Summary Over-expression of erbB-2 is associated with shortened survival of patients with lung adenocarcinomas. We demonstrated that human lung epithelial cells, overexpressing erbB-2, formed tumours in nude mice only when high levels of transforming growth factor (TGF-\(\alpha\)) were produced (E6T cells). To define the role that TGF-\(\alpha\) production played in induction of tumorigenicity, a non-tumorigenic TGF-\(\alpha\)-negative clone of ErbB-2 overexpressing cells (E2 cells) was transfected with an expression vector for TGF-\(\alpha\) (E2\(\alpha\) cells). Transfected clones produced TGF-\(\alpha\) at 11–25% of the level produced by the E6T cell line. Tumorigenic E6T cells transfected with a TGF-\(\alpha\) antisense vector (E6TA cells) expressed only 6% of the TGF-\(\alpha\) level of the parental cells. Clones of E6T, E6TA, E2 and E2\(\alpha\) were inoculated into athymic nude mice to measure tumorigenic potential. E6T cells formed tumours with a 70% efficiency. E2, E6TA and E2\(\alpha\) cells failed to form tumours. The levels of EGFR were similar in non-tumorigenic E2 and tumorigenic E6T cells but higher in E2\(\alpha\) and E6TA cells, and ErbB-2 were greatly overexpressed in an E2\(\alpha\) clone. In vitro, ErbB-2 co-immunoprecipitated with EGFR in lysates of unstimulated E6T and E2\(\alpha\) TGF-\(\alpha\)-producing cells, indicating that the lower TGF-\(\alpha\) levels were sufficient to induce in vitro heterodimerization. These studies suggest that induction of the tumorigenic phenotype depends on achieving a threshold level of TGF-\(\alpha\) sufficient to activate downstream signalling by ErbB-2 containing active heterodimers.

Keywords: lung cancer; ErbB-2 receptors; transforming growth factor \(\alpha\)

Lung cancer is currently the leading cause of cancer deaths in many Western countries (Johnson, 1995). As most lung cancers arise in the epithelium of the bronchial tree, the study of bronchial epithelial cells and processes leading to their malignant conversion is of considerable interest. The role that erbB-2 plays in the transformation of bronchial epithelial cells is currently being assessed. Thirty per cent of non-small-cell lung cancers overexpress erbB-2 (Kern et al, 1990; Shi et al, 1994). Overexpression of normal erbB-2 has been linked to shortened survival in lung adenocarcinoma (Kern et al, 1992; 1994), suggesting that the expression of this proto-oncogene may contribute to tumour progression. High levels of ErbB-2 are also associated with intrinsic multiple drug resistance (Hancock et al, 1991) and increased metastatic potential (Yu et al, 1994). However, the mechanism by which overexpression of ErbB-2 may induce a transformed phenotype is not known.

Although in animal models erbB-2 was shown to cause tumorigenic conversion because of a single point mutation in the membrane-spanning region, such mutations are not observed in human tumours (DiFiore et al, 1987). Human epithelial cells have stringent requirements for cellular transformation; for example, Pierce et al (1991) demonstrated that introduction of a normal erbB-2 gene into immortalized human mammary epithelial cells by transfection conferred a growth advantage in vitro. However, these cells only sporadically produced tumours in nude mice. The additional genetic changes needed to elicit a fully tumorigenic phenotype in the presence of erbB-2 are not known.

The expression of other epidermal growth factor receptor (EGFR) family members and their ligands has been postulated to contribute to erbB-2-induced tumorigenicity. EGFR family members have been shown to form heterodimers, the paradigm being the heterodimerization of EGFR and ErbB-2 induced by EGFR ligands (King et al, 1988; Kokai et al, 1988). Overexpression of both EGFR and ErbB-2 is necessary to induce a tumorigenic phenotype in NR6 mouse fibroblasts (Kokai et al, 1989). EGFR ligands do not bind ErbB-2 directly, but cause EGFR-induced tyrosine phosphorylation of ErbB-2. The functional consequence of this interaction after EGF treatment appears to be the concomitant activation of the in vitro kinase activity of ErbB-2. In addition, kinase-deficient ErbB-2 proteins display a dominant negative mutant phenotype, inhibiting both normal EGFR function and cell transformation induced by the overexpressed EGFR (Qian et al, 1994). Studies using transgenic mice suggest that interactions of ErbB-2 and transforming growth factor (TGF-\(\alpha\)) may also play a role in induction of tumorigenicity. Transgenic strains expressing an EGFR-specific ligand, TGF-\(\alpha\) and wild-type ErbB-2 develop mammary tumours at an accelerated rate (Muller et al, 1996).

To examine malignant progression of human lung epithelial cells in a model system, erbB-2 was transfected into the immortalized
human lung epithelial BEAS-2B cell line (Noguchi et al, 1993). Clonal cell lines were screened for tumorigenicity. Only one of five tested clones was tumorigenic. This clone, B2BE6 (E6), expressed the EGFR ligand TGF-α as well as ErbB-2. Clones expressing equivalent levels of ErbB-2 and EGFR, but not TGF-α, failed to produce tumours. We, therefore, postulated that high TGF-α production induced heterodimerization of EGFR and ErbB-2, and that signalling pathways activated by this heterodimer contributed significantly to the development of the malignant phenotype.

To test this hypothesis, we manipulated TGF-α production of ErbB-2-overexpressing cells. Non-tumorigenic E2 cells were transfected with a sense expression vector for TGF-α, whereas tumorigenic E6 cells (E6T) were transfected with the same construct in the antisense orientation. E6T cells expressing TGF-α antisense showed a 94% reduction in TGF-α production and were no longer tumorigenic. However, E2 cells transfected with TGF-α in the sense orientation, produced only 9–26% as much TGF-α as E6T cells and were not tumorigenic. These results indicate that production of TGF-α contributes to the tumorigenic potential of these immortalized human bronchial epithelial cells. In addition, they suggest that expression of the characteristics required for malignant conversion may require high levels of TGF-α.

**MATERIALS AND METHODS**

**Cell culture**

The BEAS-2B cell line is a non-tumorigenic immortalized human bronchial epithelial cell line derived from the infection of normal human bronchial epithelial cells with SV40 adenovirus 12 hybrid virus. This cell line retains sensitivity to TGF-β induced squamous differentiation as well as other characteristics of human bronchial epithelial cells (Ke et al, 1988). It was grown in LHC-8 medium (Biofluids, Rockville, MD, USA) according to established protocols (Reddel et al, 1988).

The B2BE2 (E2) and B2BE6 derivatives were prepared by introducing a wild-type human c-erbB-2 expression vector into BEAS-2B cells, as previously described (Noguchi et al, 1993). The B2BE6TM17 cell line (here referred to as E6T) was derived from B2BE6 cells that had been passaged once in nude mice and recultured in vitro. These cells were shown to be derived from BEAS-2B by karyotypic analysis (Noguchi et al, 1993).

**Construction of the TGF-α mRNA retroviral expression vector**

Sense and antisense expression vectors for TGF-α were prepared by subcloning a 924-bp restriction fragment that contains the complete coding sequence for TGF-α (Jhappan et al, 1990) into the Xhol site of the pLTRneo vector (DiFiore et al, 1987). The neomycin resistance gene of pLTRneo was replaced by a Sall hygromycin resistance cassette. This cassette was generated in pSV2hygro (Southern and Berg, 1982), which contains a unique Sall site 5' of the hygromycin resistance gene. An XmnI–Hpal fragment from pSV2neo was inserted in place of the XmnI–Hpal fragment of pSV2hygro. This manoeuvre inserted a second Sall site 3' of the hygromycin resistance gene, generating the Sall hygromycin cassette, which could be exchanged for the Sall neomycin cassette, originating from pSV2neo, contained in pLTRneo (DiFiore, 1987).

**Transfection and subcloning**

To obtain TGF-α-producing E2 cells, cells were transfected with the TGF-α sense vector by DNA strontium phosphate co-precipitation as previously described (Noguchi et al, 1993). Mass cultures of hygromycin-resistant cells were frozen. They were later cloned by limiting dilution in 96-well plates and expanded into cell lines. The TGF-α antisense expression vector was introduced into E6T clones using Lipofectin (Gibco-BRL, Gaithersburg, MD, USA) according to the manufacturer’s protocol. Cells (1 × 10^6) were plated into 100-mm dishes and transfected with 10 μg of TGF-α cDNA cloned in the antisense direction. The cells were exposed to the Lipofectin–DNA mixture for 4 h. Two days after transfection, the vector containing cells were grown in LHC-8 media containing 3% chemically denatured serum (UBI, Lake Saranac, NY, USA) and hygromycin (200 μg ml⁻¹) (Sigma, St Louis, MO, USA). The cell culture medium was changed twice weekly. Transformed cells were cloned using cylinders 22 days after transfection and expanded into cell lines.

**Tumorigenicity assay**

Athymic nude mice were irradiated 24 h before inoculation with 3.5 Gy using a 60Co radiation source. Mice were inoculated subcutaneously in a single site with each of the cell lines tested (5 × 10⁶ cells per mouse) and were monitored weekly for tumour formation for 52 weeks or until sacrifice.

**TGF-α detection**

Media conditioned for 48 h by 70% confluent cell cultures in T75 flasks (2 × 10⁶ cells per flask) were concentrated tenfold using Centricon-3 filters (Amicon, Danvers, MA, USA). When media were collected, cells were trypsinized and counted, using a haemacytometer to determine the final cell number. The media were frozen at −20°C until the time of assay. The enzyme-linked immunosorbent assay (ELISA) was performed using a commercially available kit (Oncogene Science, Mineola, NY, USA) with a sensitivity of 50 pg ml⁻¹. TGF-α concentration was calculated as pg ml⁻¹ per million cells. Two independent experiments were performed. In each experiment, medium was collected from two separate cultures per cell line and ELISA values were measured in duplicate for each culture. The presence of membrane-associated TGF-α was determined by indirect immunofluorescence and FACS analysis. Cells were harvested using trypsin EDTA. Cells were incubated for 3 min at 4°C with 0.2 mM acetic acid, 0.5 mM sodium chloride pH 2.5 to remove secreted TGF-α bound to cell-surface receptors. Unfixed cells were labelled at 4°C for 1 h with a monoclonal antibody against human TGF-α (Ab-2, Oncogene Sci) and a fluorescein-labelled rabbit anti-mouse antibody (Sigma).

**Immunoblot analysis**

Cells were grown to 90% confluence in 100-mm² tissue culture dishes in LHC-8 media. The cells were starved for 4 h in LHC-8 basal medium without epidermal growth factor (EGF), (UBI, Lake Saranac, NY, USA) but supplemented with insulin (5 μg ml⁻¹), transferrin (5 μg ml⁻¹) and selenium (5 ng ml⁻¹) (Sigma). Sodium orthovanadate (100 μM) was added in the last hour of incubation. For stimulated samples, 15 min before lysis, cells were treated at 37°C with EGF (50 ng ml⁻¹) or TGF-α (20 ng ml⁻¹) (Gibco-BRL).
Cells were then washed three times with cold phosphate-buffered saline (PBS), lysed in RIPA (50 mM Tris, pH 7.4, 150 mM sodium chloride, 1% Triton X-100, 1% deoxycholic acid, sodium salt, 0.1% sodium dodecyl sulphate (SDS), 100 μg ml phenylmethylsulphonyl fluoride (PMSF), 1 μg ml-1 aprotinin, 1 mM dithiothreitol (DTT), 1 mM sodium orthovanadate) buffer for 10 min and scraped. The extracts were centrifuged at 16 000 g for 30 min at 4°C. For analyses of EGFR and ErbB-2, lysates (100 μg per sample) were resolved on 7.5% SDS gels. For immunoprecipitation, approximately 1 mg of lysate was incubated overnight with 1 μg of antibody to EGFR (antibody 528, Oncogene Science, Mineola, NY, USA) and 15 μl of protein A–protein G agarose (Oncogene Science). Immunoprecipitates were centrifuged at 7500 g for 20 min and then washed four times for 5 min each with PBS and 0.05% Tween-20. Beads were resuspended in 2 x sample buffer and heated at 95°C for 5 min. Supernatants were electrophoresed on 7.5% polyacrylamide gels and electrophoretically transferred to Immobilon-P membranes (Millipore, Bedford, MA, USA). Blots were stained with a 1:500 dilution of antibody to ErbB-2 (antibody 3 Oncogene Science), or a 1:500 dilution of antibody to EGFR (SC-03, Santa Cruz Laboratories, Santa Cruz, CA, USA). One to ten-thousandfold dilutions of appropriate secondary antibodies (Amersham, Arlington Heights, IL, USA) were used for detection. Blots were visualized using an enhanced chemiluminescence (ECL) kit and Hyperfilm (Amersham).

**RESULTS**

**Manipulation of TGF-α production in clonal isolates**

To evaluate the contribution of TGF-α production to tumorigenicity, cultures of non-tumorigenic E2 cells were transfected with the TGF-α sense expression vector (for construction, see Materials and methods), cloned by limiting dilution and expanded into cell lines (E2α cells). In addition, tumorigenic E6T cells were transfected with a TGF-α antisense vector and subcloned to produce the E6TA cell line. TGF-α protein levels in conditioned media were measured using a TGF-α-specific ELISA. Twelve TGF-α-sense transfected clones were isolated. Cells secreted between 22 and 62 pg TGF-α per ml per 10⁶ cells in 48 h. The TGF-α production of the five clones inoculated into nude mice is presented in Table 1. E6T cells, the tumorigenic line derived after passage in nude mice, produced 243 pg of TGF-α per ml per 10⁶ cells. Four clones of E6TA cells were also isolated. All clones secreted approximately 5% of the level of TGF-α as produced by E6T. The E6TA clone injected into nude mice showed a 94% reduction in TGF-α protein levels to 17 pg per ml per 10⁶ cells.

We then evaluated membrane-bound TGF-α from E6T, E2, E6TA and E2α 2B3 cells by indirect immunofluorescence and FACS analyses. Of 15 000 cells examined, no E2 or E6TA cells stained positive for TGF-α. In contrast, 8.1% and 18.9% of E2α and E6T cells, respectively, were TGF-α positive. Mean fluorescence per cell was approximately 5% greater for E6T than E2α cells.

**Tumorigenicity assay**

A representative sample of the transfected cell lines was tested for tumorigenic potential by s.c. inoculation in athymic nude mice. Table 1 compares TGF-α production and tumorigenicity. E6T cells expressed a relatively high tumorigenic potential with small (60 mm³) tumours first observed after a mean latency of 9 weeks in seven out of ten animals. All tumours continued to grow, reaching more than 2000 mm³ by 22 weeks. All tumours were examined morphologically and classified as adenocarcinomas with polygonal neoplastic cells lining cystic spaces. Cells from one experimental tumour were explanted and examined. Cells were of human origin as determined by karyotypic analysis. Cells were also examined by Western blot analysis. In contrast, no tumours were observed after 52 weeks in mice inoculated with 5 E2α cells or the E6T cells. The differences in tumours incidence of E6T cells and the E6TA, E2, or E2α clones were statistically significant at P ≤ 0.05 using Fisher’s exact test.

**EGFR and ErbB-2 status**

As the biological consequences of interactions of EGFR ligands with cells is dependent on the status of EGFR and ErbB-2, we examined levels of EGFR and ErbB-2 in clones that had been injected into nude mice. The data in Figure 1 indicate that roughly equivalent levels of EGFR were expressed in the non-tumorigenic, non-TGF-α-producing E2 and the tumorigenic E6T cells. EGFR expression was elevated at higher levels in the non-tumorigenic E2α clone (2B3) and the TGF-α antisense clone E6TA.

The levels of ErbB-2 were also examined by Western blot analysis (Figure 2) and were equivalent in the tumorigenic E6T, and non-tumorigenic E6TA and E2 cells. In contrast, the E2α cells (clone 2B3) greatly overexpressed erbB-2.

**Heterodimerization of EGFR with ErbB-2**

We previously postulated that chronic stimulation of EGFR by autocrine production of TGF-α in E6T cells led to heterodimerization of EGFR with ErbB-2 (Noguchi et al, 1993). To evaluate EGFR/ErbB-2 heterodimer formation, E2, E2α (clone 2B3), E6T and E6TA cells were starved and treated with EGF or TGF-α as described and then lysed and immunoprecipitated with antibody to EGFR. Immunoprecipitates were electrophoresed and immunoblotted with antibody to ErbB-2. As shown in Figure 3A, ErbB-2 was detected in immunoprecipitates of E6T in unstimulated E6T and E2α cells, but not unstimulated E2 and E6TA cells suggesting a requirement for TGF-α (Figure 3B). Incubation with exogenous TGF-α induced detectable association of ErbB-2 with EGFR in E2 and E6TA cells as expected (King et al, 1988).

### Table 1 Tumorigenicity of ErbB-2 transfected BEAS 2B cells in athymic nude mice

| Cell line | TGF-α (pg per 10⁶ cells) | Number of tumours | Number of mice |
|-----------|--------------------------|-------------------|----------------|
| E2        | 0.2 ± 0.2*               | 0/20              |                |
| E6T       | 243 ± 8                  | 7/10              |                |
| E6TA      | 17 ± 1                   | 0/10              |                |
| E2α transfectants | | | |
| E2α 1D4   | 36 ± 4                   | 0/10              |                |
| E2α 3A3   | 38 ± 6                   | 0/10              |                |
| E2α 1C5   | 27 ± 1                   | 0/10              |                |
| E2α 2B3   | 62 ± 7                   | 0/10              |                |
| E2α 1C3   | 22 ± 1                   | 0/10              |                |

*The number of tumours observed; mean ± s.d. (four wells).*

DISCUSSION

Overexpression of normal erbB-2 has been linked to shortened survival in lung adenocarcinoma (Kern et al., 1994), suggesting that the expression of this proto-oncogene may contribute to tumour progression. However, several studies (Pierce et al., 1991; Ciardello et al., 1992) indicate that additional genetic changes are necessary to elicit a fully tumorigenic phenotype in erbB-2 transfected human epithelial cells.

In an attempt to further understand this problem in the context of human lung adenocarcinoma, we examined the consequences of the overproduction of ErbB-2 in the T-antigen-expressing immortalized human bronchial epithelial cell line, BEAS-2B. We (Noguchi et al, 1993) had previously demonstrated that the tumorigenicity of clones of erbB-2 transfected cells did not correlate with the level of expression of ErbB-2. However, we observed that tumorigenic clones produced the EGFR ligand TGF-α. We postulated that interactions between TGF-α and EGFR could be important in inducing a malignant phenotype by heterodimerization and subsequent activation of ErbB-2.

To this end, we transfected tumorigenic TGF-α-producing cells (E6T) with an antisense vector that inhibited TGF-α production as demonstrated by immunoassays for the protein. Such cells were unable to produce tumours in nude mice. Conversely, non-tumorigenic, non-TGF-α-producing cells were transfected with an expression vector for TGF-α. Cells isolated after this transfection increased TGF-α production approximately 30-fold. However, this amount of TGF-α production was only 25% of that observed for the tumorigenic clone and these cells were non-tumorigenic (Table 1). These results suggest that a critical level of TGF-α is needed to induce tumour formation in vivo. As cell-surface-associated TGF-α has been shown to influence cell growth in a juxtacrine manner (Massague, 1990), cell lines were evaluated by FACS analysis after staining with anti-TGF-α antibody. No cellsurface TGF-α was detected on E2 or E6TA cells. In contrast, the mean level of fluorescence and the numbers of positive cells were greater for E6T than E2α or E6TA cells. High EGFR expression was noted in both clones of transfected cells. Whether the presence of high EGFR levels was due to the transfection procedure or random clonal variation is not known.

ErbB-2 levels were roughly equivalent in all clones, except the E2α clone 2B3. This line produced a very high level of ErbB-2 receptor. These data agree with our previous finding that the degree of overexpression of ErbB-2 did not correlate with tumorigenicity (Noguchi et al, 1993). The high degree of ErbB-2 expression in 2B3 may be typical of the E2 TGF-α transfected cells, or may be due to random clonal variation.

In the present study, we have demonstrated constitutive EGFR/ErbB-2 complexes in the TGF-α producing E6T and E2α clones. However, complexes were demonstrated in all cells tested in the presence of exogenous EGF and TGF-α, indicating that EGFR and ErbB-2 were capable of heterodimerizing in the presence of ligand. We hypothesized that the secretion of TGF-α in E6T cells induced constitutive heterodimer formation between EGFR and ErbB-2 and a change in configuration of ErbB-2. Stimulation of mitogenic pathways by this activated complex may have contributed to the development of a tumorigenic phenotype in E6T cells. Although in vitro heterodimerization of EGFR-ErbB-2 was observed in E2α cells, tumour formation was absent. The presence of EGFR-ErbB-2 heterodimers may not strictly correlate
with the tumorigenic phenotype as recently demonstrated by Muller et al. (1996) in transgenic mice bearing mammary tumours. In addition, neither the number of EGFR-ErbB-2 heterodimers nor their distribution was analysed in our study. These factors may also have contributed to the differential expression of the tumorigenic phenotype.

In this study, we did not examine downstream molecules in the EGFR-ErbB-2 signal transduction pathway. However, immunoblot analysis revealed that both EGFR and ErbB-2 were constitutively tyrosine phosphorylated in E2 and E6T cells. Constitutive tyrosine phosphorylation in the absence of ligand stimulation has been similarly noted in human breast cancer cell lines (Alimandi et al., 1995) and is thought to be due to overexpression of ErbB-2. These data are consistent with the possibility that different tyrosine residues may be phosphorylated and quantitatively different distributions of heterodimers and docking of downstream signalling molecules may occur in the different cell lines.

A very complex series of ligand–receptor interactions regulating the biological function of ErbB family receptors is emerging (Riese et al., 1995; Chen et al., 1996; Karunagaran et al., 1996). It is becoming clear that there exist ligand-dependent hierarchies of heterodimer formation among ErbB receptors in response to specific ligands that continue to be discovered (Carraway et al., 1997; Chang et al., 1997). Ligands specific for one receptor may activate other receptors to which they do not directly bind. We have demonstrated that all cell variants described in this report also express ErbB-3 and ErbB-4 (A Fernandes, in preparation). It is known that stimulation of EGFR by EGFR-specific ligands, such as amphiregulin, TGF-α and EGF, can activate both ErbB-3 (Kim et al., 1994) and Erb-4 (Tzahar et al., 1996). Thus, for example, it is possible that activation of ErbB-3 occurs only in tumorigenic cells with subsequent increased enzymatic activity of downstream signalling molecules, such as phosphatidylinositol 3-kinase, that are selectively and potently recruited by ErbB-3. Future work will evaluate these receptor interactions.

In summary, we have demonstrated that a high level of expression of TGF-α in ErbB-2-overexpressing human bronchial epithelial cell lines was necessary for the induction of the tumorigenic phenotype. The clonal cell lines E2 and E6T and their TGF-α derivatives should provide a model system for the study of heterodimeric signalling by ErbB family members in lung epithelium and the consequences of these signals for tumorigenic progression.
