Strength distribution of repeatedly broken chains

Received: date / Accepted: date

Abstract We determine the probability distribution of the breaking strength for chains of \(N\) links, which have been produced by repeatedly breaking a very long chain.

Keywords Fragmentation · Chain breaking

1 Introduction

Consider a chain assembled from \(N\) random links with independent, identically distributed breaking strengths \(x\), which have probability density \(\rho(x)\). It is easy to calculate the probability density \(\rho(x|N)\) for the strength of the chain being less than \(x\). In some contexts, however, the relevant question is a different one: what are the strengths of chain segments of length \(N\) which are obtained by repeatedly breaking a very long chain? Such chain segments are expected to be stronger than their randomly assembled counterparts, because they have been produced by a process which has eliminated the weakest links. Here we calculate the distribution of the strength of a chain segment of length \(N\) which has been produced by repeatedly breaking a very long chain, of length \(N'\), say. Specifically, we break the chain of length \(N'\) at its weakest link, then break each fragment at its weakest link and continue the process. We collect the links of length \(N\) produced by this process, and determine the probability density of their strengths, \(\rho^*(x|N)\). In this paper we obtain formulae which are precise asymptotic results for the limit where \(N \gg 1\).

The calculation of this distribution involves the use of prior information: we know that the chain segment of length \(N\) and breaking strength \(x\) was produced by breaking a longer and weaker chain, of length \(N_0\) and breaking strength \(x_0\). What makes the problem difficult is that the prior information, in the form of the values of \(N_0\) and \(x_0\), is itself uncertain. It is hard to solve this problem for the case of a chain which has previously been broken only once. In the case of a chain which has been broken...
many times, the distributions of \( x_0 \) and \( N_0 \) themselves depend on previous breakages. The problem appears to be very difficult when the chain has previously been broken many times.

We consider the case where the chain is very long, and we anticipate that there is an asymptotic form for the strength distribution which is independent of the initial length \( N \). We use a self-consistent calculation and obtain \( \rho^*(x|N) \) in closed form in terms of the cumulative strength distribution of an individual link, \( P(X) \), and the corresponding probability density \( \rho(x) = \frac{dP(x)}{dx} \):

\[
\rho^*(x|N) \sim N^3 \rho(x) \left[ \int_0^x dx_0 \rho(x_0)P(x_0) \right] \exp[-NP(x)] .
\] (1)

(We use \( A(N) \sim B(N) \) to mean that \( A(N) \) and \( B(N) \) are asymptotically equal in the limit as \( N \to \infty \).)

For comparison, the corresponding probability density for the strength of a randomly assembled chain is

\[
\rho(x|N) \sim N \rho(x) \exp[-NP(x)] .
\] (2)

Figure 1 shows the comparison between equation (1) and a histogram of data from a numerical simulation of the chain-breaking process, for a particular choice of link strength distribution \( \rho(x) \).

We were motivated to study this chain-breaking process because it models fragmentation process in which the distribution of strengths of fragments (rather than the distribution of fragment sizes) is the principal concern. We are not aware of any earlier investigations of the strength distribution of fragments. The chain-breaking process is of interest because it is a fundamental model for such processes, which has an explicit solution for the distribution \( \rho^*(x|N) \). The model also has direct application to the degradation of long chain polymers.

In section 2 we consider the distribution of the sizes of fragments of a repeatedly broken chain, and section 3 describes elementary results for randomly assembled chains. In section 4 these expressions are used to obtain a recursion for a sequence of distributions which are related to \( \rho^*(x|N) \). Finally section 5 shows how the limiting distribution of this sequence is obtained self-consistently, and used to derive equation (1) above.

2 Distribution of fragment sizes

First we discuss the distribution of sizes of chain fragments. After \( i \) steps of splitting the chain, we have \( 2^i \) fragments. Let \( W_i(N) \) be the number of segments of lengths \( N \) at step \( i \), and let us consider the case where these numbers are so large that it is sufficient to calculate expectation values and ignore the statistical fluctuations of \( W_i(N) \) (this assumption is valid in the limit as \( \mathcal{N} \to \infty \)). Using the fact...
that the position of the weakest link has equal probability to be at any site, these numbers satisfy a recursion relation
\[
W_{i+1}(N) = \sum_{M=N+1}^{\infty} \frac{2}{M-1} W_i(M).
\] (3)

Rather than following this iteration for a single chain being broken, it is easier to consider a steady state \(W(N)\), with destruction of one additional chain being initiated at each step. Thus we seek to solve
\[
W(N) = \sum_{M=N+1}^{\infty} \frac{2}{M-1} W(M).
\] (4)

We find \(W(N) \sim C/N^2\) for \(N \to \infty\) for some constant \(C\).

3 Strength of a random chain segment

By way of preparation we discuss elementary results on the distribution of strengths for a chain with completely random links. Let \(P(x|N)\) be the probability that a chain of length \(N\) breaks at a tension which is less than \(x\). For \(N = 1\), we have \(P(x|1) = P(x)\). The probability that a chain of \(N\) links is unbreakable at tension \(x\) is \(1 - P(x|N) = [1 - P(x)]^N\). In the limit where \(N \gg 1\), the power may be approximated by exponentiation: we find \(P(x|N) \sim 1 - \exp[-NP(x)]\) (which gives 2 upon differentiation).

We also require the conditional probability \(P_c(x|x_0, N)\) that a chain of length \(N\) breaks at tension \(x\) if we know that it is definitely not broken by a tension \(x_0\). In this case we know that the probability of the strength of an individual element being less than \(x\) is \([P(x) - P(x_0)]/[1 - P(x_0)]\), so that
\[
P_c(x|x_0, N) = 1 - \left[ \frac{P(x) - P(x_0)}{1 - P(x_0)} \right]^N
\] (5)
provided that \(x > x_0\) (and zero otherwise). When \(N \gg 1\), this may be approximated by
\[
P_c(x|x_0, N) \sim \left[1 - \exp(-N[P(x) - P(x_0)])\right] \Theta(x - x_0)
\] (6)
where \(\Theta(x)\) is the unit increasing step function (Heaviside function).

4 A recursion relation for probabilities of successive breaking tensions

Our objective is to obtain the probability density \(\rho^*(x|N)\) that a chain of length \(N\), which has been produced by repeatedly breaking a very long chain, has breaking strength \(x\).

We determine this distribution of strengths by calculating a related distribution. Consider the subdivision of the chain, starting from a very long chain of length \(N\). When this is repeatedly split, for convenience we always discuss the leftmost segment. At the \(i\)th stage of subdivision, this segment having length \(N_i\) is produced by breaking a link of strength \(x_i\). Let the probability density for the strength of this broken link be \(\rho_i(x_i|N_i)\). The corresponding probability for the \(i\)th split to occur at a tension less than \(x_i\) for a segment of length \(N_i\) is \(P(x_i|N_i)\). We shall obtain a recursion formula which expresses \(\rho_{i+1}(x_{i+1}, N_{i+1})\) in terms of this distribution. The chain fragment at stage \(i + 1\) is produced by breaking a segment of length \(N_i\), in which all of the links are known to be stronger than \(x_i\). Both of these items of prior information have uncertain values.

Consider first the distribution of values of \(N_i\), for a given value of \(N_{i+1}\). We have already seen (equation 3) that repeated random sub-division of an interval produces a steady-state distribution of lengths \(W(N) \sim 1/N^2\). Subdivision of an interval of length \(N_i > N_{i+1}\) produces an interval of length \(N_{i+1}\) with probability \(1/N_i\). The probability distribution for \(N_i\) is therefore proportional to \(N_i^{-3}\) for \(N_i > N_{i+1}\) (and zero otherwise). For \(N_{i+1} \gg 1\), the normalised distribution of \(N_i\) is therefore
\[
P_n(N_i|N_{i+1}) \sim \begin{cases} 2N_i^2 & N_{i+1} < N_i \\ 0 & N_{i+1} \geq N_i \end{cases}.
\] (7)
The probability \( P_{i+1}(x_{i+1}|n_{i+1}) \) is obtained from \( P_i(x_{i+1}|x_i, n_i) \) by averaging over the probability densities of both \( n_i \) and \( x_i \). (Note that the latter probability density is related to the unknown function that we wish to calculate):

\[
P_{i+1}(x_{i+1}|n_{i+1}) = \sum_{n_i=n_{i+1}+1}^{\infty} P_n(n_i | n_{i+1}) \int_0^{x_{i+1}} dx_i \ P_i(x_{i+1}|x_i, n_i) \rho_i(x_i | n_i).
\]  
(8)

Differentiating (8) with respect to \( x_{i+1} \) and substituting the known expressions for \( P_n(n_i | n_{i+1}) \) and \( P_i(x_1|x_0, n_0) \) we obtain

\[
\rho_{i+1}(x_{i+1}|n_{i+1}) \sim \sum_{n_i=n_{i+1}+1}^{\infty} \frac{2N^2}{N^2} \int_0^{x_{i+1}} dx_i \ \rho(x_i) \exp\{-n_i[P(x_{i+1}) - P(x_i)]\} \rho_i(x_i | n_i).
\]  
(9)

5 Self-consistent solution

We assume that the distribution \( \rho_i(x|N) \) becomes independent of the generation index \( i \) when we consider the subdivision of a very long chain. This leads to a ‘self-consistency’ condition for the probability density \( \rho_i(x|N) = dP_i(x|N)/dx \). Approximating the sum in equation (9) by an integral, and replacing \( \rho_i \) and \( \rho_{i+1} \) by the asymptotic, self-consistent function \( \rho_\infty \) yields

\[
\rho_\infty(x|N) \sim 2N^2 \int_N^\infty dx_0 \ \frac{1}{N_0} \int_0^{x_0} \ exp\{-n_0[P(x) - P(x_0)]\} \rho_\infty(x_0 | N_0).
\]  
(10)

We assume that the corresponding probability \( P_\infty(x|N) \) is of the form \( P_\infty(x|N) = F(NP(x)) \) for some function \( F \) (which increases monotonically from \( F(0) = 0 \) to \( F(\infty) = 1 \)). Writing \( w = P(x) \), the derivative \( f = F' \) satisfies

\[
f(Nw) = 2N \int_N^\infty dx_0 \ \frac{1}{N_0} \int_0^{w} \exp\{-n_0(w - w_0)\}f(N_0w_0).
\]  
(11)

We express this integral equation in terms of \( g(X) = \exp(X)f(X) \), and differentiate. We find that the primitive of \( g(X) \), namely \( G(X) \), satisfies

\[
G''(X) = \frac{X+1}{X}G'(X) - \frac{2}{X}G(X).
\]  
(12)

The solution of this equation is of the form

\[
G(X) = AX^2 + B[\exp(-X)(1 + X) - X^2\text{Ei}(X)]
\]  
(13)

where \( A, B \) are constants and \( \text{Ei}(X) = e \int_{-\infty}^{X} \frac{e^z}{z}dz \) is the exponential integral. The requirement that \( G(0) = 0 \) implies that \( B = 0 \), so that the normalised function \( f(x) \) is \( f(x) = x \exp(-x) \). Thus we find the probability density for a chain segment of length \( N \) being formed by breaking a link of strength \( x \) in the form

\[
\rho_\infty(x|N) = N^2 \rho(x)P(x) \exp[-NP(x)].
\]  
(14)

Finally, we are in the position to obtain the desired result, the probability density for a segment of length \( N \) having a weakest link of strength \( x \). This is obtained from the distribution \( \rho_\infty(x|N) \) as follows

\[
\rho^*(x|N) = \int_0^x dx_0 \ \frac{d}{dx}P_c(x|x_0, N)\rho_\infty(x_0|N)
\]
\[= N\rho(x) \int_0^x dx_0 \ \exp\{-N[P(x) - P(x_0)]\} \rho_\infty(x_0|N).
\]  
(15)

In the limit of large \( N \) we find the simple, asymptotically exact result (11).

In the case where \( \rho(x) \) has a finite limit for very weak chains, \( \rho_0 = \rho(0) \), the strength distribution (11) has a simple universal scaling form when \( N \gg 1 \):

\[
\rho^*(x|N) \sim \frac{1}{2}N^3\rho_0^2x^2 \exp(-N\rho_0x).
\]
