose \( A : [0, \infty) \rightarrow [0, \infty) \) is a continuous function with the property that for some constants \( c, C > 0 \),

\[
A(t) \int_0^s e^{-\tilde{f}(z)} A(t-u) du d\tau \leq ce^{-Ct} \text{ for all } s \in [0, t \land 1].
\]

Then there are constants \( k, K > 0 \) such that

\[
A(t) \leq Ke^{-kt} \text{ for all } t > 0.
\]

**Proof.** For each \( n \geq 1 \), let \( m_n = \sup_{t \in [n, n+1]} A(t) \) and \( M_n = \sup_{t \in [n-1, n+1]} A(t) \). Notice that the exponential decay we are looking for is actually equivalent to \( m_n \leq Ke^{-kn} \) for large enough \( n \).

Now, for \( t \in [n, n+1] \) and \( s \in [0, 1] \), we have \( t-s \in [n-1, n+1] \) and therefore \( -A(t-u) \geq -M_n \), which combined with (50) yields, for \( t \) near the supremum of \( A(t) \) on \([n, n+1]\), and eventually another constant \( c > 0 \)

\[
m_n \int_0^1 e^{-\tau M_n} d\tau = m_n \frac{1 - e^{-M_n}}{M_n} \leq e^{-cn} \text{ for all large } n.
\]

which in turn gives

\[
(\star) \quad m_n \leq \frac{M_n}{1 - e^{-M_n} e^{-cn}}.
\]

Now, for each particular \( n \), we have one of the following two alternatives:
Corollary 13. Under the same assumptions as in Theorem 11,

(51) \[ P(s < \sigma) \leq C \frac{p_0}{\sqrt{s}} \text{ for } s \in (0, t]. \]

Proof. This follows by combining (48), (49), and the fact that \( \tilde{c}(s)/s \) is bounded (due to the gradient estimate).

\[ \square \]

9. Triple Coupling

9.1. Basic idea. We have just used coupling to prove the exponential convergence of \( \tilde{p} \) to 0 in the \( C^1 \)-topology. The next step in our analysis is the estimate of the decay of the Hessian of \( \tilde{p} \), which, from the Ricci flow equation, implies the convergence of the curvature to a constant. The basic idea starts with writing

\[ \langle \text{Hess} \tilde{p}(z) \xi, \xi \rangle = \lim_{\rho_0 \to 0} \frac{\tilde{p}_t(\gamma(-\rho_0)) - 2\tilde{p}_t(z) + \tilde{p}_t(\gamma(\rho_0))}{\rho_0^2} \]
where $\xi$ is a unit vector at $z$, and $\gamma$ is a geodesic running at unit speed started (at $t = 0$) at $z$ with velocity $\xi$. Now we are concerned with three points, $x = \gamma(-\rho_0), y = \gamma(\rho_0)$, and the middle point $z$. As in the gradient estimate case, we want to write $\tilde{p}(x), \tilde{p}(y),$ and $\tilde{p}(z)$ as integrals of some functions of the associated Brownian motions and then use probabilistic estimates to find bounds for $\tilde{p}(\gamma(-\rho_0)) - 2\tilde{p}(z) + \tilde{p}(\gamma(\rho_0))$ in terms of $\rho_0$.

There is very little literature on this idea, though it certainly seems that this probabilistic tool is quite useful for estimating second-order derivatives for evolution equations. The only reference to this approach we’re aware of is in [17], where it is essentially used to estimate the Hessian of harmonic functions on Euclidean domains.

To make this idea more precise, we will develop a mechanism of triple coupling (that is, a coupling of three particles, as opposed to just two). We will use mirror coupling for the processes corresponding to the particles $x$ and $y$, taking them as time changed Brownian motions, as in the previous section. Now we wish to include a third particle, namely $z$, which we want to couple together with $x$ and $y$. It is natural to want to have this “middle particle” remains on the geodesic joining the other two as it is pictured in Figure 6.

![Figure 6](image_url)

**Figure 6.** The configuration of the three particles $x_\tau, y_\tau$ being mirror coupled and $z_\tau$ on the geodesic between them.

We will see that this is possible (at least in the cases we’re considering) if we allow it to evolve as time-changed Brownian motion, possibly with drift along the direction of the geodesic.

Instead of starting with a time-changed Brownian motion with a drift, $z_\tau$, and then trying to figure out the time change and drift necessary so that it stays on the geodesic, we do it the other way around. Namely, since we want the particle $z_\tau$ to move on the geodesic, we determine the conditions on the distance to one of the other points so that the corresponding point on the geodesic is a time-changed Brownian motion with a drift along the geodesic. For the purpose of the Hessian estimates, and in light of the gradient decay, this will be sufficient.

### 9.2. Rigorous Approach.

Assume we start with an arbitrary Riemannian surface $M$ and that $x_\tau, y_\tau$ run as time-changed Brownian motions with the time changes $a$ and $b$, as above in Figure 6. The idea is that the middle point $z_\tau$ on the geodesic joining $x_\tau$ and $y_\tau$ is completely described by specifying the distance $\rho_{1,\tau}$ from $z_\tau$ to one of the ends, say $x_\tau$. We use a mirror coupling of the particles $x_\tau$ and $y_\tau$ and $\rho_{1,\tau}$ will be described in terms of a real-valued SDE. In addition to $\rho_{1,\tau}$, we will also consider $\rho_{2,\tau}$, which in intuitive terms is just the distance from the middle particle $z_\tau$ to $y_\tau$. We are seeking several key symmetry properties which will play an important role in the economy of the Hessian estimates to follow.

In what follows, as always, fix a time horizon $t > 0$, and assume that $a = a(\tau, x, y, \rho_1, \rho_2)$ and $b = b(\tau, x, y, \rho_1, \rho_2)$ are two positive functions defined on $[0, t] \times M \times M \times [0, \infty) \times [0, \infty)$, which will be time changes for the processes $x_\tau$ and $y_\tau$. To describe this, again denote by $m_{x,y} : T_xM \to T_yM$ the mirror map, that is, the parallel transport along the minimal unit speed geodesic $\gamma_{x,y}$ joining $x$ and $y$ (assuming that $x, y$ are not at each other’s cut locus) followed by the reflection about the orthogonal direction to the geodesic at $y$. 
The system we start with is the following

\[
\begin{align*}
 dx_\tau &= a(\tau) \left[ \sum_{i=1}^{2} \varepsilon_i(x_\tau) \circ dW^i_\tau \right] \\
 dy_\tau &= b(\tau) \left[ \sum_{i=1}^{2} \Psi_\tau[\varepsilon_i(y_\tau)] \circ dW^i_\tau \right] \\
 d\rho_{1,\tau} &= -a(\tau) \sum_{i=1}^{2} \langle \varepsilon_i(x_\tau), \dot{\gamma}_\tau(0) \rangle dW^i_\tau + \alpha(\tau) dW^3_\tau + \beta(\tau) d\tau \\
 d\rho_{2,\tau} &= b(\tau) \sum_{i=1}^{2} \langle \Psi_\tau[\varepsilon_i(y_\tau)], \dot{\gamma}_\tau(l(\tau)) \rangle dW^i_\tau + \tilde{\alpha}(\tau) dW^3_\tau + \tilde{\beta}(\tau) d\tau,
\end{align*}
\]

(52)

where \( \Psi_\tau = m_{x_\tau,y_\tau} \varepsilon(x_\tau) \varepsilon(y_\tau)^{-1} \) is the reflection map acting on \( T_{y_\tau} M, \gamma_\tau \) is the minimal geodesic running at unit speed from \( x_\tau \) to \( y_\tau \), and \( W^3 \) is a one-dimensional Brownian motion independent of \( (W^1, W^2) \). As a notation, let \( l(\tau) \) be the length of the geodesic \( \gamma_\tau \). Here we do not specify what the functions \( \alpha, \tilde{\alpha}, \beta, \tilde{\beta} \) are as we will do this along the way, depending on the properties we want to reveal. They are defined, like \( a \) and \( b \), on \([0, t] \times M \times M \times [0, \infty) \times [0, \infty) \). The equations for \( \rho_1 \) and \( \rho_2 \) can be thought of as the equations of the distances from the middle point \( z_\tau \) to \( x_\tau \) and \( y_\tau \), as indicated in the previous section, and also as discussed for the coupling in [24, Section 6.6]. Notice here an important point, namely, since

\[ \langle \Psi_\tau[\varepsilon_i(y_\tau)], \dot{\gamma}_\tau(l(\tau)) \rangle = -\langle \varepsilon_i(x_\tau), \dot{\gamma}_\tau(0) \rangle, \]

the last equation of (52) can be rewritten as

\[ d\rho_{2,\tau} = -b(\tau) \sum_{i=1}^{2} \langle \varepsilon_i(x_\tau), \dot{\gamma}_\tau(0) \rangle dW^i_\tau + \tilde{\alpha}(\tau) dW^3_\tau + \tilde{\beta}(\tau) d\tau. \]

We should also point out that to be in tune with the system (12) we should take \( \sqrt{2}a \) instead of \( a \) and \( \sqrt{2}b \) instead of \( b \). Since this is not important for this section and to avoid carrying around an extra \( \sqrt{2} \) factor we will work with the system in the form (52).

There is no problem with the existence of a solution for the system (52) (as long as the entries \( a, b, \alpha, \beta, \tilde{\alpha}, \) and \( \tilde{\beta} \) are smooth) up to the stopping time \( T \), which is the first time \( \tau \) when \( \rho_{1,\tau} \rho_{2,\tau} \) hits 0 or when \( d(x_\tau, y_\tau) \) hits a (small) \( r_0 \) smaller than the injectivity radius (with respect to the background metric \( h \)). This way we have a well-defined system and do not have to worry about the extension beyond the cut locus, as we did in the previous (two particle) coupling case. From now on, during this section we will assume that the time in the system (52) is run until \( T \).

The object of interest to us is the process \((x, y, \rho_1, \rho_2)\). It is clear that this is a diffusion, and it is a relatively straightforward task to determine that the generator of \((x, y, \rho_1, \rho_2)\) is

\[
\frac{a^2}{2} \Delta_x + \frac{b^2}{2} \Delta_y + \frac{\alpha^2}{2} \partial^2_{\rho_1} + \frac{\beta^2}{2} \partial^2_{\rho_2} + ab(m_{x,y} X_{1,i} Y_{2,j}) X_{1,i} Y_{2,j} \\
- a^2 \langle X_{1,i}, \dot{\gamma}_{x,y}(0) \rangle X_{1,i} \partial_{\rho_1} - ab \langle X_{1,i}, \dot{\gamma}_{x,y}(0) \rangle X_{1,i} \partial_{\rho_2} \\
- ab \langle X_{1,i}, \dot{\gamma}_{x,y}(0) \rangle m_{x,y} X_{1,i} \partial_{\rho_1} - b^2 \langle X_{1,i}, \dot{\gamma}_{x,y}(0) \rangle m_{x,y} X_{1,i} \partial_{\rho_2} \\
+ (\alpha \tilde{\alpha} - ab \sum_{i=1}^{2} \langle X_{1,i}, \dot{\gamma}_{x,y}(0) \rangle^2) \partial_{\rho_1} \partial_{\rho_2} + \beta \partial_{\rho_1} + \tilde{\beta} \partial_{\rho_2},
\]

with \( X_{1,i}, i = 1, 2 \) being an orthonormal basis of \( T_x M \) and \( Y_{2,j}, j = 1, 2 \) an orthonormal basis of \( T_y M \). In fact, we can choose \( X_{1,1} = \dot{\gamma}_{x,y}(0) \) and \( X_{1,2} = \xi_1 \in T_x M \), which is perpendicular to \( \dot{\gamma}_{x,y}(0) \). Similarly, choose \( Y_{2,1} = \dot{\gamma}_{y,x}(0) \) and \( Y_{2,2} = \xi_2 = m_{x,y} \xi_1 \), or, in simpler terms, the parallel transport of \( \xi_1 \) along the
geodesic $\gamma_{x,y}$. With these choices, the generator simplifies to
\[
\mathcal{L} = \frac{a^2}{2}\Delta_x + \frac{b^2}{2}\Delta_y + \frac{a^2 + \alpha^2}{2}\partial_{\rho_1}^2 + \frac{b^2 + \tilde{\alpha}^2}{2}\partial_{\rho_2}^2 + ab(\gamma_{x,y}(0)\dot{\gamma}_{y,x}(0) + \xi_1\xi_2)
\]
(54)

The first property we want to see is that $\rho_1 + \rho_2 = \rho$. This property is nothing but the geometric picture that $\rho_1$ is the distance from $z_\tau$ to $x_\tau$ while $\rho_2$ is the distance between $z_\tau$ to $y_\tau$.

To do this we recall that the distance $\rho$ is the distance from $1$ to $\gamma(0)$, which is what we want. □

Furthermore a simple integration by part gives that $\beta$ is the Jacobi field along the geodesic $\gamma$ with $\tilde{\beta}$ is the index form of the Jacobi field $J$ being the length of the geodesic $1$. It is clear now that we have
\[
\tilde{\beta}(\tau, x, y, \rho_1, \rho_2) = \frac{1}{2} \int_0^{\rho_1} \left( |\dot{J}(u)|^2 + \langle R(\dot{\gamma}(u), J(u))\dot{\gamma}(u), J(u) \rangle \right) du
\]
and
\[
\tilde{\beta}(\tau, x, y, \rho_1, \rho_2) = \frac{1}{2} \int_0^{l(\tau)} J(\gamma(0)) \left( |\dot{J}(u)|^2 + \langle R(\dot{\gamma}(u), J(u))\dot{\gamma}(u), J(u) \rangle \right) du
\]
where $J$ is the Jacobi field along the geodesic $\gamma$ from $x$ to $y$ and having values $aE$ at $0$ and $bE$ at $l(\gamma)$.

If in addition, $\rho_{1,0} = \rho_{2,0} = \rho_0/2$, then almost surely $\rho_\tau = \rho_{1,\tau} + \rho_{2,\tau}$.

Proof. Take $\tilde{\rho}_{1,\tau} = \rho_\tau - \rho_{2,\tau}$. It is clear now that we have
\[
d(\tilde{\rho}_{1,\tau} - \rho_{1,\tau}) = \int_0^{\tilde{\rho}_{1,\tau}} A(u) du - \int_0^{\rho_{1,\tau}} A(u) du
\]
with
\[
A(u) = \frac{1}{2} \left[ |\dot{J}(u)|^2 + \langle R(J(u), \dot{\gamma}(u))\dot{\gamma}(u), J(u) \rangle du \right].
\]
From here, the fact that $\tilde{\rho}_{1,0} = \rho_{1,0}$ (or $\tilde{\rho}_{1,0} - \rho_{1,0} = 0$) and standard application of Gronwall’s inequality leads to $\tilde{\rho}_{1,\tau} = \rho_{1,\tau}$, which is what we want.
We return now to the case where the curvature is constant and start with [11, Lemma 3.4] which says that

\[ R(X, Y)Z = -r(\langle X, Z \rangle Y - \langle Y, Z \rangle X). \]

We should point out that Do Carmo [11] takes the curvature to be given by the negative of the curvature we consider here, or for that matter other people as for instance [12]. Then the Jacobi field equation becomes

\[ \ddot{J} - R(\dot{\gamma}, J)\dot{\gamma} = 0 \]

or equivalently,

\[ \ddot{J} + rJ - r(\dot{\gamma}, J)\dot{\gamma} = 0. \]

Since this Jacobi field is perpendicular to the geodesic, it follows that

\[
\begin{cases}
\ddot{J} + rJ = 0 \\
J(0) = aE \\
J(l(\gamma)) = bE.
\end{cases}
\]

The solution is

\[ J(s) = (aw_1(s) + bw_2(s))E(s) \text{ for } s \in [0, l(\gamma)] \]

where \( w_1, w_2 \) are defined on the interval \([0, l(\gamma)]\) by the following odes

\[
\begin{cases}
\ddot{w}_1 + rw_1 = 0 \\
w_1(0) = 1 \\
w_1(l(\gamma)) = 0.
\end{cases}
\]

\[
\begin{cases}
\ddot{w}_2 + rw_2 = 0 \\
w_2(0) = 0 \\
w_2(l(\gamma)) = 1.
\end{cases}
\]

Combining now (56) and the Jacobi field just considered reveals that

\[
\int_0^s |\dot{J}(u)|^2 - \langle R(J(u), \dot{\gamma}(u))\dot{\gamma}(u), J(u) \rangle du = \int_0^s |\dot{J}(u)|^2 - r|J(u)|^2 du \\
= \langle \dot{J}(s), J(s) \rangle - \langle \dot{J}(0), J(0) \rangle = (aw_1(s) + bw_2(s))(aw_1(s) + bw_2(s)) - (aw_1(0) + bw_2(0))
\]

and

\[
\int_{l(\gamma)}^{l(\gamma)} |\dot{J}(u)|^2 - \langle R(J(u), \dot{\gamma}(u))\dot{\gamma}(u), J(u) \rangle du = \langle \dot{J}(l(\gamma)), J(l(\gamma)) \rangle - \langle \dot{J}(s), J(s) \rangle \\
= b(aw_1(l(\gamma)) + bw_2(l(\gamma))) - (aw_1(s) + bw_2(s))(aw_1(s) + bw_2(s)).
\]

A direct consequence of these formulae and the fact that \( w_2(s) = w_1(l(\gamma) - s) \), plus a few elementary manipulations, results in

\[
\int_{l(\gamma)}^{l(\gamma)} |\dot{J}(u)|^2 - \langle R(J(u), \dot{\gamma}(u))\dot{\gamma}(u), J(u) \rangle du = (bw_1(s) + aw_2(s))(bw_1(s) + aw_2(s)) - b(bw_1(0) + aw_2(0)).
\]

Summarizing, the choices of \( \beta \) and \( \tilde{\beta} \) from (57) in the case of constant curvature become more explicit as:

\[
\begin{cases}
\beta = \frac{1}{2} ((aw_1(p_1) + bw_2(p_1))(aw_1(p_1) + bw_2(p_1)) - a(aw_1(0) + bw_2(0))) \\
\tilde{\beta} = \frac{1}{2} ((bw_1(p_2) + aw_2(p_2))(bw_1(p_2) + aw_2(p_2)) - b(bw_1(0) + aw_2(0))).
\end{cases}
\]

It goes without saying that here \( a \) and \( b \) are evaluated at \((\tau, x, y, \rho_1, \rho_2)\).

We say that a function \( f(\tau, x, y, \rho_1, \rho_2) \) is symmetric in \( \rho_1 \) and \( \rho_2 \) if \( f(\tau, x, y, \rho_1, \rho_2) = f(\tau, x, y, \rho_2, \rho_1) \).

Before we move on to another property of the diffusion \((x, y, \rho_1, \rho_2)\), we close the discussion so far with the following property of the choices of \( \beta \) and \( \tilde{\beta} \) from (62):

If \( a \) and \( b \) are equal and symmetric in \( \rho_1 \) and \( \rho_2 \), then

\[ \beta(\tau, x, y, \rho_1, \rho_2) = \tilde{\beta}(\tau, x, y, \rho_2, \rho_1). \]

A symmetry which plays a crucial role in the Hessian estimates is the following.
Theorem 15. If, in equation (52), we take
\[
\begin{align*}
\alpha & \text{ and } \beta \text{ symmetric in } \rho_1 \text{ and } \rho_2 \\
b & = a \\
\tilde{\alpha} & = -\alpha \\
\beta(\tau, x, y, \rho_1, \rho_2) & = \beta(\tau, x, y, \rho_2, \rho_1) \\
\rho_{1,0} & = \rho_{2,0},
\end{align*}
\]
then the processes \((x, y, \rho_1, \rho_2)\) and \((x, y, \rho_2, \rho_1)\) have the same law. In particular, the processes \((x, y, \rho_1)\) and \((x, y, \rho_2)\) have the same law.

Proof. Although this is almost trivial, we say a word about it. If \(\mathcal{L}\) is the generator of a diffusion \(\omega,\tau\) on a manifold \(\mathcal{M}\) and \(\pi : \mathcal{M} \rightarrow \mathcal{M}\) is such that for any smooth function \(\varphi : \mathcal{M} \rightarrow \mathbb{R}\),
\[
\mathcal{L}(\varphi \circ \pi) = (\mathcal{L}\varphi) \circ \pi,
\]
then uniqueness of the diffusion implies that \(\omega\) and \(\pi(\omega)\) have the same law. This can be easily seen from the martingale characterization of the law of the diffusion. We apply this to the operator \(\mathcal{L}\) from (54) and the map \(\pi(x, y, \rho_1, \rho_2) = (x, y, \rho_2, \rho_1)\). The rest follows. \(\square\)

Notice that (cf. (62)), the choices of \(\beta\) and \(\tilde{\beta}\) from Theorem 14 are actually consistent with the conditions of Theorem 15 under the assumptions that \(a\) and \(b\) are equal and symmetric.

The “middle particle” process we are interested is
\[
z_\tau = \gamma_{x_\tau, y_\tau}(\rho_{1,\tau}).
\]

The symmetry between \(\rho_1\) and \(\rho_2\) should be interpreted as saying that the reflection of the process \(z_\tau\) with respect to the middle point of the geodesic \(\gamma_{x_\tau, y_\tau}\) has the same law as \(z_\tau\) itself.

Our next objective is the law of \(z_\tau\). Before we jump into the heart of the matter, we take up a discussion on the following class of vector fields that are the main actors in our computation.

Assume we have a geodesic \(\gamma\) from \(x\) to \(y\) with length \(l\) and consider a smooth, two-parameter geodesic perturbation \(f : (-\epsilon, \epsilon) \times (-\epsilon, \epsilon) \times [0, l] \rightarrow \mathcal{M}\) of \(\gamma\), i.e. \(f(0, 0, s) = \gamma(s)\) and for each fixed choice of \(u\) and \(v\), the curve \(s \rightarrow f(u, v, s)\) is a geodesic. One of the things we want to understand is the field
\[
\mathcal{H}(s) = \frac{D}{du} \frac{D}{dv} f(u, v, s)\bigg|_{u=0, v=0},
\]

Let \(J_v(s) = \frac{D}{dv} f(u, v, s)\bigg|_{u=0, v=0}\) be the Jacobi field obtained by differentiating \(f\) with respect to \(v\) and we will use \(J_v(u, s) = \frac{D}{dv} f(u, v, s)\bigg|_{u=0, v=0}\) as the Jacobi field which is still depending on \(u\). Similarly let \(J_u(s) = \frac{D}{du} f(u, v, s)\bigg|_{u=0, v=0}\) be the Jacobi field obtained by differentiating \(f\) with respect to \(u\) and use \(J_u(v, s) = \frac{D}{du} f(u, v, s)\bigg|_{u=0, v=0}\). In order to determine the equation satisfied by \(\mathcal{H}\), we recall here [11, Lemma 4.1], which asserts that for any two-parameter family \(g(a, b)\) and vector field \(V\) along \(g\),
\[
\frac{D}{da} \frac{D}{db} V - \frac{D}{db} \frac{D}{da} V = -R \left( \frac{Dg}{db}, \frac{Dg}{da} \right) V.
\]

Now, what we want to do is to find a differential equation satisfied by \(\mathcal{H}\). As pointed out already, \(\mathcal{H}(s) = \frac{D}{da} J_v(u, s)\bigg|_{u=0}\) and starting with (59) for \(J_v(u)\), namely,
\[
\frac{D^2}{ds^2} J_v(u) + r J_v(u) - r \langle \dot{\gamma}, J_v \rangle \dot{\gamma} = 0
\]
we take the derivative with respect to \(u\) at \(u = 0\) to arrive at
\[
\frac{D}{du} \frac{D^2}{ds^2} J_v + r \mathcal{H} - r \langle \frac{D}{du} \dot{\gamma}, J_v \rangle \dot{\gamma} - r \langle \dot{\gamma}, \mathcal{H} \rangle \dot{\gamma} - r \langle \dot{\gamma}, J_v \rangle \frac{D}{du} \dot{\gamma} = 0.
\]

To move forward, use that \(\frac{D}{da} \dot{\gamma}\bigg|_{u=0} = \frac{D}{ds} \frac{D}{da} \gamma\bigg|_{u=0} = \dot{J_u}\) to re-write the previous equation as
\[
\frac{D}{du} \frac{D^2}{ds^2} J_v + r \mathcal{H} - r \langle \mathcal{H}, \dot{\gamma} \rangle \dot{\gamma} - r \langle \dot{J_u}, J_v \rangle \dot{\gamma} - r \langle \dot{\gamma}, J_v \rangle \dot{J_u} = 0.
\]
Our task now is to commute the derivatives with respect to \(u\) and \(s\). For this, use (64) and (58) to justify that at \(u = 0\),

\[
\frac{D}{du} \frac{D^2}{ds^2} J_v = \frac{D}{ds} \frac{D}{du} \frac{D}{ds} J_v = R \left( \frac{Df}{ds}, \frac{Df}{du} \right) \right|_{u,v} = \frac{D}{ds} \frac{D}{du} \frac{D}{ds} J_v - R(\dot{\gamma}, J_u) \dot{J}_v
\]

\[(*)\]

and once again employing (64),

\[
\frac{D}{ds} \frac{D}{du} \frac{D}{ds} J_v = \frac{D}{ds^2} \frac{D^2}{du^2} J_v - \frac{D}{ds} \left( R \left( \frac{Df}{ds}, \frac{Df}{du} \right) \right) \right|_{u,v} = \ddot{\mathcal{H}} - \frac{D}{ds} \left( R(\dot{\gamma}, J_u) J_v \right)
\]

\[(**)\]

Putting together (*) and (**) we obtain

\[
\frac{D}{du} \frac{D^2}{ds^2} J_v = \ddot{\mathcal{H}} + r \frac{D}{ds} \left( \langle \dot{\gamma}, J_v \rangle J_u - \langle J_u, J_v \rangle \dot{\gamma} \right)
\]

and finally since the boundary conditions are pretty straightforward we get the following

\[
\begin{align*}
\mathcal{H}(0) & = \left. \frac{D}{du} \frac{D}{ds} f(u, v, 0) \right|_{u=v=0} \\
\mathcal{H}(l) & = \left. \frac{D}{du} \frac{D}{ds} f(u, v, l) \right|_{u=v=0}.
\end{align*}
\]

(65)

We discussed the case of a two-parameter perturbation of the geodesic \(\gamma\) in the form \(f(u, v, s)\) but exactly the same argument works also for the case where \(f(u, s)\) is a perturbation with geodesics of \(\gamma\), and we consider the field

\[
\mathcal{H}(s) = \left. \frac{D^2}{du^2} f(u, s) \right|_{u=0}.
\]

The main result from the argument above then gives that

\[
\begin{align*}
\ddot{\mathcal{H}} + r\dot{\mathcal{H}} - k\langle \dot{\gamma}, \dot{\gamma} \rangle \dot{\gamma} + 2r \langle \langle \dot{\gamma}, J_v \rangle J_u - \langle J_u, J_v \rangle \dot{\gamma}, \dot{\gamma} \rangle & = 0, \\
\mathcal{H}(0) & = \left. \frac{D^2}{du^2} f(u, 0) \right|_{v=0} \\
\mathcal{H}(l) & = \left. \frac{D^2}{du^2} f(u, l) \right|_{u=0}
\end{align*}
\]

with \(J_u(s) = \left. \frac{D}{du} f(u, s) \right|_{u=0}\).

The perturbation \(g(u, v, s)\) that will appear below is slightly different from the perturbation \(f(u, v, s)\) considered above. To describe it, take a unit speed geodesic \(\gamma\) defined on \([0, l]\) and consider two geodesic curves, \(\eta_{1,u}\) with \(\eta_{1,0} = \gamma(0)\) and another, \(\eta_{2,v}\) so that \(\eta_{2,0} = \gamma(l)\). Let \(f(u, v, \cdot)\) be the geodesic run at unit speed from \(\eta_{1,u}\) to \(\eta_{2,v}\). One problem immediately arising with this choice is that the parameter in the geodesic direction, namely \(s\), is no longer running in the interval \([0, l]\) and this is the reason we have to treat it separately. Consequently, the above calculations do not apply in the same way as they were carried out in the case of \(f(u, v, s)\).

To fix this, let’s denote by \(l(u, v)\), the length of the geodesic \(\gamma_{u,v} = \gamma_{\eta_{1,u},\eta_{2,v}}\) and reparametrize this geodesic such that it has constant speed equal to \(l(u, v)/l\). More precisely if \(\tilde{\gamma}_{u,v}\) is the reparametrized geodesic, then \(\gamma_{u,v}(s) = \gamma_{u,v}(sl/l(u, v))\). Now let \(f(u, v, s) = \tilde{\gamma}_{u,v}(s)\). Clearly now the parameter \(s\) for \(f(u, v, s)\) runs in the interval \([0, 1]\) and

\[
g(u, v, s) = f(u, v, sl/l(u, v)).
\]

Our interest is again in the understanding of the field \(\mathcal{K}(s) = \left. \frac{D}{du} \frac{D}{du} g(u, v, s) \right|_{u=v=0}\). We do this via the fact that \(f(u, v, s) = g(u, v, sl(u, v)/l)\) and upon differentiation with respect to \(u\) to get

\[
\left. \frac{D}{du} f(u, v, s) \right|_{u=v=0}
\]

Therefore, the above calculations do not apply in the same way as they were carried out in the case of \(f(u, v, s)\).
and from this and the first variation formula [12, Eq. (1.3) page 5] to get the relation between Jacobi field \( J_u^I \) generated by \( g \) and \( J_v^I \) as
\[
J_u^I(s) = J_u^0(s) + \frac{s}{l} (\dot{\eta}_{1,0}(s)) \dot{\gamma}(s).
\]
Similarly
\[
J_v^I(s) = J_v^0(s) - \frac{s}{l} (\dot{\eta}_{2,0}, \dot{\gamma}(l)) \dot{\gamma}(s).
\]
Now taking the derivative with respect to \( v \) in (67), set \( u = v = 0 \) to obtain
\[
\mathcal{H}(s) = \mathcal{K}(s) + \frac{s}{l} (\dot{\eta}_{2,0}, \dot{\gamma}(l)) J_v^0(s) - \frac{s}{l} (\dot{\eta}_{1,0}, \dot{\gamma}(0)) J_u^0(s) + s \left( \frac{d^2}{dv^2} l(u, v) \right) \bigg|_{u=v=0} \dot{\gamma}(s).
\]

The case of interest in the sequel is the case of geodesics \( \eta_{1,u} \) and \( \eta_{2,v} \) such that \( \dot{\eta}_{1,0} = E(0) \) and \( \dot{\eta}_{2,0}(l) = E(l) \). In this case, the second and the third terms vanish while the last term is computed using the second variation formula which is [12, Eq (1.14) page 20]. We also learn that \( J_u^0 = J_u^I \) and \( J_v^0 = J_v^I \) and the last term becomes
\[
\left( \frac{d^2}{dv} l(u, v) \right) \bigg|_{u=v=0} = \mathcal{I}(J_u^I, J_v^I) = \dot{w}_1(l) - \dot{w}_2(0)
\]
where in between we used a polarization argument for (56) together with (60) and (61). Thus we get
\[
\mathcal{K}(s) = \mathcal{H}(s) - \frac{s}{2l} (\dot{w}_1(l) - \dot{w}_2(0)) \dot{\gamma}(s).
\]

Another situation we encounter below is the following. Take \( \eta_{1,u} \) a geodesic starting at \( \dot{\gamma}(0) \) such that \( \dot{\eta}_{1,0} = E(0) \). Then we take \( g(u, s) \) to be the geodesic \( \gamma_u(s) \) run at unit speed from \( \eta_{1,u} \) to \( \dot{\gamma}(l) \). The field we are interested in is \( \mathcal{K}(s) = \frac{d^2}{du^2} g(u, s) \big|_{u=0} \). With a very similar argument we can show that
\[
\mathcal{K}(s) = \mathcal{H}(s) + \frac{s}{l} \dot{w}_1(0) \dot{\gamma}(s)
\]
where \( \mathcal{H}(s) = \frac{d^2}{du^2} g(u, sl/l(u)) \big|_{u=0} \) with \( l(u) \) being the length of the geodesic from \( \eta_{1,u} \) to \( \dot{\gamma}(l) \).

Similarly if we take \( \eta_{2,v} \) the geodesic starting at \( \dot{\gamma}(l) \), such that \( \dot{\eta}_{2,0} = E(l) \) and \( g(v, s) \) being the unit speed geodesic joining \( \eta_{2,v} \) to \( \dot{\gamma}(0) \), and \( \mathcal{K}(s) = \frac{d^2}{dv^2} g(v, s) \big|_{v=0} \) then
\[
\mathcal{K}(s) = \mathcal{H}(s) - \frac{s}{l} \dot{w}_2(l) \dot{\gamma}(s)
\]
with \( \mathcal{H}(s) = \frac{d^2}{dv^2} g(v, sl/l(v)) \big|_{v=0} \) and \( l(v) \) the length of the geodesic from \( \eta_{2,v} \) to \( \dot{\gamma}(0) \).

We are finally ready for the next result.

**Theorem 16.** Assume that
\[
\alpha(\tau, x, y, \rho_1, \rho_2) = a(\tau, x, y, \rho_1, \rho_2) w_1(\rho_1) + b(\tau, x, y, \rho_1, \rho_2) w_2(\rho_1)
\]
\[
\beta(\tau, x, y, \rho_1, \rho_2) = \beta(x, y, \rho_1, \rho_2)
\]
\[
+ \frac{\rho_1}{\rho} \left( \frac{a(\tau, x, y, \rho_1, \rho_2)^2 + b(\tau, x, y, \rho_1, \rho_2)^2}{2} \dot{w}_1(0) - a(\tau, x, y, \rho_1, \rho_2) b(\tau, x, y, \rho_1, \rho_2) \dot{w}_1(l) \right)
\]
\[
+ \frac{1}{l} \int_0^l \left( a(\tau, x, y, \rho_1, \rho_2) w_1(\sigma) + b(\tau, x, y, \rho_1, \rho_2) w_2(\sigma) \right)^2 d\sigma
\]
\[
- \frac{\rho_1}{l} \int_0^l a(\tau, x, y, \rho_1, \rho_2) w_1(\sigma) + b(\tau, x, y, \rho_1, \rho_2) w_2(\sigma)^2 d\sigma
\]
with \( w_1 \) and \( w_2 \) defined by (61). With these choices, the process \( z_\tau = \gamma_{x_\tau, y_\tau}(\rho_{1,\tau}) \) has the property that, for any smooth function \( \varphi \) on \( M \),
\[
\varphi(z_\tau) - \int_0^\tau \left( \frac{\alpha^2(u)}{2} [\Delta \varphi](z_u) + \beta(u) (\nabla \varphi(z_u), \dot{\gamma}_{x_\tau, y_\tau}(\rho_{1,u})) \right) du
\]
is a martingale with respect to the filtration generated by $W_1$, $W_2$, and $W_3$, where inside the integral, $\alpha(u)$ and $\theta(u)$ are shorthand for $\alpha$ and $\theta$ evaluated at $(u, x_u, \eta_u, \rho_{1,u}, \rho_{2,u})$. In other words, $z_x$ is a time-changed Brownian motion (with the time change given by $\alpha$) with a drift in the geodesic direction from $x_x$ to $y_x$.

**Proof.** The idea of the proof is to start with the generator of the diffusion $(x, y, \rho_1)$ and a function $\varphi$ and look at the process $\varphi(z_x)$. More precisely, we find the bounded variation part of this. It is clear that, in terms of the generator (54), we need to compute the action of each term of this expression on $\varphi(\gamma_x(s))$. Notice that the part which involves derivatives of $\rho_2$ simply drops out in this calculation.

For simplicity we will drop the dependence on $\tau, x$, and $y$ in the notation and let $l = d(x, y)$. Thus the geodesic $\gamma_{x,y}$ will appear as $\gamma$ if we do not prescribe otherwise. Let $E$ denote the parallel vector field along $\gamma$ which is obtained by parallel translation of $\xi_1$.

Before we start the proof, let us mention that all geodesics appearing in this proof are geodesics run at unit speed.

Now we take the terms one by one. Again for simplicity in writing, we use $s$ instead of $\rho_1$ as the parameter in the geodesic direction.

1. We write the Laplacian term as

$$
\Delta_x[\varphi(\gamma_x(s))] = \frac{d^2}{du^2} \varphi(\gamma_{1,u}, y(s)) + \frac{d^2}{du^2} \varphi(\gamma_{2,u}, y(s))
$$

where $\gamma_{1,u}$ and $\gamma_{2,u}$ are geodesics starting at $x$ and having derivatives given by $\dot{\gamma}_{1,u} = \dot{\gamma}_{x,y}(0)$ and $\dot{\gamma}_{2,u} = \xi_1$. Then we continue with

$$
\Delta_x[\varphi(\gamma_x(y(s))] = \langle \text{Hess} \varphi(\gamma(s)), \dot{\gamma}(s) \rangle + \langle \text{Hess} \varphi(\gamma(s)), J_1(s), J_1(s) \rangle + \langle \nabla \varphi(\gamma(s)), \frac{D^2}{du^2} \gamma_{1,u}, y(s) \rangle + \langle \nabla \varphi(\gamma(s)), \frac{D^2}{du^2} \gamma_{2,u}, y(s) \rangle
$$

where $J_1$ is the Jacobi field along $\gamma$ given by $J_1(s) = \frac{D^2}{du^2} \gamma_{1,u}, y(s)|_{u=0}$, which can also be characterized as the Jacobi field with the boundary conditions $J_1(0) = \xi_1$ and $J_1(l) = 0$ which is solves as $J_1(s) = w_1(s) E(s)$.

Now notice that the third term vanishes because $\gamma_{1,u}(s) = \gamma(s + u)$ and $\gamma$ is a geodesic. Next we look at $K(s) = \frac{D^2}{du^2} \gamma_{2,u}, y(s)|_{u=0}$. Using (69) we need to focus on finding $H$ now. Exploiting (66), the equation for $H$ becomes

$$
\begin{cases}
\dot{H} + rH - r \langle H, \dot{\gamma} \rangle \dot{\gamma} + 2r \left( \langle \dot{\gamma}, \dot{J} \rangle J_1 - 2 \langle J_1, \dot{J} \dot{\gamma} \rangle \right) = 0 \\
H(0) = 0 \\
H(l) = 0.
\end{cases}
$$

Notice here that the boundary conditions follow from the fact that $\gamma_{2,u}$ is a geodesic and that $\gamma_{2,u}(l(u)) = y$, where $l(u)$ is the length of the geodesic joining $\gamma_{2,u}$ and $y$.

Now, the Jacobi field $J_1$ is given by

$$
J_1(s) = w_1(s) E(s)
$$

and this in turn gives the equation of $H$ as

$$
\begin{cases}
\dot{H} + rH - r \langle H, \dot{\gamma} \rangle \dot{\gamma} + 4rw_1 \dot{w}_1 \dot{\gamma} = 0 \\
H(0) = 0 \\
H(l) = 0.
\end{cases}
$$

We solve this as

$$
H = w_{1,0} \dot{\gamma} \text{ with } w_{1,0}(s) = 2r \int_0^s w_1^2(\sigma)d\sigma - \frac{2sr}{l} \int_0^l w_1^2(\sigma)d\sigma.
$$
The conclusion is that

\[
\Delta_x[\varphi(x,y(s))] = (\nabla^2 \varphi(\gamma(s))) \dot{\gamma}(s), \quad \ddot{\gamma}(s) + w_1^2(s)(\nabla \varphi(\gamma(s))) E(s) + \left( w_{1,0}(s) + \frac{s}{l} \dot{w}_1(0) \right) \langle \nabla \varphi(\gamma(s)), \dot{\gamma}(s) \rangle.
\]

(2) In the same vein, with very few changes, we can treat the next term, which is the Laplacian \( \Delta_y \) applied to \( \varphi(\gamma(s)) \). To this end, take \( \eta_{1,u} \) a geodesic starting at \( y \) with initial speed given by \( \dot{\gamma}(l) \), and \( \eta_{2,u} \) a geodesic starting at \( y \) with initial speed \( \xi_2 = E(l) \) and write

\[
\Delta_y[\varphi(x,y(s))] = \frac{d^2}{du^2} \varphi(\eta_{1,u}(s)) + \frac{d^2}{du^2} \varphi(\eta_{2,u}(s)).
\]

Notice that \( \varphi(x, \eta_{1,u}(s)) = \varphi(s) \) for small \( u \) and thus the first derivative is 0. Thus we arrive at

\[
\Delta_y[\varphi(\gamma(s))] = \langle \nabla \varphi(\gamma(s)), J_2(s), J_2(s) \rangle + \left( \nabla \varphi(\gamma(s)), \frac{D^2}{du^2} \gamma_{x, \eta_{2,u}}(s) \right)_{u=0}
\]

where \( J_2 \) is the Jacobi field which is 0 at 0 and \( \xi_2 \) at \( l \) which is exactly solved by \( J_2(s) = w_2(s) E(s) \).

The second term in the equation above can be dealt with in a similar way to that outlined above for \( \Delta_x \). We skip the details and give the main result. From (70),

\[
\mathcal{K}(s) = \left. \frac{D^2}{du^2} \gamma_{x, \eta_{2,u}}(s) \right|_{u=0} = \mathcal{H} - \frac{s}{l} \dot{w}_2(l) \dot{\gamma}(s).
\]

From (66), the equation satisfied by \( \mathcal{H} \) (with \( w_2 \) given by (61)) is given by

\[
\begin{cases}
\dot{\mathcal{H}} + r \mathcal{H} - r \langle \dot{\mathcal{H}}, \dot{\gamma} \rangle \dot{\gamma} = 4r w_2 \dot{w}_2 \dot{\gamma} \\
\mathcal{H}(0) = 0, \\
\mathcal{H}(l) = 0,
\end{cases}
\]

which is solved for

\[
\mathcal{H} = w_{0,1} \dot{\gamma} \text{ with } w_{0,1}(s) = 2r \int_0^s w_2^2(\sigma) d\sigma - \frac{2sr}{l} \int_0^l w_2^2(\sigma) d\sigma.
\]

Then we have

\[
\Delta_y[\varphi(x,y(s))] = w^2_2(s)(\nabla \varphi(\gamma(s))) E(s), E(s) + \left( w_{0,1}(s) - \frac{s}{l} \dot{w}_2(0) \right) \langle \nabla \varphi(\gamma(s)), \dot{\gamma}(s) \rangle.
\]

(3) For the next term, matters are fairly simple. Namely, because we are differentiating with respect to the geodesic parameter \( s \),

\[
\partial_s^2[\varphi(\gamma(s))] = \langle \nabla \varphi(\gamma(s)) \dot{\gamma}(s), \dot{\gamma}(s) \rangle.
\]

(4) Next in line is

\[
\partial^2_s[\varphi(\gamma(s))](0) \dot{\gamma}_{y,x}(0)[\varphi(\gamma(s))] = 0
\]

because

\[
\dot{\gamma}_{y,x}(0)[\varphi(\gamma,y(s))] = 0,
\]

which follows from the fact that perturbing \( y \) along a curve \( \eta_{2,u} \) in the geodesic direction of \( \gamma_{x,y} \) yields that \( \gamma_{x, \eta_{2,u}}(s) = \gamma_{x,y}(s) \), and thus is independent of \( u \).

(5) Now we deal with

\[
\xi_1 \xi_2[\varphi(\gamma_{x,y}(s))].
\]

To this end, consider the geodesics \( \eta_{1,u} \) and \( \eta_{2,v} \) which start at \( x \) (respectively \( y \)) and have the initial tangent vectors \( \xi_1 \) (respectively \( \xi_2 \)). What we need to compute is

\[
\frac{D}{du} \frac{D}{dv} [\varphi(x,y(s))]_{u=v=0} = \langle \nabla \varphi(\gamma_{x,y}(s)) J_1(s), J_2(s) \rangle + \langle \nabla \varphi(\gamma_{x,y}(s)), \frac{D}{du} \frac{D}{dv} \gamma_{\eta_{1,u}, \eta_{2,v}}(s) \rangle_{u=v=0}
\]

with \( J_1 = w_1 E \) and \( J_2 = w_2 E \). If we let

\[
\mathcal{K}(s) = \left. \frac{D}{du} \frac{D}{dv} \gamma_{\eta_{1,u}, \eta_{2,v}}(s) \right|_{u=v=0},
\]

we have

\[
\mathcal{K}(s) = \left. \frac{D}{du} \frac{D}{dv} \gamma_{\eta_{1,u}, \eta_{2,v}}(s) \right|_{u=v=0}.
\]
from (68), we have \( K = H - \frac{s}{2l}(\dot{w}_1(l) - \dot{w}_2(0)) \tilde{\gamma}(s) \). Now, from (65), we obtain
\[
\begin{aligned}
\dot{H} + rH - r\langle H, \tilde{\gamma} \rangle \tilde{\gamma} &= 2r(\dot{w}_1 \dot{w}_2 + \dot{w}_2 \dot{w}_1) \\
H(0) &= 0 \\
H(l) &= 0,
\end{aligned}
\]
which we solve as
\[
H = w_{1,1} \tilde{\gamma} \quad \text{with} \quad w_{1,1}(s) = 2r \int_0^s w_1(\sigma)w_2(\sigma) d\sigma - \frac{2sr}{l} \int_0^l w_1(\sigma)w_2(\sigma) d\sigma.
\]
We conclude that
\[
\xi_1 \xi_2[\varphi(\gamma_{x,y}(s))] = w_1(s)w_2(s)\langle \text{Hess} \varphi(\gamma(s))E(s), E(s) \rangle + \left( w_{1,1}(s) - \frac{s}{2l}(\dot{w}_1(l) - \dot{w}_2(0)) \right) \langle \nabla \varphi(\gamma(s)), \tilde{\gamma}(s) \rangle.
\]
(6) Next is
\[
\dot{\gamma}_{x,y}(0) \partial_s[\varphi(\gamma_{x,y}(s))] = \dot{\gamma}(0) \langle \nabla \varphi(\gamma(s)), \dot{\gamma}(s) \rangle = \langle \text{Hess} \varphi(\gamma(s)) \dot{\gamma}(s), \dot{\gamma}(s) \rangle.
\]
(7) Now,
\[
\dot{\gamma}_{y,x}(0) \partial_s[\varphi(\gamma_{x,y}(s))] = 0,
\]
as can be easily seen from the fact that perturbing \( y \) in the geodesic direction (say, along \( \eta_0 \)) reveals that \( \gamma_{x,\eta_0}(s) = \gamma_{x,y}(s) \), and thus the derivative with respect to \( v \) vanishes.
(8) The last term is easy to deal with and gives
\[
\partial_s[\varphi(\gamma_{x,y}(s))] = \langle \nabla \varphi(\gamma(s)), \dot{\gamma}(s) \rangle.
\]
Putting together all the results from (75)-(84) and using that \( w_2(s) = w_1(l - s) \) we arrive at
\[
\mathcal{L}[\varphi(\gamma(s))] = \frac{\alpha^2}{2} (\text{Hess} \varphi(\gamma(s)) \dot{\gamma}(s), \dot{\gamma}(s)) + \frac{(aw_1(s) + bw_2(s))^2}{2} \langle \text{Hess} \varphi(\gamma(s))E(s), E(s) \rangle
\]
\[
+ \left( \beta + \frac{s^2}{l} \right) \left( \frac{a^2 + b^2}{2} \dot{w}_1(0) - ab \dot{w}_1(l) \right) + \frac{a^2 w_{1,0} + b^2 w_{0,1} + 2abw_{1,1}}{2} \langle \nabla \varphi(\gamma(s)), \dot{\gamma}(s) \rangle.
\]
A little simplification follows from
\[
a^2 w_{1,0} + b^2 w_{0,1} + 2abw_{1,1} = 2r \left( \int_0^s (a(s)w_1(\tau) + b(s)w_2(\tau))^2 d\tau - \frac{2s}{l} \int_0^l (a(s)w_1(\tau) + b(s)w_2(\tau))^2 d\tau \right)
\]
which then gives the result for the choice of \( \alpha \) as in (71).
\[\square\]
We close this section with the following result summarizing all of the important findings of this section which is used in the next section.

**Corollary 17.** Assume that the entries of (52) satisfy
\[
\begin{aligned}
a & \text{ is symmetric in } \rho_1 \text{ and } \rho_2 \\
b &= a \\
\tilde{\alpha} &= -\alpha \\
\alpha(\tau, x, y, \rho_1, \rho_2) &= a(\tau, x, y, \rho_1, \rho_2)w(\rho_1) \\
\beta(\tau, x, y, \rho_1, \rho_2) &= \frac{1}{2} a^2(\tau, x, y, \rho_1, \rho_2)(w(\rho_1)\dot{w}(\rho_1) - \dot{w}(0)) \\
\tilde{\beta}(\tau, x, y, \rho_1, \rho_2) &= \frac{1}{2} a^2(\tau, x, y, \rho_1, \rho_2)(w(\rho_2)\dot{w}(\rho_2) - \dot{w}(0)) \\
\rho_{1,0} &= \rho_{2,0} = \rho_0/2 \\
\end{aligned}
\]
Then
\[
(1) \ \rho_{1,\tau} + \rho_{2,\tau} = \rho_\tau \text{ almost surely.}
\]
(2) The diffusions \((x_\tau, y_\tau, \rho_{1,\tau}, \rho_{2,\tau})\) and \((x_\tau, y_\tau, \rho_{2,\tau}, \rho_{1,\tau})\) have the same law. In particular, \((x_\tau, y_\tau, \rho_{1,\tau})\) and \((x_\tau, y_\tau, \rho_{2,\tau})\) have the same law.
(3) If \( z_{t} = \gamma_{x_{t}, y_{t}}(\rho_{1, t}) \), then for any smooth function \( \varphi \) on \( M \),

\[
\varphi(z_{t}) - \int_{0}^{\tau} \left( \frac{\alpha^{2}(u)}{2} [\Delta \varphi](z_{u}) + \theta(u) \langle \nabla \varphi(z_{u}), \gamma_{x_{u}, y_{u}}(\rho_{1, u}) \rangle \right) du
\]

is a martingale with respect to the filtration generated by \( W_{1}, W_{2}, \) and \( W_{3} \), where

\[
\theta(\tau, x, y, \rho_{1}, \rho_{2}) = \beta(\tau, x, y, \rho_{1}, \rho_{2}) + a^{2}(\tau, x, y, \rho_{1}, \rho_{2}) \left( \frac{\rho_{1}}{d(x, y)} \dot{w}(0) + r \left( \int_{0}^{\rho_{1}} w^{2}(\sigma) d\sigma - \frac{\rho_{1}}{d(x, y)} \int_{0}^{d(x, y)} w^{2}(\sigma) d\sigma \right) \right).
\]

A word is in place here. The statement of Theorem 15 requires the symmetry of \( \alpha \) with respect to \( \rho_{1} \) and \( \rho_{2} \). This is not satisfied by the choice in (86) for arbitrary \( \rho_{1} \) and \( \rho_{2} \). However, because of the choice of \( \beta \) and \( \tilde{\beta} \) and Theorem 14, we know that (almost surely) \( \rho_{1, t} + \rho_{2, t} = \rho_{t} \). So it suffices to ensure the symmetry of \( \alpha \) and \( \tilde{\alpha} \) with respect to \( \rho_{1} \) and \( \rho_{2} \) only in the case that \( \rho_{1} + \rho_{2} = \rho = d(x, y) \), which follows from the fact that \( w(s) = w(d(x, y) - s) \) for \( s \in [0, d(x, y)] \).

For a given \( l \), the solution \( w \) to (86) is

\[
w(s) = \begin{cases} 
1, & r = 0 \\
\frac{\cosh((t-2s)/2)}{\cosh(t/2)}, & r = -1 \\
\frac{\cosh((t-2s)/2)}{\cosh(t/2)}, & r = 1.
\end{cases}
\]

In particular, if \( l \) is small enough, \( w(s) \) and all its derivatives stay bounded. In addition to this \( \dot{w}(0) = O(l) \), a property which will play an important role in the coming section. Thus, if \( a \) is a bounded function, then

\[
\sup_{\tau \in [0, d(x, y)]} \theta(\tau, x, y, \rho_{1}, \rho_{2}) = O(\rho_{1}).
\]

10. Estimates on the Hessian decay for \( \chi(M) \leq 0 \)

For Euler characteristic less than or equal to 0, we know that \( \bar{p}_{t} \) and \( \nabla \bar{p}_{t} \) decay exponentially fast. Our goal is now to extend this to the Hessian of \( \bar{p}_{t} \), resulting in the convergence of the metric to the constant curvature metric in \( C^{2} \). In particular, the curvature converges to a constant.

To estimate the Hessian decay, we proceed in a similar way to the estimation of the gradient, only that now we need to use the coupling procedure for three points rather than two.

Let us denote, for \( t > 0 \),

\[
H(t) = \sup_{x \in M} |\text{Hess } \bar{p}_{t}(x)|.
\]

What we want to show is that \( H(t) \) decays to 0 exponentially fast.

**Theorem 18.** For the case \( \chi(M) \leq 0 \), \( H(t) \) converges to 0 exponentially fast as \( t \to \infty \).

**Proof.** To begin with, notice that

\[
\langle \text{Hess } \bar{p}_{t}(z), \xi, \xi \rangle = \lim_{\rho_{0} \to 0} \frac{\bar{p}_{t}(\gamma(-\rho_{0})) - 2\bar{p}_{t}(z) + \bar{p}_{t}(\gamma(\rho_{0}))}{\rho_{0}^{2}}
\]

where \( \gamma \) is the unique geodesic passing through \( z \) and having the initial velocity given by \( \xi \). Thus, similarly to the case of the gradient estimate, we will use the three particle coupling to get a handle on the right-hand side of the above quantity, for sufficiently small \( \rho_{0} \).

For convenience, fix a time \( t > 0 \) and let \( s \in [0, 1 \wedge t] \). Pick two points \( x, y \in M \), with \( d(x, y) = \rho_{0} \) small enough, and let \( z \) be the middle point on the geodesic between \( x \) and \( y \) such that \( d(x, z) = d(y, z) = \rho_{0}/2 \). Consider the triple coupling described by (52) with the choices from Corollary 17. All the data there is completely described by the choice of the time change \( a \) of the processes \( x_{t} \) and \( y_{t} \). In this section we choose

\[
a(\tau, x, y, \rho_{1}, \rho_{2}) = \sqrt{2}e^{-\bar{p}_{t-\tau}(\lambda_{x, y})}
\]
where \( \lambda_{x,y} \) is the middle point on the geodesic between \( x \) and \( y \). This choice does not depend on \( \rho_1 \) or \( \rho_2 \), and consequently it is symmetric in \( \rho_1 \) and \( \rho_2 \), as required by Corollary 17. Other choices are possible for the argument here, but we stick with this one because it is symmetric with respect to \( x \) and \( y \) and makes some of the estimates look more natural.

Now, we consider \( \bar{p}_{t-\sigma}(z_\sigma) \), where \( z_\tau \) is defined in the previous section. Again invoking Corollary 17, we learn that
\[
d\bar{p}_{t-\tau}(z_\tau) = M_{1,\tau} + \left( -\partial_t \bar{p}_{t-\tau}(z_\tau) + \frac{\alpha^2(\tau)}{2}\Delta \bar{p}_{t-\tau}(z_\tau) + \theta(\tau)\langle \nabla \bar{p}_{t-\tau}(\tau), \dot{\gamma}_\tau \rangle \right) d\tau.
\]
where \( M_{1,\tau} \) is a martingale. From the Ricci flow equation, \( \partial_t \bar{p}_{t-\tau}(z_\tau) = e^{-2\bar{p}_{t-\tau}(z_\tau)} \Delta \bar{p}_{t-\tau}(z_\tau) + r(1 - e^{-2\bar{p}_{t-\tau}(z_\tau)}) \) so we continue with
\[
d\bar{p}_{t-\tau}(z_\tau) = M_{1,\tau} + \left( \frac{\alpha^2(\tau)}{2} - e^{-2\bar{p}_{t-\tau}(z_\tau)} \right) \Delta \bar{p}_{t-\tau}(z_\tau) + \theta(\tau)\langle \nabla \bar{p}_{t-\tau}(\tau), \dot{\gamma}_\tau \rangle - r(1 - e^{-2\bar{p}_{t-\tau}(z_\tau)}) d\tau.
\]
For the semimartingale \( \bar{p}_{t-\tau}(x_\tau) \) we have from (52) and the Ricci flow equation that
\[
d\bar{p}_{t-\tau}(x_\tau) = M_{2,\tau} + \left( e^{-2\bar{p}_{t-\tau}(\lambda_\tau)} - e^{-2\bar{p}_{t-\tau}(x_\tau)} \right) \Delta \bar{p}_{t-\tau}(x_\tau) - r(1 - e^{-2\bar{p}_{t-\tau}(x_\tau)}) d\tau
\]
where \( \lambda_\tau \) is the middle point of the geodesics joining \( x_\tau \) and \( y_\tau \). Similarly for \( \bar{p}_{t-\tau}(y_\tau) \),
\[
d\bar{p}_{t-\tau}(y_\tau) = M_{3,\tau} + \left( e^{-2\bar{p}_{t-\tau}(\lambda_\tau)} - e^{-2\bar{p}_{t-\tau}(y_\tau)} \right) \Delta \bar{p}_{t-\tau}(y_\tau) - r(1 - e^{-2\bar{p}_{t-\tau}(y_\tau)}) d\tau.
\]
Now, putting these together,
\[
\bar{p}_{t-\tau}(x_\tau) - 2\bar{p}_{t-\tau}(z_\tau) + \bar{p}_{t-\tau}(y_\tau) = \bar{p}_t(x) - 2\bar{p}_t(z) + \bar{p}_t(y) + M_\tau
\]
\[
+ \int_0^\tau \left( \frac{\alpha^2(u)}{2} - e^{-2\bar{p}_{t-u}(z_u)} \right) \Delta \bar{p}_{t-u}(z_u) \, du
\]
\[
+ \int_0^\tau \theta(u) \langle \nabla \bar{p}_{t-u}(u), \dot{\gamma}_u \rangle du
\]
\[
+ \int_0^\tau \left( e^{-2\bar{p}_{t-u}(\lambda_u)} - e^{-2\bar{p}_{t-u}(x_u)} \right) \Delta \bar{p}_{t-u}(x_u) + \left( e^{-2\bar{p}_{t-u}(\lambda_u)} - e^{-2\bar{p}_{t-u}(y_u)} \right) \Delta \bar{p}_{t-u}(y_u) \, du
\]
\[
+ r \int_0^\tau \left( e^{-2\bar{p}_{t-u}(x_u)} - e^{-2\bar{p}_{t-u}(z_u)} + e^{-2\bar{p}_{t-u}(y_u)} \right) du
\]
where \( M_\tau \) is a martingale.

From the definition of \( \alpha \) in Corollary 17 and the fact that we stop the processes before the distance between \( x \) and \( y \) hits some small number \( r_0 \), it is not hard to prove (for instance directly from (88)) that there is a constant \( C > 0 \) such that
\[
|\alpha(u) - a(u)| \leq C\rho_u,
\]
which in turn, using the gradient decay estimates and the fact that \( d(z_u, \lambda_u) \leq d(x_u, y_u)/2 = \rho_u/2 \), leads to
\[
\left| \frac{\alpha^2(u)}{2} - e^{-2\bar{p}_{t-u}(z_u)} \right| \leq C\rho_u + \left| e^{-2\bar{p}_{t-u}(z_u)} - e^{-2\bar{p}_{t-u}(\lambda_u)} \right| \leq C\rho_u^2 + C e^{-Ct} \rho_u \leq C\rho_u.
\]
Observe here that we do not need the full power of the exponential decay of the gradient; just the boundedness suffices for this particular estimate, but used in conjunction with (89), for any \( u \in [0, 1 \wedge t] \),
\[
|\theta(u) \langle \nabla \bar{p}_{t-u}(z_u), \dot{\gamma}_u \rangle| \leq c\rho_u e^{-Ct}.
\]
Finally, from the exponential decay of the gradient and elementary arguments, as long as \( u \in [0, 1 \wedge t] \),
\[
\left| e^{-2\bar{p}_{t-u}(x_u)} - e^{-2\bar{p}_{t-u}(z_u)} \right| + \left| e^{-2\bar{p}_{t-u}(y_u)} - e^{-2\bar{p}_{t-u}(z_u)} \right| \leq c\rho_u e^{-Ct}
\]
and also
\[
\left| e^{-2\bar{p}_{t-u}(x_u)} - e^{-2\bar{p}_{t-u}(\lambda_u)} \right| + \left| e^{-2\bar{p}_{t-u}(y_u)} - e^{-2\bar{p}_{t-u}(\lambda_u)} \right| \leq c\rho_u e^{-Ct}.
\]
Now, let \( \sigma \) be the first time \( u \) when \( \rho_{1,u} \) or \( \rho_{2,u} \) becomes 0, and let \( \zeta \) be the first time \( u \) when either \( \rho_{1,u} \) or \( \rho_{2,u} \) hits \( r_0 \), a small number (less than half of the injectivity radius). Replacing \( \tau \) by \( \tau \wedge \sigma \wedge \zeta \) in (95) and then taking the expectation at \( \tau = 0 \) and \( \tau = s \), combined with the above estimates, lead to
\[
|\bar{p}_t(x) - 2\bar{p}_t(z) + \bar{p}_t(y)| \leq |E[\bar{p}_{t-s\wedge\zeta}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s\wedge\zeta}(z_{s\wedge\zeta}) + \bar{p}_{t-s\wedge\zeta}(y_{s\wedge\zeta})]| \\
+ ce^{-Ct}E \left( \int_0^{s\wedge\zeta} \rho_u du \right) + cE \left( \int_0^{s\wedge\zeta} \rho_u H(t-u) du \right)
\] (96)
for any \( s \in [0, 1 \land t] \).

Next, the stopping time \( \sigma \) is \( T_1 \land T_2 \), where \( T_1 \) and \( T_2 \) are, respectively, the first time \( \rho_1 \) hits 0 and the first time \( \rho_2 \) hits 0. Now we can write
\[
E[\bar{p}_{t-s\wedge\zeta}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s\wedge\zeta}(z_{s\wedge\zeta}) + \bar{p}_{t-s\wedge\zeta}(y_{s\wedge\zeta})] \\
= E[\bar{p}_{t-s\wedge\zeta}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s\wedge\zeta}(z_{s\wedge\zeta}) + \bar{p}_{t-s\wedge\zeta}(y_{s\wedge\zeta})], \zeta < \sigma] \\
+ E[\bar{p}_{t-s\wedge\zeta}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s\wedge\zeta}(z_{s\wedge\zeta}) + \bar{p}_{t-s\wedge\zeta}(y_{s\wedge\zeta})], \sigma \leq \zeta]
\] (97)
\[
\leq E[\bar{p}_{t-s\wedge\zeta}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s\wedge\zeta}(z_{s\wedge\zeta}) + \bar{p}_{t-s\wedge\zeta}(y_{s\wedge\zeta})], \zeta < \sigma] \\
+ E[\bar{p}_{t-s}(x_{s\wedge\zeta}) - \bar{p}_{t-s}(z_{s\wedge\zeta}) + \bar{p}_{t-s}(y_{s\wedge\zeta}), \sigma \leq \zeta].
\]

Here we bear to fruit the work done in the previous section and argue that due to the symmetry with respect to \( \rho_1 \) and \( \rho_2 \) from Corollary 17, we have the crucial cancellations
\[
E[\bar{p}_{t-s\wedge\zeta}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s\wedge\zeta}(z_{s\wedge\zeta}) + \bar{p}_{t-s\wedge\zeta}(y_{s\wedge\zeta})], \zeta < \sigma] \\
+ E[\bar{p}_{t-s}(x_{s\wedge\zeta}) - \bar{p}_{t-s}(z_{s\wedge\zeta}) + \bar{p}_{t-s}(y_{s\wedge\zeta}), \sigma \leq \zeta] = 0
\] (98)
and also
\[
E[\bar{p}_{t-s\wedge\zeta}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s\wedge\zeta}(z_{s\wedge\zeta}) + \bar{p}_{t-s\wedge\zeta}(y_{s\wedge\zeta})], T_1 < T_2 \leq s \land \zeta] + E[\bar{p}_{t-T_1}(x_{T_1}) - \bar{p}_{t-T_2}(y_{T_2}), T_2 < T_1 \leq s \land \zeta] \\
+ E[\bar{p}_{t-T_1}(y_{T_1}) - \bar{p}_{t-T_2}(x_{T_2}), T_2 \leq s \land \zeta < T_1] + E[\bar{p}_{t-T_2}(x_{T_2}) - \bar{p}_{t-T_2}(y_{T_2}), T_2 \leq s \land \zeta < T_1] = 0.
\] (99)

Furthermore, from the exponential decay of \( \bar{p} \) and \( \nabla \bar{p} \), for any \( s \in [0, 1 \land t] \) we have
\[
|E[\bar{p}_{t-s\wedge\zeta}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s\wedge\zeta}(z_{s\wedge\zeta}) + \bar{p}_{t-s\wedge\zeta}(y_{s\wedge\zeta})], \zeta < \sigma] + E[|\bar{p}_{t-s}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s}(z_{s\wedge\zeta}) + \bar{p}_{t-s}(y_{s\wedge\zeta}), s \leq \sigma \leq \zeta] \\
\leq e^{-Ct}\mathbb{P}(\zeta \leq s \land \sigma) + ce^{-Ct}E[\rho_s, s \leq \sigma \land \zeta],
\]
where we used the following inequalities
\[
|E[\bar{p}_{t-s\wedge\zeta}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s\wedge\zeta}(z_{s\wedge\zeta}) + \bar{p}_{t-s\wedge\zeta}(y_{s\wedge\zeta})], \zeta < \sigma]| \\
\leq E[|\bar{p}_{t-s}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s}(z_{s\wedge\zeta}) + \bar{p}_{t-s}(y_{s\wedge\zeta})|, s < \zeta < \sigma] + E[|\bar{p}_{t-s}(x_{s\wedge\zeta}) - 2\bar{p}_{t-s}(z_{s\wedge\zeta}) + \bar{p}_{t-s}(y_{s\wedge\zeta})|, s \leq \zeta \land \sigma] \\
\leq ce^{-Ct}E[\rho_s, s < \sigma \land \zeta] + ce^{-Ct}\mathbb{P}(\zeta \leq s \land \sigma).
\]
Putting these together into (96), plus a little simplification, gives that for any \( s \in [0, 1 \land t] \)
\[
|\bar{p}_t(x) - 2\bar{p}_t(z) + \bar{p}_t(y)| \leq ce^{-Ct}\mathbb{P}(\zeta < s \land \sigma) + ce^{-Ct}E[\rho_s, s \leq \sigma \land \zeta] \\
+ ce^{-Ct} \int_0^s E[\rho_{u}, u \leq \sigma \land \zeta] du + c \int_0^s H(t-u)E[\rho_{u}, u \leq \sigma \land \zeta] du.
\]
A further simplification is due to the symmetry with respect to \( \rho_1 \) and \( \rho_2 \) from Corollary 17, which has the effect that
\[
E[\rho_{u}, u < \sigma \land \zeta] = 2E[\rho_{1,u}, u < \sigma \land \zeta],
\]
and thus for \( s \in [0, 1 \land t] \),
\[
|\bar{p}_t(x) - 2\bar{p}_t(z) + \bar{p}_t(y)| \leq Ce^{-Ct}\mathbb{P}(\zeta < s \land \sigma) + Ce^{-Ct}E[\rho_{1,u}, s < \sigma \land \zeta] \\
+ e^{-Ct} \int_0^s E[\rho_{1,u}, u < \sigma \land \zeta] du + C \int_0^s H(t-u)E[\rho_{1,u}, u < \sigma \land \zeta] du.
\] (100)
The key step forward is the following result.
Theorem 19. Let $W^1$, $W^2$, and $W^3$ be three independent, one-dimensional Brownian motions, and let $\tilde{\rho}_1$ and $\tilde{\rho}_2$ be two processes such that $\tilde{\rho}_{1,0} = \tilde{\rho}_{2,0} = \tilde{\rho}_0 > 0$ and

\begin{align}
\begin{cases}
    d\tilde{\rho}_{1,\tau} = (1 + O(\tilde{\rho}_1,\tau))(A_{x,\tau}dW^1_x + B_{x,\tau}dW^2_x) + (1 + O(\tilde{\rho}_1,\tau))dW^3_x + O(1)d\tau \\
    d\tilde{\rho}_{2,\tau} = (1 + O(\tilde{\rho}_2,\tau))(A_{x,\tau}dW^1_x + B_{x,\tau}dW^2_x) - (1 + O(\tilde{\rho}_2,\tau))dW^3_x + O(1)d\tau
\end{cases}
\end{align}

with $A^2_x + B^2_x = 1$.

Let $\tilde{\sigma}$ be the first hitting time of 0 for the process $\tilde{\rho}_1 \tilde{\rho}_2$ and $\tilde{\zeta}$ the first time either $\tilde{\rho}_1$ or $\tilde{\rho}_2$ hits some value $\tilde{r}_0$. Assume that (101) is valid for $\tau \in [0, \tilde{\sigma} \wedge \tilde{\zeta}]$, and in addition that for some constant $C > 0$

\begin{equation}
E[\tilde{\rho}_{2,s}, s < \tilde{\sigma} \wedge \tilde{\zeta}] \leq C E[\tilde{\rho}_{1,s}, s < \tilde{\sigma} \wedge \tilde{\zeta}] \text{ for all } s \in [0, 1 \wedge t].
\end{equation}

Then, there is a constant $C > 0$ such that, for all $s \in [0, 1 \wedge t]$ and sufficiently small $\tilde{\rho}_0 > 0$,

\begin{equation}
E[\tilde{\rho}_{1,s}, s < \tilde{\sigma} \wedge \tilde{\zeta}] \leq C \tilde{\rho}_0^2 / \sqrt{s}
\end{equation}

and

\begin{equation}
P(\tilde{\zeta} < s \wedge \bar{\sigma}) \leq C \tilde{\rho}_0^2.
\end{equation}

Proof. If we regard the process $(\tilde{\rho}_{1,\tau}, \tilde{\rho}_{2,\tau})$ as a process in the first quadrant, the equations in (101) tell us that near the axes the process is near $\sqrt{2}$ times a two dimensional Brownian motion which certainly satisfies both properties (103) and (104). Consequently, what we will do is to compare $E[\tilde{\rho}_{1,s}, s < \tilde{\sigma}]$ with the analogous quantity in which $\tilde{\rho}_1$ and $\tilde{\rho}_2$ run as independent Brownian motions.

In the simplest case in which $(\tilde{\rho}_1, \tilde{\rho}_2)$ is $\sqrt{2}$ times a planar Brownian motion started at $(\tilde{\rho}_0, \tilde{\rho}_0)$ the quantity $\mathbb{E}[f(\tilde{\rho}_{1,s}, \tilde{\rho}_{2,s}), s < \tilde{\sigma}]$ is simply $\varphi(s, \tilde{\rho}_0, \tilde{\rho}_0)$, with $\varphi$ being the solution to the following PDE on the upper-right quadrant $\Omega = \{(x, y) \in \mathbb{R}^2, x, y > 0\}$,

\begin{equation}
\begin{cases}
    \partial_t \varphi = \Delta \varphi \\
    \varphi(t, (x, y)) = 0, \quad (x, y) \in \partial \Omega \\
    \varphi(0, (x, y)) = f(x, y), \quad (x, y) \in \Omega.
\end{cases}
\end{equation}

This solution can be written in an explicit form in terms of the heat kernel, which we discuss now. On the half line, the heat kernel for the Laplacian with the Dirichlet boundary condition is given by

\[ h_t(x, y) = \frac{1}{\sqrt{4\pi t}} \left( e^{-\frac{(x-y)^2}{4t}} - e^{-\frac{(x+y)^2}{4t}} \right) \]

for all $x, y, t > 0$. On $\Omega$, the heat kernel with the Dirichlet boundary condition is simply

\[ h_t((x_1, x_2), (y_1, y_2)) = h_t(x_1, y_1) h_t(y_1, y_2). \]

Turning back to the PDE (105), the solution is given by

\[ \varphi(t, x, y) = \int_0^\infty \int_0^\infty h_t((x, y), (x_1, y_1)) f(x_1, y_1) dx_1 dy_1. \]

For the case we are most interested in, namely $f(x, y) = x$, the solution above can be computed as

\[ \varphi(s, x, y) = x \Phi \left( \frac{y}{\sqrt{s}} \right) \text{ with } \Phi(x) = \frac{1}{\sqrt{\pi}} \int_0^y e^{-u^2/4} du. \]

Now we go back to the system (101) and take $\varphi(s - \tau, \tilde{\rho}_{1,\tau}, \tilde{\rho}_{2,\tau})$ as a semimartingale which, from Itô’s formula and $\partial_t \varphi = \Delta \varphi$, becomes

\[ d\varphi(s - \tau, \tilde{\rho}_{1,\tau}, \tilde{\rho}_{2,\tau}) = \partial_x \varphi d\tilde{\rho}_{1,\tau} + \partial_y \varphi d\tilde{\rho}_{2,\tau} - \partial_t \varphi d\tau + \frac{1}{2} \partial^2_{xx} \varphi d\langle \tilde{\rho}_1 \rangle + \frac{1}{2} \partial^2_{yy} \varphi d\langle \tilde{\rho}_2 \rangle + \frac{1}{2} \partial^2_{xy} \varphi d\langle \tilde{\rho}_1, \tilde{\rho}_2 \rangle + O(1) \]

\[ = M_\tau + O(1) \Phi \left( \frac{\tilde{\rho}_{2,\tau}}{\sqrt{s - \tau}} \right) + \frac{\tilde{\rho}_{1,\tau}}{\sqrt{s - \tau}} \Phi' \left( \frac{\tilde{\rho}_{2,\tau}}{\sqrt{s - \tau}} \right) d\tau \\
+ \frac{\tilde{\rho}_{1,\tau} O(\tilde{\rho}_{2,\tau}) \Phi'' \left( \frac{\tilde{\rho}_{2,\tau}}{\sqrt{s - \tau}} \right)}{s - \tau} d\tau + \frac{O(\tilde{\rho}_{1,\tau} + \tilde{\rho}_{2,\tau}) \Phi' \left( \frac{\tilde{\rho}_{2,\tau}}{\sqrt{s - \tau}} \right)}{s - \tau} d\tau, \]
where $M_\tau$ is a martingale. Since $\Phi'$ and $y\Phi''(y)$ are bounded, we deduce that the drift in the above is bounded in absolute value by $\frac{C(\tilde{p}_{1,\tau}+\tilde{p}_{2,\tau})}{\sqrt{s-\tau}}$. Now replacing $\tau$ by $\tau \land \tilde{\sigma} \land \tilde{\zeta}$ and evaluating at $\tau = 0$ and $\tau = s$, we are led to

$$
\mathbb{E}[\tilde{p}_{1,s}, s < \tilde{\sigma} \land \tilde{\zeta}] \leq \mathbb{E}[\varphi(s - s \land \tilde{\sigma} \land \tilde{\zeta}, \tilde{p}_{1,s} \land \tilde{\sigma} \land \tilde{\zeta}, \tilde{p}_{2,s} \land \tilde{\sigma} \land \tilde{\zeta})] \leq \varphi(s, \tilde{p}_0, \tilde{p}_0) + C \mathbb{E} \left[ \int_0^{s \land \tilde{\sigma} \land \tilde{\zeta}} \frac{\tilde{p}_{1,\tau} + \tilde{p}_{2,\tau}}{\sqrt{s-\tau}} d\tau \right]
$$

Denote for simplicity $f(s) = \mathbb{E}[\tilde{p}_{1,s}, s < \tilde{\sigma} \land \tilde{\zeta}]$ and $g(s) = C\tilde{p}_0 \Phi \left( \frac{\tilde{p}_s}{\sqrt{s}} \right)$. Now condition (102) implies for all $s \in [0, 1 \land t]$ that

$$
f(s) \leq g(s) + C \int_0^s \frac{f(\tau)}{\sqrt{s - \tau}} d\tau.
$$

This functional inequality is interesting enough to be treated separately, and so we do this formally in the following result. Incidentally this also appears in renewal theory, but we were not able to pinpoint exactly this statement in the literature.

**Lemma 20.** Assume $f, g : [0, t] \to [0, \infty)$ are bounded, continuous functions such that for all $s \in [0, 1 \land t]$

$$
f(s) \leq g(s) + C \int_0^s \frac{f(\tau)}{\sqrt{s - \tau}} d\tau.
$$

If $g(s) \leq C\rho^2 / \sqrt{s}$ for all $s \in [0, 1 \land t]$, then

$$
f(s) \leq C\rho^2 / \sqrt{s} \text{ for all } s \in (0, 1 \land t].
$$

**Proof.** Rewrite (107) in the form

$$
f(s) \leq g(s) + C \int_0^s \frac{f(\tau)}{\sqrt{s - \tau}} d\tau = g(s) + C\sqrt{s} \int_0^1 \frac{f(sw)}{\sqrt{1 - w}} dw.
$$

Now introduce the random variable $W$ with density $\frac{1}{\sqrt{1 - w}}$ and observe that the right hand side of the above equation becomes $g(s) + C\sqrt{s} \mathbb{E}[f(sW)]$. Hence, the inequality at hand can be re-written as

$$
f(s) \leq g(s) + C\sqrt{s} \mathbb{E}[f(sW)].
$$

Iterating this inequality, one can prove that if we pick an iid sequence $W_1, W_2, \ldots$ with the same distribution as $W$, then for any $n \geq 1$,

$$
f(s) \leq \sum_{k=0}^{n} (C\sqrt{s})^k \mathbb{E}[\sqrt{W_1} \sqrt{W_1W_2} \cdots \sqrt{W_1W_2\cdots W_{k-1}} g(sW_1W_2\cdots W_k)]
$$

$$
+ (C\sqrt{s})^{n+1} \mathbb{E}[\sqrt{W_1} \sqrt{W_1W_2} \cdots \sqrt{W_1W_2\cdots W_{n+1}} f(sW_1W_2\cdots W_{n+1})].
$$

The random variable $W$ has moments

$$
\mathbb{E}[W^k] = \frac{\sqrt{\pi} \Gamma(k + 1)}{2\Gamma(k + 3/2)} \text{ for all } k > -1.
$$

Particularly important is the case of $k = -1/2$, so that $\frac{1}{\sqrt{W}}$ is integrable, and in fact $\mathbb{E}[1/\sqrt{W}] = \pi/2$. It is an elementary task to obtain from this that, for some constant $C > 0$,

$$
\mathbb{E}[W^k] \leq C/\sqrt{k} \text{ for all } k > 0.
$$

Since $g$ is bounded, the series

$$
\sum_{k=0}^{\infty} (C\sqrt{s})^k \mathbb{E}[\sqrt{W_1} \sqrt{W_1W_2} \cdots \sqrt{W_1W_2\cdots W_{k-1}} g(sW_1W_2\cdots W_k)]
$$
is absolutely convergent and \((C\sqrt{s})^n\mathbb{E}[\sqrt{W_1}\sqrt{W_2}\ldots\sqrt{W_{n+1}}f(sW_1\ldots W_{n+1})]\) goes to 0 as \(n \to \infty\). Consequently,

\[
f(s) \leq \sum_{k=0}^{\infty} (C\sqrt{s})^k \mathbb{E}[\sqrt{W_1}\sqrt{W_2}\ldots\sqrt{W_{k-1}}g(sW_1\ldots W_k)].
\]

If \(g(s) \leq C\rho^2/\sqrt{s}\), the above yields

\[
f(s) \leq C\rho^2 \sum_{k=0}^{\infty} (C\sqrt{s})^k \mathbb{E}\left[\frac{\sqrt{W_1}\sqrt{W_2}\ldots\sqrt{W_{k-1}}}{\sqrt{W_1}\ldots W_k}\right] = \frac{C\rho^2}{\sqrt{s}},
\]

where we used the decay of the moments of \(W\) together with the fact that \(1/\sqrt{W}\) is integrable to justify that the series is convergent.  

The rest of the proof of (103) follows now from Lemma 20. We now turn our attention to (104) and observe that, from (101), we easily obtain that

\[
d(\tilde{\rho}_1,\tilde{\rho}_2) = \tilde{\rho}_1 d\tilde{\rho}_2 + \tilde{\rho}_2 d\tilde{\rho}_1 + d(\tilde{\rho}_1,\tilde{\rho}_2)_\tau = dM_\tau + O(\tilde{\rho}_1 + \tilde{\rho}_2) d\tau
\]

with \(M_\tau\) a martingale. Using this at the times \(\tau = 0\) and \(\tau = s \wedge \tilde{\sigma} \wedge \tilde{\zeta}\) with \(0 \leq s \leq 1 \wedge t\) and integrating, we get

\[
\tilde{\rho}_0^2 \mathbb{P}(\tilde{\zeta} < s \wedge \tilde{\sigma}) \leq \mathbb{E}[\tilde{\rho}_{1,s\wedge\tilde{\sigma}\wedge\tilde{\zeta}} \tilde{\rho}_{2,s\wedge\tilde{\sigma}\wedge\tilde{\zeta}}] \leq \tilde{\rho}_0^2 + C \mathbb{E}\left[\int_0^s (\tilde{\rho}_{1,\tau} + \tilde{\rho}_{2,\tau}) d\tau \right]
\]

\[
\leq \tilde{\rho}_0^2 + C \int_0^s \mathbb{E}[\tilde{\rho}_{1,\tau} + \tilde{\rho}_{2,\tau}, \tau < \tilde{\sigma} \wedge \tilde{\zeta}] d\tau
\]

\[
\leq \tilde{\rho}_0^2 + C \int_0^s \tilde{\rho}_0^2 d\tau = C \tilde{\rho}_0^2.
\]

which is what we needed.  

Now we go back to (100). We cannot use Theorem 19 to conclude that \(\mathbb{E}[\rho_{1,s}, s < \sigma \wedge \zeta] \leq C\rho_0^2/\sqrt{s}\) because the equations satisfied by \(\rho_1\) and \(\rho_2\) are not of the form (101). However, if we take \(\tilde{\rho}_{1,s} = \rho_{1,s} e^{\tilde{\rho}_{1-s}(\lambda_s)}, \tilde{\rho}_{2,s} = \rho_{2,s} e^{\tilde{\rho}_{1-s}(\lambda_s)}\), then (52) and an application of It\'o's formula (followed by several rearrangements) show that \(\tilde{\rho}_1\) and \(\tilde{\rho}_2\) do satisfy (101). In addition, Corollary 17 combined with the fact that \(e^{\tilde{\rho}_{1-s}(\lambda_s)}\) is bounded shows that (102) is also satisfied. Therefore, according to Theorem 19, \(\mathbb{E}[\tilde{\rho}_{1,s}, s < \sigma \wedge \zeta] \leq C\rho_0^2/\sqrt{s}\) and this in turn implies

\[
\mathbb{E}[\rho_{1,s}, s < \sigma \wedge \zeta] \leq C\rho_0^2/\sqrt{s} \text{ and } \int_0^s \mathbb{E}[\rho_{1,u}, u < \sigma \wedge \zeta] du \leq C\rho_0^2 \sqrt{s}.
\]

Using the preceding in (100), we write the resulting equation as

\[
|\tilde{p}_t(x) - 2\tilde{p}_t(z) + \tilde{p}_t(y)| \leq c\rho_0 e^{-Ct} \sqrt{s} + c\rho_0 \int_0^s \frac{H(t-u)}{\sqrt{u}} du \quad \text{for any } s \in [0, 1 \wedge t].
\]

Now dividing both sides by \(\rho_0^2\) and then letting \(\rho_0\) tend to 0, we arrive at

\[
H(t) \leq c e^{-Ct} \sqrt{s} + c \int_0^s \frac{H(t-u)}{\sqrt{u}} du \quad \text{for any } s \in [0, 1 \wedge t].
\]

From here, the rest is taken care of by the following Lemma.

**Lemma 21.** If \(H : [0, \infty) \to [0, \infty)\) is a continuous function such that, for some constant \(C > 0\),

\[
H(t) \leq c \left( e^{-Ct} \sqrt{s} + \int_0^s \frac{H(t-u)}{\sqrt{u}} du \right), \quad 0 < s \leq 1 \wedge t,
\]
then there are constants \( k, K > 0 \) such that

\[
H(t) \leq Ke^{-kt} \quad \text{for all } t > 0.
\]

**Proof.** It suffices to concentrate on the case \( t \geq 1 \). The strategy is similar to the one for proving Lemma 12 with a few tweaks.

Let \( m_n = \sup_{t \in [n,n+1]} H(t) \) and \( M_n = \sup_{t \in [n-1,n+1]} H(t) \). Clearly, \( m_n \leq M_n \) and \( M_n \) is either \( m_n \) or \( m_{n-1} \).

Now, if we take the \( t \) which maximizes \( H(t) \) on \([n, n+1]\) and use \((108)\), we get that for some constant \( C > 0 \) and any \( s \in [0,1] \),

\[
m_n \leq c \left( \frac{e^{-Cn}}{\sqrt{s}} + \sqrt{s}M_n \right).
\]

We want to minimize the right hand side of the above expression over \( s \in [0,1] \). For any \( a, b > 0 \), the minimum of \( a/\sqrt{s} + b\sqrt{s} \) with \( s \in [0,1] \) is attained at \( \frac{a}{b} \land 1 \). Hence

\[
m_n \leq c \left( \frac{e^{-Cn}}{\sqrt{M_n} \land 1} + M_n \left( \frac{e^{-Cn}}{M_n \land 1} \right) \right).
\]

Now, for each given \( n \), we have one of the following two cases:

1. **Case: \( e^{-Cn/2} \leq M_n \).** This leads first to \( e^{-Cn}/M_n < e^{-Cn/2} < 1 \), and then to

   \[
m_n \leq 2ce^{-Cn/2} \sqrt{M_n} \leq 2ce^{-Cn/4} M_n.
   \]

   This is enough to conclude that for a large \( n_1 \) (for instance such that \( 2ce^{-Cn_1/4} < 1/2 \)) and \( n \geq n_1 \) one gets \( m_n \leq M_n/2 \), which means that we cannot have \( M_n = m_n \) unless \( m_n = m_{n-1} = 0 \). Hence \( M_n = m_{n-1} \), which in turn implies that for some \( k > 0 \)

   \[
m_n \leq e^{-k}m_{n-1} \text{ if } n \geq n_1.
   \]

2. **Case: \( M_n \leq e^{-Cn/2} \).** This already yields

\[
m_n \leq e^{-kn}.
\]

Notice that we can arrange the constant \( k > 0 \) to be the same in (*) and (**) simply by taking the smaller.

By combining (*) and (**), we can show that \( m_n \) decays exponentially fast. Indeed, if there is \( n_2 \geq n_1 \) for which the second alternative holds, then \( m_{n_2} \leq e^{-kn_2} \). Then an easy induction and use of both alternatives yields that \( m_n \leq e^{-kn} \) for all \( n \geq n_2 \). On the other hand, if there is no such \( n_2 \), that means the first alternative holds, and this means that \( m_n \leq m_{n-1}e^{-k} \) for all \( n \geq n_1 \). This then results in \( m_n \leq m_n e^{-k(n-n_1)} \) and thus the exponential decay follows again. \( \square \)

This completes the proof of Theorem 18. \( \square \)

11. \( C^k \) CONVERGENCE OF \( \bar{p} \) ON SURFACES WITH \( \chi(M) \leq 0 \)

In the previous two sections, using the same notation and assumptions, we proved there exists a constant \( C > 0 \) such that

\[
(109) \quad \sup_{x \in M} |\bar{p}_t(x)| + \sup_{x \in M} |\nabla \bar{p}_t(x)| + \sup_{x \in M} |\text{Hess} \bar{p}_t(x)| \leq ce^{-Ct} \text{ for all } t > 0.
\]

Alternatively stated, \( \bar{p} \) converges to 0 exponentially fast in the \( C^2 \)-norm. In particular, this proves that the metric \( g_t \) converges to the constant curvature metric \( h \) in the \( C^2 \)-topology, and thus the curvature of \( g_t \) converges uniformly to a constant.

We now complete our discussion of the convergence to the constant curvature metric by extending this to \( C^\infty \)-convergence. The culmination of the last several sections is the following Theorem.
Theorem 22. Let \( M \) be a smooth, compact surface with \( \chi(M) \leq 0 \), with a reference metric \( h \) of constant curvature 0 or \(-1\), and let \( g_0 \) be a smooth initial metric in the same conformal class as \( h \) and with the same area. Then if we let \( \tilde{p}_t \) for \( t \in [0, \infty) \) be the associated solution to the normalized Ricci flow (as given in equation \( (9) \)), we have that
\[
\tilde{p}_t \to 0 \quad \text{in} \quad C^\infty, \text{exponentially fast},
\]
in the sense that this convergence takes place exponentially fast in the \( C^k \)-norm for all positive integers \( k \). Stated differently, if \( g_t \) for \( t \in [0, \infty) \) is the family of solution metrics to the normalized Ricci flow (and so the metrics corresponding to \( \tilde{p}_t \)), then \( g_t \to h \) in \( C^\infty \), exponentially fast.

Proof. We start with the equation
\[
\partial_t \tilde{p} = e^{-2\tilde{p}} \Delta \tilde{p}_t + r(1 - e^{-2\tilde{p}}).
\]

Now we can assume, by induction, that all derivatives of \( \tilde{p}_t \) of order \( l \) with \( 0 \leq l \leq k - 1 \) decay to 0 exponentially fast as \( t \) goes to infinity. In light of the \( C^2 \)-convergence, we may assume that \( k \geq 3 \).

Taking the \( k \)th derivative \( \tilde{p}_t^{(k)} = \nabla^{(k)} \tilde{p}_t \), after commuting the Laplacian with the covariant derivative we obtain
\[
\partial_t \tilde{p}_t^{(k)} = e^{-2\tilde{p}} \Delta \tilde{p}_t^{(k)} + 2re^{-2\tilde{p}_t^{(k)}} + Q_t^{(k)}
\]
where \( Q_t^{(k)} \) depends on the lower order derivatives of \( \tilde{p}_t \), and thus we may assume by induction that for \( k \geq 2 \),
\[
|Q_t^{(k)}| \leq ce^{-Ct}.
\]

The idea now is to write a Feynman-Kac formula for the solution to \( (110) \) and get the estimates from this. Indeed, notice that if \( x_\sigma \) is the time changed Brownian motion starting at \( x \) which is defined by \( (12) \), then
\[
\exp \left( 2r \int_0^\sigma e^{-2\tilde{p}_t - u(x_u)du} \right) \mathcal{T}_u \tilde{p}_t^{(k)}(x_\sigma) + \exp \left( 2r \int_0^\sigma e^{-2\tilde{p}_t - v(x_v)dv} \right) \mathcal{T}_v Q_t^{(k)}(x_v)
\]
is a martingale, where \( T_u \) is the extension to tensors of the parallel transport (with respect to the underlying metric \( h \)) along the path \( x|_{[u,0]} \) from \( x_u \) to \( x_0 = x \). From the technical side this expression can be seen in a clear way by lifting the equation \( (110) \) to the orthonormal frame bundle, where the lift of \( \tilde{p}_t^{(k)} \) takes values in a tensor product space of a fixed 2-dimensional Euclidean space. This is standard in stochastic analysis and we do not belabor it.

One result of equation \( (112) \) is that evaluation at \( \sigma = 0 \) and \( \sigma = t \) yields
\[
\tilde{p}_t^{(k)}(x) \equiv \mathbb{E} \left[ \exp \left( 2r \int_0^t e^{-2\tilde{p}_t - u(x_u)du} \right) \mathcal{T}_u \tilde{p}_0^{(k)}(x_t) \right] + \mathbb{E} \left[ \int_0^t \exp \left( 2r \int_0^u e^{-2\tilde{p}_t - v(x_v)dv} \right) \mathcal{T}_v Q_t^{(k)}(x_v)du \right].
\]

Notice the first consequence of this, namely that \( |\tilde{p}_t^{(k)}| \) is bounded for \( r \leq 0 \) (which is the case under consideration). We consider separately the cases \( r = -1 \) and \( r = 0 \).

Case: \( r = -1 \). From the exponential decay of \( \tilde{p}_t \) and the induction hypothesis (the decay of \( Q_t^{(k)} \)) it is easy to see that
\[
|\tilde{p}_t^{(k)}(x)| \leq ce^{-Ct} \quad \text{for all} \quad t \geq 0,
\]
and thus the induction is done.

Case: \( r = 0 \). For the flat case, we still learn from \( (113) \) that \( \tilde{p}_t^{(k)}(x) \) is uniformly bounded in \( t \) and \( x \).

To finish the argument, we are going to use the coupling technique we already exploited for the gradient estimates. Start with a fixed point \( x_\in M \) and a unit vector \( \xi \), and write
\[
\tilde{p}_t^{k}(x)\xi = \nabla_\xi \tilde{p}_t^{(k-1)} = \lim_{h \to 0} \frac{T_h \tilde{p}_t^{(k-1)}(\gamma(h)) - \tilde{p}_t^{(k-1)}(x)}{h},
\]
where here $T_h$ is the parallel transport from $T_{\gamma(h)}$ to $T_x$ along the geodesic $\gamma$ started at $x$ with initial velocity $\xi$.

Now we use the martingale representation (112) with $k$ replaced by $(k - 1)$ to see that, for $x$ and $y$ close enough and $T$ the parallel transport from $T_y$ to $T_x$ along the minimizing geodesic,

$$
T_{P_{1-1}^{(k-1)}(y)} - T_{P_{1-1}^{(k-1)}(x)} = \mathbb{E} \left[ T T_{\sigma P_{1-\sigma}^{(k-1)}(y_\sigma)} - T_{\sigma P_{1-\sigma}^{(k-1)}(x_\sigma)} \right] - \mathbb{E} \left[ \int_0^\sigma \left( T T_u Q_{1-u}^{(k-1)}(y_u) - T_{u Q_{1-u}^{(k-1)}(x_u)} \right) du \right].
$$

Take $t \geq 1$ and let $\sigma$ be $1 \wedge \tau$ with $\tau$ the coupling time of $x_u$ and $y_u$ which run mirror coupled. Now, because the holonomy group is trivial, it follows that

$$
\mathbb{E} \left[ T_{1 \wedge \tau} P_{1-1}^{(k-1)}(y_{1 \wedge \tau}) - T_{1 \wedge \tau} P_{1-1}^{(k-1)}(x_{1 \wedge \tau}) \right] = \mathbb{E} \left[ T_{1} P_{1-1}^{(k-1)}(y_1) - T_{1} P_{1-1}^{(k-1)}(x_1), 1 < \tau \right].
$$

From this and the exponential decay of $\tilde{p}_t^{(k-1)}$ and $Q_t^{(k-1)}$, we have

$$
|T_{P_{1}^{(k-1)}(y)} - \tilde{p}_t^{(k-1)}(x)| \leq e^{-Ct} \mathbb{P}(1 < \tau) + e^{-Ct} \int_0^1 \mathbb{P}(u < \tau) du.
$$

Finally, using the estimate (51), we get

$$
|T_{\tilde{P}_t}^{(k-1)}(y) - \tilde{p}_t^{(k-1)}(x)| \leq e^{-Ct} d(x, y) + e^{-Ct} \int_0^1 \frac{d(x, y)}{\sqrt{u}} du = C e^{-Ct} d(x, y).
$$

Now taking $y = \gamma(h)$ and considering the limit as $h$ goes to 0 leads to

$$
|\tilde{P}_t^{(k)}(x) \xi| \leq C e^{-Ct}
$$

for any unit vector $\xi$, which implies the exponential convergence of $\tilde{P}_t^{(k)}$.

\section*{Acknowledgements}

We would like to express our true appreciation and gratitude for the scholarly, careful, pertinent and sharp remarks of the anonymous reviewers which transformed the present paper into a much better one.

The second author thanks Sergiu Moroianu for very useful discussions on the geometry of surfaces particularly enlightening being the uniformization of surfaces arguments from the manuscript [35].
