Spin correlations in the algebraic spin liquid - implications for high \( T_c \) superconductors

Walter Rantner and Xiao-Gang Wen
Dept. of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139
(Dated: March 22, 2022)

We propose that underdoped high \( T_c \) superconductors are described by an algebraic spin liquid (ASL) at high energies, which undergoes a spin-charge recombination transition at low energies. The spin correlation in the ASL is calculated via its effective theory - a system of massless Dirac fermions coupled to a \( U(1) \) gauge field. We find that without fine tuning any parameters the gauge interaction strongly enhances the staggered spin correlation even in the presence of a large single particle pseudo-gap. This allows us to show that the ASL plus spin-charge recombination picture can explain many highly unusual properties of underdoped high \( T_c \) superconductors.

I. INTRODUCTION

One of the intriguing questions about the cuprate superconductors - to many possibly the key to understanding superconductivity - is the role played by spin correlations in these materials. By now it is well established that the insulating parent compound of the copper oxide superconductors is well described as a two dimensional Heisenberg Antiferromagnet in the temperature regime above the three dimensional Neel ordering temperature \( (T_N \sim 300 K) \). Between \( T_N \) and a temperature of about 600 K the materials seem to follow the renormalized classical results of Chakravarty, Halperin and Nelson. At higher temperatures the system appears to cross over to quantum scaling behavior with a dynamical exponent \( z \). On doping with holes, away from stoichiometry, these insulating compounds develop into high \( T_c \) superconductors even for very low hole concentration of order 5%. For such low doping the low energy Hilbert space should still be dominated by spin fluctuations - as a memory effect of the undoped parent compound. The question that needs to be addressed is the peculiar interplay of short range antiferromagnetic correlations as a remnant of the ordered Neel state at zero doping competing with spin singlet formation present in the superconducting state. Depending on the importance attached to those two spin correlations we can distinguish two schools of thought that have strongly influenced the high \( T_c \) research.

The first takes the strong antiferromagnetic (AF) spin fluctuations seriously as providing the “mechanism” for superconductivity. Assuming the normal state is a Fermi liquid, the antiferromagnetic spin fluctuations were shown to lead to a \( d \)-wave superconducting state. The spin fluctuations can be modeled phenomenologically a la Millis, Monien and Pines in the context of a nearly antiferromagnetic Fermi liquid (NAFL). The main degrees of freedom are spin and charge carrying quasiparticles coupled to their own spin fluctuations. The strength of the spin fluctuations is modeled by a susceptibility which is strongly peaked near the commensurate antiferromagnetic wavevector \( \vec{Q} = (\pi/a, \pi/a) \). This strong enhancement is achieved via an RPA in the form

\[
\chi(q,\omega) = \frac{\chi_0(q,\omega)}{1 - J(q,T)\chi_0(q,\omega)}
\]

as proposed by Monthoux and Pines (\( \chi_0(q,\omega) \) is calculated by taking spin fluctuations mediated interactions between the quasiparticles into account). In a series of papers Monthoux and Pines have given what they call a “proof of concept” for spin-fluctuation driven pairing for the cuprates near optimal doping. They study the competition of spin-density wave (SDW) order with superconducting pairing by solving two-dimensional Eliashberg equations for spin-fluctuation induced interactions between the quasiparticles. These approaches could account for both the \( d \)-wave pairing symmetry and the high \( T_c \)’s seen in the cuprates. One interesting question is of course the interplay of SDW and superconductivity as instabilities of the NAFL. Monthoux and Pines concluded that superconductivity always prevails as the dominant instability. With the realization that the quasiparticles are not too close to a SDW instability they however needed a strong fine tuning of their Stoner enhancement factor \( J(q) \) as a function of both momentum dependence (strongly peaked at \( Q = (\pi/a, \pi/a) \)) and strength \( (J(q)\chi_0(Q,0)) \sim 0.97 \) to account in a “self-consistent” manner for their empirical input spin spectrum.

The discussion so far was centered on the optimally doped case, in this paper we shall however be concerned with the underdoped cuprates where the spin behavior shows the peculiar competition of antiferromagnetic order and singlet formation in a particularly striking way as is evidenced by various spin-pseudo-gaps seen in NMR and Neutron scattering. Let us briefly mention the approaches to this regime which have emphasized the antiferromagnetic order and the concomitant spin wave excitations as the dominant degrees of freedom. In an extensive study of the 2d antiferromagnetic Heisenberg model Chubukov, Sachdev and Ye have identified the spin correlations in the quantum critical regime at the transition from Neel order to paramagnetism. In their paper they also argue for the appearance of quantum critical scaling away from zero doping by incorporating the effect of the doped charge degrees of freedom into a reduction of the
spin stiffness (finite in the ordered Neel state of the 2d Heisenberg model) Sokol and Pine have similarly argued for quantum critical behavior and its cross over to a quantum disordered regime driven by the frustration of antiferromagnetism via the hole motion as the physics behind the strange spin correlations in the pseudo-gap regime. They postulate a susceptibility which is dominated by the effect of a finite coherence length in the quantum disordered regime and the appearance of the corresponding full energy gap for spin excitations.

As we shall argue below this phenomenology qualitatively agrees with what we obtain within the slave boson approach to the \(tJ\)-model, where however in contrast to the above, spin singlet formation (or more precisely, the formation of the d-wave/staggered-flux phase – a state with a particular quantum order \(U1\text{Cu}_0\text{In}\)) is the driving force behind all of the strange phenomenology in the underdoped samples. The slave boson approach is a microscopic theory for high \(T_c\) superconductors which takes the on-site repulsion \(U\) and the resulting charge gap (\(\sim 2eV\)) as the largest scale in the theory. It naturally reproduces the Mott insulator phase at half filling and low charge carrier density at low doping. Furthermore this framework allows us to calculate various line-shapes when the AF-correlation is short ranged. The line-shapes can be quite different from those obtained from phenomenological models.

The slave boson approach is strongly tied to the strong coupling phenomenology incorporated in the Hubbard or \(tJ\)-model and was guided by Anderson’s exciting proposal of a spin liquid as a realization of the strongly correlated Mott insulator in the parent compound of the high \(T_c\) superconductors. More specifically, Anderson proposed that the cuprate physics could be understood in terms of doping holes into a state which consists of preformed spin singlet dimers on nearest neighbor bonds whose quantum fluctuations lead to uniform strength AF-correlations on all nearest neighbor bonds (termed resonating valence bond (RVB) state). The RVB state also has short range antiferromagnetic spin correlations (no true long range order) due to the singlet formation and hence comprises a spin liquid phase. However, due to the success of the two dimensional Heisenberg antiferromagnet in describing the insulating parent compound of the cuprates this idea of a spin liquid ground state was partly rejected.

Nevertheless the RVB picture has a lot of appeal. Let us mention briefly the rational behind the opinion that the spin singlet formation dominates antiferromagnetic correlations in the underdoped cuprates. The slave boson approach treats the underdoped cuprates as doped Mott insulators - the key experimental fact of high \(T_c\) superconductors. It also naturally incorporates the spin singlet formation and predicted, ahead of experiments, the pseudo-gap metallic phase in the underdoped cuprates and the superconducting d-wave order (preferred over s-wave by strong Coulomb correlations present in the Mott insulator). The pseudo-gap metallic phase is a new state of matter and it is very rare in the history of condensed matter physics that a new state of matter was predicted before its experimental observation. An important effect of the preformed spin singlets, present in the RVB picture, is the fact that the spin on the doped holes can become an excitation on top of the RVB collective state whereas the charge remains tied to the empty site. This led to the notion of separate spin and charge carrying excitations called spinons and holons respectively. Superconductivity then appears as a consequence of establishing coherence among the doped holes which naturally incorporates a low (proportional to \(x\) the hole doping concentration) superfluid density present in the underdoped cuprates. This picture of the spin fluctuations is quite different from the NAFL where (1) a metallic state with no pseudo-gap is assumed (which does not apply to the underdoped regime) and (2) strong antiferromagnetic spin fluctuations couple to spin and charge carrying quasiparticles. It is the exchange of those antiferromagnetic fluctuations which gives rise to the pairing necessary for superconductivity.

However, underdoped cuprates have a very puzzling property which seems hard to explain using the spin liquid approach (or other approaches). As the doping is lowered, both the pseudo-gap and the AF correlation in the normal state increase. Naively, one expects the pseudo-gap and the AF correlations to work against each other. That is the larger the pseudo-gap, the stronger the spin-singlet formation and the weaker the AF correlations. One result coming out of the research reported here is a connection of the quantum scaling regime of the underdoped compounds at high temperature with Anderson’s RVB picture via the algebraic spin liquid (ASL) phase. We find that the ASL can explain both the pseudo-gap and the strong AF correlations in the underdoped high \(T_c\) superconductors. Due to the \(U(1)\) gauge fluctuations in the ASL phase, the AF spin fluctuations in the ASL are as strong as those of a nested Fermi surface, despite the pseudo-gap. The doped holes suppress the \(U(1)\) gauge fluctuations which explains the decrease of the AF spin fluctuations with increasing doping even though the pseudo-gap is smaller at higher doping. We would like to stress that the ASL approach to the AF fluctuations is distinct from RPA-like approaches. Due to the small density of states in the pseudo-gap phase, one needs to fine tune a large coupling constant within the RPA to fit the experimental data for underdoped samples. Such a fine tuning is not necessary in the ASL approach. Thus the \(U(1)\) gauge structure and the associated spin-charge separation in the ASL lie at the heart of the strange phenomenology of the underdoped cuprates in the so called pseudo-gap phase.

The starting point of the slave boson approach is a microscopic lattice model. Among the popular models, the \(tJ-\text{GtJ}\) (Generalized-\(tJ\)) model seems particularly promising as a description for the low doping regime where the competition between delocalization energy \(t\)
and the spin fluctuations $J$ becomes manifest.

$$H = \sum_{(ij)} [J(\vec{S}_i \cdot \vec{S}_j - \frac{1}{4} n_in_j) - t(c^{\dagger}_{i\sigma}c_{i\sigma} + h.c.)] + ... \quad (1)$$

The form of the $tJ$ Hamiltonian can be justified starting from the Hubbard model in the limit of strong on-site Coulomb repulsion energy which in the cuprates leads to an insulating charge transfer gap of 2eV. As the Coulomb energy is the largest energy scale in the problem it is natural to treat the kinetic energy as a perturbation which to lowest order in $t^2$ leads to the $tJ$ Hamiltonian with the single site Hilbert space restricted to the three states spin up/down and empty. For zero doping the $tJ$ Hamiltonian reduces to the Heisenberg model with antiferromagnetic exchange coupling (virtual hopping on top of strong onsite Coulomb repulsion naturally leads to antiferromagnetic exchange).

The organization of the paper is as follows; In the next two sections (II,III) we review the ideas underlying the ASL and discuss the spin correlations in this phase sketching the calculations involved (details can be found in the appendix). Following this we give a brief discussion on how the recently introduced concept of quantum order (15) affects the current results (IV). Section (V) addresses the problem of what happens to the ASL physics at low energies where the interactions between spinons and holons become strong. This will be followed up by a discussion of possible implications for the cuprates and a short comparison with other approaches to the same region of the phase diagram (VI). The final section (VII) will summarize the main results and discuss open problems for further study.

II. SU(2) SLAVE BOSON APPROACH AND ALGEBRAIC SPIN LIQUID

Taking the charge gap as the largest energy scale, we have argued that the natural starting point to the description of underdoped cuprates is a strongly correlated model. The question of spin correlations in the cuprates ties into the question of how to reconcile local moment magnetism with itinerant electron spin density fluctuations which is a longstanding problem in condensed matter physics. There seems to be consensus in the community on how best to describe the two extreme limits of the cuprate phase diagram - the Mott insulator at zero doping as a Heisenberg antiferromagnet and the heavily doped regime in terms of itinerant electron magnetism. Of course as always the most interesting regime is the one lying in between the two limits which shows the antiferromagnetic-singlet dichotomy described above. For the lightly doped regime one could argue that clearly a perturbation about the Neel ordered state with frustration due to holes, a la Sokol and Pines makes the most sense. However, this approach does not specify the nature of the quantum spin liquid in the disordered phase. Understanding the properties of the quantum spin liquid is very important since it is the quantum spin liquid that controls the pseudo-gap metallic state in the underdoped cuprates. Another drawback with the NAFL approach to the spin and charge fluctuations is the fact that it cannot explain naturally the small charge carrier density without breaking translation symmetry.

The picture of spin fluctuations followed here is the one of preformed singlets (RVB) which incorporates the spin correlations in the spin disordered phase (such as the superconducting state and the pseudo-gap normal state) in a natural way by paying the price of throwing away a lot of antiferromagnetic correlations. The aim of the current paper is to show a way of reconciling the singlet formation with the strong dynamic antiferromagnetic correlations seen in NMR and Inelastic Neutron Scattering (INS) with the help of a gauge theory based on a slave boson decoupling of the $tJ$-model.

As we discussed briefly above, the (generalized) $tJ$-model can be shown to be an excellent description of the low energy physics embodied in the Hubbard model under the condition that the single site Hilbert space is constraint such that double occupation is forbidden. On an operative level this problem can be attacked by introducing slave particles that change the constraint $c^\dagger c(i) \leq 1$ (where $c(i)$ is the physical electron destruction operator of spin $\sigma$ on site $i$) into $\Sigma_c f^\dagger_c f_c(i) + b^\dagger b(i) = 1$ where the $b(i)$ is a bosonic operator - the holon - that keeps track of the empty sites and carries the charge of the physical hole, whereas the spin of the hole is carried by $f_{\sigma}$ - the fermionic spinon. This is achieved by writing $c_{\sigma} = f_{\sigma} b^\dagger$ and should be read as an equality in the constraint Hilbert space. With the introduction of the slave bosons we have however introduced a redundancy in the description of our physical problem which is a $U(1)$ phase rotation of $f$ and $b$ that leaves the physical electron operator invariant. As the system evolves under the $tJ$ Hamiltonian (1) this phase will strongly fluctuate as a function of space and time. It is this phase degree of freedom that corresponds to $U(1)$ gauge fluctuations and makes the description of the constraint problem of spin + hopping in terms of fermionic and bosonic operators possible. The above program can be summarized under the name of $U(1)$ slave boson theory and was implemented widely in the early days of high $T_c$ research(14). Early on it was also realized(15) that the Heisenberg model in the fermionic representation has an extra $SU(2)$ invariance organizing the spinons into doublets

$$\psi_{\uparrow i} = \begin{pmatrix} f^{\dagger}_{\uparrow i} \\ f^{\dagger}_{\downarrow i} \end{pmatrix}, \quad \psi_{\downarrow i} = \begin{pmatrix} f^{\dagger}_{\downarrow i} \\ -f^{\dagger}_{\uparrow i} \end{pmatrix}, \quad (2)$$

In the usual $U(1)$ slave boson approach this invariance was lost on introducing holes. More recently Wen and Lee introduced a slave boson formulation(14,15) which maintains this $SU(2)$ structure away from half filling. This was achieved via the introduction of slave boson doublets and representing the physical electron operator...
as
\[ c_{\uparrow i} = \frac{1}{\sqrt{2}} b_{\downarrow i} \psi_{\uparrow i} = \frac{1}{\sqrt{2}} (b_{\downarrow i}^\dagger f_{\uparrow i} + b_{\downarrow i} f_{\uparrow i}^\dagger) \]
\[ c_{\downarrow i} = \frac{1}{\sqrt{2}} b_{\uparrow i} \psi_{\downarrow i} = \frac{1}{\sqrt{2}} (b_{\uparrow i}^\dagger f_{\downarrow i} - b_{\uparrow i} f_{\downarrow i}^\dagger) \]

with
\[ h_i = \begin{pmatrix} b_{\downarrow i} \\ b_{\uparrow i} \end{pmatrix} \]
the doublet of bosonic fields keeping track of the doped holes.

The slave boson approach to the $tJ$ Hamiltonian then is to use this decoupling and perform a mean-field analysis\cite{1, 13}. This has led to a mean-field phase diagram as a function of hole doping $x$ and temperature $T$ which is in qualitative agreement with the phase diagram of the cuprates. Within the mean-field description however the gauge freedom is treated only on the average - i.e. replaced by a static configuration of phases which in turn determine the band-structure of the spinons and holons. However as is usually the case with the identification of phases via a mean-field decoupling we need to consider fluctuations about the mean-fields to determine their stability. In particular the gauge field - unconstrained by any dynamics - will affect the physical properties in each phase drastically.

In the present paper we are concerned with the pseudogap regime of the cuprates which - within the $U(1)$ formulation - was identified as the d-wave paired state for the spinons. Within the $SU(2)$ approach this phase can also be described as the so called staggered-Flux (sF) phase without explicit fermion pairing. As it turns out (see for more details) the $SU(2)$ formulation allows for a more straightforward identification of low-lying (massless) gauge modes and it was shown that the sF phase breaks the $SU(2)$ gauge structure down to $U(1)$. This massless $U(1)$ mode was missed in the early discussions (within the $U(1)$ slave boson approach) on the pseudogap phase and plays a crucial role in the pseudo-gap phase of the underdoped cuprates. It is responsible for the emergence of the ASL. In the next section we shall discuss the physical spin correlations in the ASL.

Before closing this section, we would like to remark that the ASL (the sF phase) is only one of many possible symmetric spin liquids. All symmetric spin liquids have the same symmetry, and hence cannot distinguish different symmetric spin liquids by their symmetries. The concept of quantum order was introduced to distinguish the different internal structures present in the symmetric spin liquids. For the symmetric spin liquids constructed within the $SU(2)$ slave boson approach, one can use the projective symmetry group (PSG) to characterize their different quantum orders. One finds that the sF phase is described by the particular PSG with the name U1Cn01n and it is one of an infinite number of possible symmetric $U(1)$ spin liquids. Thus the sF phase can be more accurately called U1Cn01n phase. Quantum order and its PSG characterization is a very important concept for our discussion (See section IV).

III. SPIN SUSCEPTIBILITY

Our starting point is the sF (or U1Cn01n) state in the $SU(2)$ mean-field phase diagram where the effective degrees of freedom are spinons and holons coupled to a massless $U(1)$ gauge field. In order to analyze this problem we have mapped the lattice effective theory for the sF state (at zero doping) onto a continuum theory of massless Dirac spinors coupled to a gauge field whose Euclidean action reads
\[ S = \int d^3x \sum_{\mu \sigma} \bar{\Psi}_\sigma v_{\sigma,\mu} (\partial_\mu - ia_\mu) \gamma_\mu \Psi_\sigma \]

where $v_{\sigma,0} = 1$ and $N = 2$, but in the following we will treat $N$ as an arbitrary integer. In general $v_{\sigma,1} \neq v_{\sigma,2}$. However, for simplicity we will assume $v_{\sigma,i} = 1$ here. The Fermi field $\Psi_\sigma$ is a $4 \times 1$ spinor which describes lattice spinons with momenta near $(\pm \pi/2, \pm \pi/2)$. The $4 \times 4$ $\gamma_\mu$ matrices form a representation of the Dirac algebra $\{ \gamma_\mu, \gamma_\nu \} = 2 \delta_{\mu\nu}$ ($\mu, \nu = 0, 1, 2$) and are taken to be
\[ \gamma_0 = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}, \quad \gamma_1 = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \]
\[ \gamma_2 = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} \]

with $\sigma_\mu$ the Pauli matrices. Finally note that $\bar{\Psi}_\sigma = \Psi_\sigma^\dagger \gamma_0$. The dynamics for the $U(1)$ gauge field arises solely due to the screening by bosons and fermions, both of which carry gauge charge. In the low doping limit, however, we will only include the screening by the fermion fields which yields
\[ Z = \int Da_\mu \exp \left( -\frac{1}{2} \int d^3q \frac{1}{2} a_\mu(q) \Pi_{\mu\nu} a_\nu(-q) \right) \]
\[ \Pi_{\mu\nu} = \frac{N}{8} \sqrt{q^2} \left( \delta_{\mu\nu} \frac{q_\mu q_\nu}{q^2} - \frac{q_\mu q_\nu}{q^2} \right) \]

By simple power counting we can see that the above polarization makes the gauge field a marginal perturbation at the free spinon fixed point. Importantly however we should note that since the conserved current (that couples to $a_\mu$) cannot have any anomalous dimension, this interaction is an exact marginal perturbation protected by current conservation.

A. Uniform correlations

Let us now discuss how the gauge fluctuations affect spin correlations near momentum transfer $q = (0, 0)$. 
The expression for the uniform spin correlation reads (see Appendix A)

$$\langle S_u^+(x)S_u^-(0) \rangle = \int \frac{d\vec{q}}{(2\pi)^3} e^{i\vec{q} \cdot \vec{x}} \langle S_u^+(\vec{q})S_u^-(\vec{-q}) \rangle$$

$$\langle S_u^+(\vec{q})S_u^-(\vec{-q}) \rangle = -\frac{1}{4} \int \frac{d\vec{p}}{(2\pi)^3} \text{Tr} [\gamma_0 G(\vec{p})\gamma_0 G(\vec{p} - \vec{q})]$$

where $\langle \cdots \rangle$ denotes the expectation value with respect to theory (4). From this expression we see that the uniform ferromagnetic correlations are not protected by current conservation and restore antiferromagnetic correlations which have been largely lost in the mean-field singlet state as we shall see next.

**B. Staggered correlations**

In the following we will present fluctuation corrections to the antiferromagnetic spin-spin correlations at order $1/N$. The expression for the staggered correlation is obtained in the form (see Appendix A)

$$\langle S^+_s(\vec{q})S^-_s(\vec{-q}) \rangle = -\frac{1}{4} \int \frac{d\vec{p}}{(2\pi)^3} \text{Tr} [\gamma_0 G(\vec{p})\gamma_0 G(\vec{p} - \vec{q})]$$

At the mean-field level this is simply

$$\langle S^+_s(\vec{q})S^-_s(\vec{-q}) \rangle_0 = -\frac{1}{4} \int \frac{d\vec{p}}{(2\pi)^3} \text{Tr} [\gamma_0 G_0(\vec{p})\gamma_0 G_0(\vec{p} - \vec{q})]$$

where $G_0(\vec{p}) = \frac{-i}{p^2}$ and the vertices are the $4 \times 4$ unit matrices denoted $I$. Decoupling the denominator in the usual way via Feynman parameters we obtain

$$\langle S^+_s(\vec{q})S^-_s(\vec{-q}) \rangle_0 = -\frac{\sqrt{q_0^2 + q^2}}{16}$$

Note that $\vec{q}$ is measured with respect to $(\pi, \pi)$ in units of the lattice spacing. From expression (11), we see that the antiferromagnetic correlations have been largely lost. The reason for this can be traced back to the spin singlet formation in the mean-field $s$F ($U1C01n$) phase. This motivates the inclusion of gauge fluctuations. At order $1/N$ we have the three non-vanishing diagrams depicted in Fig. 1. In order to calculate the contribution of these diagrams we note that unlike the single spinon spectral function the density density correlation is gauge invariant and hence we can choose to work in the Landau gauge where the gauge propagator reads

$$D_{\mu\nu}(\vec{q}) = \frac{8}{N\sqrt{q^2}} \left( \delta_{\mu\nu} - \frac{q_{\mu}q_{\nu}}{q^2} \right)$$

and we have the following expressions for the diagrams shown

$$\begin{align*}
[1(A)] + [\frac{1}{4}(B)] &= -\frac{1}{2} \int \frac{d^dk}{(2\pi)^d} \int \frac{d^dq}{(2\pi)^d} \text{Tr} \left[ \frac{1}{i(p+k)_{\alpha} \gamma^\alpha} \gamma^\mu \delta_{\mu\nu} \frac{1}{i(k+q)_{\beta} \gamma^\beta} \right] \\
[1(C)] &= -\frac{1}{4} \int \frac{d^dk}{(2\pi)^d} \int \frac{d^dq}{(2\pi)^d} \text{Tr} \left[ \frac{1}{i(p+k)_{\alpha} \gamma^\alpha} \gamma^\mu \delta_{\mu\nu} \frac{1}{i(k+q)_{\beta} \gamma^\beta} \right]
\end{align*}$$

After performing the trace and integrating over $k$ in $d = 3$, where the integrals are convergent (see Appendix B), we arrive at

$$\begin{align*}
[1(A)] + [\frac{1}{4}(B)] &= \frac{1}{N} \int \frac{d^dq}{(2\pi)^d} \left[ \frac{2\vec{p} \cdot \vec{q} + \vec{p}^2}{|q|^3} |p + q|^2 \frac{1}{|p||q|^2} - \frac{|\vec{p} - \vec{q}|^2 + 2\vec{p} \cdot \vec{q}}{q^2} \right] \\
[1(C)] &= \frac{1}{N} \int \frac{d^dq}{(2\pi)^d} \left[ \frac{2\vec{p}^2}{|q|^3} |p + q|^2 \frac{1}{|p||q|^2} - \frac{4|\vec{p}|^2}{q^2} |p + q|^2 \frac{|\vec{p} - \vec{q}|^2 + 2\vec{p} \cdot \vec{q}}{q^3} \right]
\end{align*}$$

In order to proceed we need to regularize the above integrals. Because of the dot-product appearing in the de-
nominator of the last term in (15) it is hard to use dimensional regularization. Hence we have set $d = 3$ and introduced an upper momentum cutoff $\Lambda$. Thus performing the final integrals over $\vec{q}$ we can extract the log-divergent term in the form

$$[\mathbb{A}] + [\mathbb{B}] + [\mathbb{C}] = -\frac{8}{12\pi^2 N} |p| \ln \left( \frac{\Lambda^2}{p^2} \right)$$

After combining this with the mean-field result (10) and continuing to real frequencies (see Appendix [3]) we obtain

$$\text{Im} \chi(\omega, q) = \chi''(\omega, q) = \text{Im} \langle S^+_s(\omega, q) S^-_s(-\omega, -q) \rangle$$

$$= C_s \frac{1}{2} \sin(2\nu\pi) \Gamma(2\nu - 2) \Theta(\omega^2 - q^2) (\omega^2 - q^2)^{1/2 - \nu}$$

where $C_s$ is a constant depending on the physics at the lattice scale. In the limit $N \to \infty$ this reduces to the mean-field result (10). From (16) it is clear that the gauge fluctuations have reduced the mean-field exponent. If we boldly set $N = 2$ which is the physically relevant case we find $\nu > 1/2$ signaling an antiferromagnetic instability. This is consistent with an earlier numerical result obtained in Ref. [21]. In Fig. 2 we plot the imaginary part of the spin susceptibility at $q = 0$.

This result is quite natural in the light of what has been said so far. The gauge fluctuations arise from the constraint of no double occupancy. The dynamics for the gauge field - in the very low doping limit assumed here - is solely due to virtual spinons. It is the low energy spinon-antispinon pairs having a nesting condition for scattering between the nodes (separated by $Q_{AF}$) in the sF (U1Cn01n) phase mean-field spectrum which are responsible for the antiferromagnetic enhancement in the ASL phase. Let us emphasize again that this enhancement of spin correlations at $Q_{AF} = (\pi, \pi)$ over the uniform component is protected, just like the gapless $U(1)$ gauge fluctuations and the gapless spinons, by the U1Cn01n quantum order.

We have thus established algebraic behavior for the staggered spin correlations. It is such an algebraic correlation that leads to the name ASL that we assigned to the phase.

C. Correlations near $(\pi, 0)$

For this momentum transfer the spinons get scattered between the two different types of nodes in the sF spectrum which yields the following expression for the corresponding correlations

$$\langle S^+_{(\pi, 0)}(\vec{q}) S^-_{(0, 0)}(-\vec{q}) \rangle = -\frac{1}{4} \int \frac{dp}{(2\pi)^3} \text{Tr} \left[ \begin{pmatrix} 0 & \sigma_1 \\ \sigma_1 & 0 \end{pmatrix} G(p) \begin{pmatrix} 0 & \sigma_1 \\ \sigma_1 & 0 \end{pmatrix} G(p - \vec{q}) \right]$$

Having worked hard to obtain the anomalous dimension of the staggered spin operator by brute force we will here resort to standard field theory renormalization apparatus which allows for a more economical derivation of the anomalous dimensions of composite operators. In order to obtain the anomalous dimension of the spin operator which is a fermion bilinear we need to obtain its wavefunction renormalization in the form

$$Z_S = Z_q Z_{\Gamma}$$

FIG. 2: Imaginary part of the spin susceptibility at $Q_{AF}$. Note the divergence at small $\omega$. 

where $\Gamma$ is the relevant vertex and as we have seen above depends on the momentum transfer ($\Gamma = \gamma_0, \gamma_1$, $\begin{pmatrix} 0 & \sigma_1 \\ \sigma_1 & 0 \end{pmatrix}$ near $(0,0), (\pi, \pi)$ and $(\pi, 0)$ respectively).
The spinon wavefunction renormalization is obtained from the self energy in the usual way and evaluates in the Landau gauge to

\[ Z_\Psi = 1 + \frac{4}{N} \frac{1}{3\pi^2} \frac{\Gamma(\frac{3-d}{2})}{(M^2)^{(3-d)/2}} \]  

(19)

where \( M \) is the renormalization scale and we have used dimensional regularization.

To obtain the vertex renormalization we need to evaluate the divergent part of the 1-loop diagram depicted in Fig. 3 which reads

\[ \int \frac{d^d l}{(2\pi)^d} \ \frac{i\gamma^\mu(-i\gamma^\epsilon)(k+l),\Gamma(-i\gamma^\delta)(l+p),\delta i\gamma^\nu D_{\mu\nu}(l)}{(k+l)^2(p+l)^2} \]

where \( \Gamma \) is the relevant vertex and \( D_{\mu\nu} \) is given by (11). Since the vertex correction diverges only logarithmically we can simply evaluate the divergent part by setting all the incoming momenta equal to 0. Hence the above simplifies to

\[ \frac{8}{N} \int \frac{d^d l}{(2\pi)^d} \left[ \frac{\gamma^\mu l_\epsilon \gamma^\nu \Gamma(\pi,0) l_\delta \gamma^\nu \delta_{\mu\nu}}{l^5} - \frac{\gamma^\mu l_\epsilon \gamma^\nu \Gamma(\pi,0) l_\delta \gamma^\nu l_\mu l_\nu}{l^7} \right] \]

where we now concentrate on the \((\pi,0)\) vertex. This can be easily evaluated with the help of

\[ \gamma_\epsilon \Gamma(\pi,0) = (1 - 2\delta_{\epsilon 2}) \Gamma(\pi,0) \gamma_\epsilon \]

\[ \int \frac{d^d l}{(2\pi)^d} \Gamma_{\text{div}} = \frac{1}{4\pi^2} \frac{2}{3 - d} \]

and results in

\[ Z_{\Gamma(\pi,0)} = 1 - \frac{4}{N} \frac{1}{3\pi^2} \frac{\Gamma(\frac{3-d}{2})}{(M^2)^{(3-d)/2}} \]  

(20)

which together with equations (18) and (19) gives

\[ Z_{S(\pi,0)} = 1 \]  

(21)

Hence the spin operator at \((\pi,0)\) doesn’t pick up any anomalous dimension from the gauge field interactions. It is not hard to check within the above outlined calculation that for the other two vertices corresponding to the uniform and staggered spin operator, we recover the results discussed in the previous sections which gives a nice check on the brute force calculation.

### IV. PERTURBATIVE STABILITY OF THE sF (U1Cn01n) PHASE

An important technical detail was hidden in the above calculation. In this section, we will expose this issue.

The sF phase contains 2 families of 4-component massless Dirac fermions, which couple to massless \( U(1) \) gauge fluctuations. At the perturbative level, the interaction can generate many possible counter terms (in this case the self-energy terms) which can

(A) generate a mass for the Dirac fermions,

(B) generate a finite chemical potential for the Dirac fermions and change the Fermi points into Fermi pockets,

(C) shift the crystal momenta of the Dirac fermions from \((\pm\pi/2,\pm\pi/2)\) to some other values.

In our perturbative calculation in the last section, we have assumed that none of the above counter terms are generated by the interaction.

In a generic interacting theory, we used to believe that all the counter terms that are consistent with symmetries will be generated. All of the above three types of counter terms are consistent with the underlying lattice symmetries and are hence allowed by the symmetries. In fact they do appear in our calculation of the continuum theory as cut-off dependent terms. It appears that the results in the last section are incorrect since the important counter terms are ignored. Those counter terms, if present, will drastically alter our previous results.

As was stressed in this paper and in Ref. 8 and Ref. 9, the sF phase, as a quantum spin liquid, is not only characterized by its symmetry but also by its quantum order. The quantum order in the sF phase is characterized by a particular PSG – U1Cn01n. The mean-field ansatz of the sF phase is invariant under the transformations of the U1Cn01n PSG. As pointed out in Ref. 8 and Ref. 9, the perturbative fluctuations around the mean-field ground state may deform the mean-field ansatz. Those deformations correspond to the counter terms. However, in our case, it is incorrect to use symmetries to determine which counter terms are allowed. One should use the PSG to determine the allowed counter terms. This is because perturbative fluctuations can only deform the ansatz in such a way that the deformed ansatz remains invariant under the same PSG. It was shown in Ref. 10 that the above three counter terms are forbidden by the U1Cn01n PSG. This is why we can drop them in our calculation.

When we calculate the effects of interactions in a continuum theory, we introduce a high energy/short distance cut-off. This cut-off destroys the structure of the underlying quantum order. Thus it is not surprising that the counter terms forbidden by the quantum order show up in continuum theory as cut-off dependent terms. To restore the quantum order that existed in the underlying lattice theory, we can simply drop all the forbidden counter terms in our calculation within the continuum theory. We see that the PSG and the concept of quantum order play an important role even in calculations within con-
tinuum theories. It is the understanding of the PSG and quantum order that makes sensible calculations in the continuum limit possible. In fact, the theory of quantum order is partly motivated by the above issue of the counter terms.

In summary, the perturbative fluctuations around the mean-field sF (U1Cn01n) state cannot change the quantum order and cannot generate energy gaps for the $U(1)$ gauge field and the spinons. Thus the gapless $U(1)$ gauge fluctuations and the gapless spinons are protected by the U1Cn01n quantum order present in the sF (U1Cn01n) phase. They remain gapless even when the interaction is finite all the way down to zero energy. The interacting gapless excitations lead to many unusual properties of underdoped cuprates, such as the non-Fermi liquid behavior of the normal metallic state, the broad electron spectral function, and the diverging AF spin fluctuations in the presence of the pseudo-gap. The U1Cn01n quantum order in the sF phase not only protects the gapless excitations, it also protects the momentum of the gapless excitations. For example the spin-1 gapless excitations can only appear near $k = (0, 0)$, $(\pi, \pi)$, $(0, \pi)$, and $(\pi, 0)$.

We would like to point out that although the ASL can be a stable quantum phase in the large N limit for the real $N = 2$ case, non-perturbative instanton effects cause an instability. Thus at low energies the ASL will change into some other state, such as the d-wave superconducting state, the AF state, stripe states, or even a Z2 spin liquid state. Since the U1Cn01n quantum order in the sF phase requires the spin-1 gapless excitations to appear at $k = (0, 0)$, $(\pi, \pi)$, $(0, \pi)$, and $(\pi, 0)$, the shift of the low frequency neutron scattering peak observed in experiments indicates a transition from the ASL to some other state at low temperatures. Studying how the momentum of spin-1 gapless excitations shifts away from $(\pi, \pi)$, $(0, \pi)$ and $(0, 0)$ will allow us to experimentally identify the low temperature phase. In the last section, we have studied the spin fluctuations in the ASL. In the following section, we will study the spin fluctuations in the low temperature phase.

V. THE FATE OF THE ASL

In section, we showed how the ASL physics reconciles the pseudo-gap formation (i.e the condensation into spin singlets within the RVB picture) with enhanced dynamical antiferromagnetic fluctuations. At lower energies the ASL is unstable - and an important question is how the ASL evolves in the underdoped regime into the superconducting state as we reduce temperature.

In the following we are going to address this question via first analyzing the effect of the opening of a gap in the gauge fluctuations on the staggered spin correlations. Intuitively we should expect that for energies below the mass gap the spin correlations should be given by mean-field correlations - which is indeed the case. Having established the profound effects of this gap formation we take a more careful look at the change of the mean-field correlations on going from the sF (U1Cn01n) phase into the fermion pairing state which will allow us to address the question of incommensurate spin fluctuations seen at low frequencies and temperatures in the cuprates. Let us now proceed to consider the effect of giving a mass to the gauge fluctuations. In the context of the spin correlations considered here, we would thus expect the destruction of the antiferromagnetic enhancement below the mass gap and a resurfacing of the singlet character of the correlations in the mean-field sF (U1Cn01n) phase.

To implement the mass gap formation we take the following phenomenological form for the gauge propagator

$$D_{\mu\nu}(q) = \frac{8}{N\sqrt{q^2 + m^2}} (\Theta(q_\mu - q_\nu) - \frac{q_\mu q_\nu}{q^2})$$

The calculation then goes through as above (with one subtlety in the analytic continuation discussed in the Appendix) resulting in the following expression for the staggered correlation

$$\text{Im}(S^+_{\omega}(\omega, q)S^-_{\omega}(\omega, q)) = \Theta(\omega^2 - q^2)\Theta\left[m^2 + q^2 - \omega^2\right] C_m \frac{\sqrt{\omega^2 - q^2}}{m\omega} + \Theta\left[\omega^2 - q^2 - m^2\right] C_m \frac{\sqrt{\omega^2 - q^2}}{\left(\sqrt{\omega^2 - q^2} + \sqrt{\omega^2 - q^2 - m^2}\right)^2}$$

where

$$\nu = \frac{32}{3\pi^2 N}$$

In Fig., we show the resulting spectra with $m = 20meV$. Fig. depicts the spectrum at the antiferromagnetic ordering wavevector $Q_{AF}$. As expected the opening of the mass gap in the gauge fluctuations has restored the mean-field result and consequently suppressed the antiferromagnetic enhancement seen in Fig. From this analysis we see that the spin correlations at low frequencies are described by the underlying mean-field. In the above calculation we have assumed that the only effect of the destruction of the massless $U(1)$ gauge structure in the sF phase is the formation of the $U(1)$ mass gap which leaves the underlying mean-field correlations in tact at low energies. On a more profound level however the massless nature of the $U(1)$ gauge structure in the sF state is a manifestation of the U1Cn01n quantum order present in this state (see introduction and section IV). Thus it is not possible to simply break the gauge structure without affecting the underlying mean-field ansatz.
represent as:

\[ c_{\uparrow i} = \frac{1}{\sqrt{2}} \bar{h}_i \psi_{\uparrow i} = \frac{1}{\sqrt{2}} (b_{1i} f_{\uparrow i} + b_{2i} f_{\downarrow i}^\dagger) \]

\[ c_{\downarrow i} = \frac{1}{\sqrt{2}} \bar{h}_i \psi_{\downarrow i} = \frac{1}{\sqrt{2}} (b_{1i} f_{\downarrow i} - b_{2i} f_{\uparrow i}^\dagger) \]

where the following SU(2) doublets were introduced

\[ \psi_{\uparrow i} = \left( \begin{array}{c} f_{\uparrow i} \\ f_{\downarrow i} \end{array} \right), \quad \psi_{\downarrow i} = \left( \begin{array}{c} f_{\downarrow i} \\ -f_{\uparrow i} \end{array} \right), \quad h_i = \left( \begin{array}{c} b_{1i} \\ b_{2i} \end{array} \right) \]

The \( \psi_{\uparrow i}, \psi_{\downarrow i} \) are the two fermion fields representing the destruction of a spin up and spin down on site \( i \) respectively and \( h_i \) is the doublet of bosonic fields keeping track of the doped holes. Putting this representation into the t-J Hamiltonian

\[ H = \sum_{\langle ij \rangle} \left[ J(S_i \cdot S_j) - \frac{1}{4} n_i n_j \right] - t(c_{\sigma i}^\dagger c_{\sigma j} + c.c.) \]

yields on performing a Hubbard-Stratonovich transformation to the appropriate bosonic bond variables the following partition function:

\[ Z = \int D\psi D\bar{\psi} D\bar{\sigma} D\bar{\sigma} e^{-\beta L} \]

\[ L = \frac{\tilde{J}}{2} \sum_{<ij>} Tr[U_{ij}^\dagger U_{ij}] + \frac{1}{2} \sum_{i,\sigma} \bar{\psi}_{\sigma i} (\partial_\tau \delta_{ij} + \tilde{J} U_{ij}) \psi_{\sigma j} \\
+ \sum_{i} a_{0i} \left( \frac{1}{2} \bar{\psi}_{\sigma i} \tau^3 \psi_{\sigma i} + h_i^0 \tau^3 h_i \right) \\
+ \sum_{ij} h_{ij} (\tau_3 - \mu) \delta_{ij} + \tilde{t} U_{ij} h_{ij} \]

The \( \bar{\sigma}_0 \) fluctuations incorporate the projection to the space of SU(2) singlets within the above representation for the electron operators. Furthermore note that \( \tilde{J} = 3J/8, \tilde{t} = t/2 \) and the matrix \( U_{ij} \) in the form

\[ U_{ij} = \left( \begin{array}{cc} -\chi_{ij} \Delta_{ij}^* & \Delta_{ij} \\ \Delta_{ij}^* & \chi_{ij} \end{array} \right) \]

contains the Hubbard-Stratonovich fields which classify the part of the phase diagram we are looking at. The mean-field phase diagram is found by minimizing the free energy for a given number of particles with respect to the bond variables \( U_{ij} \).

The d-wave pairing state can be represented as

\[ U_{i,i+x} = -\tau^3 \chi + \tau^1 \Delta \]

\[ U_{i,i+y} = -\tau^3 \chi - \tau^1 \Delta \]

\[ a_{0i}^3 \neq 0 \]

The key difference to the sF (U1Cu01n) phase is the appearance of a finite \( a_{0i}^3 \) which acts as a chemical potential for the spinons. Without this term the above ansatz
is SU(2)-gauge equivalent to the sF (U1Cn01n) ansatz. It is shown in Ref. that the appearance of such a chemical potential term is not consistent with the quantum order of the sF (U1Cn01n) phase and hence signals the presence of a different quantum order accompanying the d-wave pairing state. It is precisely a nonzero $a_0^2$ which gives rise to an anomalous fermion-fermion pairing which when combined with holon condensation leads to the d-wave superconducting state. As we shall see in the following, $a_0^2$ is also responsible for the incommensurate spin response at the lowest frequencies shifting the peak away from $Q_{\text{AF}} = (\pi, \pi)$.

Taking the above ansatz equation we can calculate the spin-spin correlations at mean-field level (see Appendix E) to obtain for the imaginary part of the spin correlation near $Q_{\text{AF}} = (\pi, \pi)$.

$$\text{Im}(S^+(\omega, Q_{\text{AF}} + k)S^-(\omega, -Q_{\text{AF}} - k))$$

$$= \frac{1}{64v_f v_2} \left\{ \theta \left[ \omega^2 - (v_f k_1 + 2a_0^3)^2 - v_2^2 k_2^2 \right] \sqrt{\omega^2 - (v_f k_1 + 2a_0^3)^2 - v_2^2 k_2^2} + \theta \left[ \omega^2 - (v_f k_1 - 2a_0^3)^2 - v_2^2 k_2^2 \right] \sqrt{\omega^2 - (v_f k_1 - 2a_0^3)^2 - v_2^2 k_2^2} + \theta \left[ \omega^2 - (v_f k_2 + 2a_0^3)^2 - v_1^2 k_1^2 \right] \sqrt{\omega^2 - (v_f k_2 + 2a_0^3)^2 - v_1^2 k_1^2} + \theta \left[ \omega^2 - (v_f k_2 - 2a_0^3)^2 - v_1^2 k_1^2 \right] \sqrt{\omega^2 - (v_f k_2 - 2a_0^3)^2 - v_1^2 k_1^2} \right\}$$

$$k_1 = \frac{k_x + k_y}{\sqrt{2}} \quad k_2 = -\frac{k_x + k_y}{\sqrt{2}} \quad v_f = 2\sqrt{2}aJ \quad v_2 = 2\sqrt{2}aJ$$

\[ (27) \]

In Fig. 6 we plot the resulting spectrum for a frequency $\omega < \omega_c \approx \frac{1}{\sqrt{3}} \left( \frac{v_f}{v_j} \right) a_0^2$ where the intensity is peaked around four points shifted diagonally away from $Q_{\text{AF}}$. In contrast to this in Fig. 7 we depict a scan for $\omega > \omega_c$ the spectrum is peaked at four points shifted horizontally $(\pi \pm \delta, \pi)$, $(\pi, \pi \pm \delta)$ where the ridges - growing out perpendicular to the diagonals - overlap. $\delta$ is related to $a_0^2$ via $\delta a = a_0^2$ with $a$ the lattice spacing. It should be noted that in the $\omega \to 0$ the peaks are always located along the diagonal, as expected, for in this regime the response is dominated by creation of particle hole pairs connecting the Fermi points. Interestingly for intermediate energies the peak intensity in the spectrum is shifted horizontally away from $Q_{\text{AF}}$ even without one dimensional phenomenology.

FIG. 6: Wave vector scan of $\chi''(k_x, k_y, \omega = 0.1J)$. Notice the incommensurate pattern at low energy with amplitude peaks shifted along the diagonals. $(0,0)$ corresponds to $Q_{\text{AF}}$ and $k_x, k_y$ are measured in units of $1/a$ with $a$ the lattice spacing.

FIG. 7: Wave vector scan of $\chi''(k_x, k_y, \omega = 0.1J)$, $k_x, k_y$ are measured in units of $1/a$. With $a_0^2$ chosen to give $\delta a = 0.1$ r.l.u. $(2\pi = 1$ r.l.u.), the value of $\omega_c$ is set by $\omega_c = \frac{v_f}{v_j} \left( \frac{2\pi}{a} \right) \delta a J$. To compare with experiments we have chosen the values $\frac{v_f}{v_j} = 1$, which gives $\omega_c = 0.2J$. Notice how the overlapping ridges lead to the horizontal incommensuration.
VI. APPLICATION TO HIGH $T_C$

Before launching into a discussion of how the above mentioned physics embodied in the ASL might shed some light on the cuprate spin physics we need to briefly digress and establish some nomenclature. As we shall see in the following each experimental community has their own set of pseudo/spin-pseudo-gaps and it is easy to get lost in the confusing terminology. Here we adopt the following convention:

*pseudo-gap* phase denotes the part in the cuprate phase diagram where angle resolved photoemission experiments observe a large gap in the single particle spectrum at $(\pi, 0)$

The term *spin-pseudo-gap* will be used in conjunction with the spectrum at the antiferromagnetic wavevector $Q_{AF} = (\pi, \pi)$ to denote the frequency range of reduced spectral weight below the peak above $T_c$ (which on cooling below $T_c$ shifts to higher frequencies and becomes the “resonance” - see discussion below).

Over the years NMR and inelastic neutron scattering (INS) have painted a very interesting picture for the spin correlations in the cuprates starting with the discovery of the by now famous $41 \text{meV}$ “resonance” peak by J. Rossat-Mignod et al. in the superconducting state of near optimally doped YBCO. In addition to this resonance mode which appears exclusively in the superconducting state there is now evidence for precursory piling up of spectral weight in the energy region of the “resonance” even in the normal state of underdoped cuprates. The energy at which this enhancement occurs in the normal state is sometimes referred to as the “spin-pseudo-gap” energy by INS workers (hence our convention). From the perspective of spin fluctuations INS is clearly the most powerful probe giving both dynamical and wavevector dependent information about the spectrum.

NMR on the other hand probes particular regions in wavevector space with Knight shift probing the uniform susceptibility $\propto \chi(q = 0, \omega \sim 0)$ - and spin lattice relaxation rate probing $\propto \text{Im} \chi(q_c, \omega \sim 0)$ where $q_c$ is the characteristic wavevectors determining the spin lattice relaxation at the planar $C_u$ and $O$ sites respectively. In addition to the above mentioned “spin-pseudo-gap”, NMR has identified two characteristic temperatures. One is the reduction of the Knight shift below a temperature which we will denote by $T_N$ which indicates the loss of spectrum for $\chi(q = 0, \omega \sim 0)$ below this characteristic temperature. Furthermore there is a second lower scale which shows up in the spin lattice relaxation rate for $C_u$ as a peak in $\frac{1}{T} \gamma(T)$ which we shall call $T_c$. Notice that $T_c < T_N$ but both of these temperatures are above the superconducting transition temperature $T_c$ in underdoped samples. From the perspective of mean-field theory it is impossible to explain these observations. Within the mean-field picture the reduction of the Knight shift below $T_N$ can be related to the reduction of spin fluctuations on condensing into the spin singlet sector identified as the sF (U1Cu01n) phase above. However there is then no way to explain the difference in the spin lattice relaxation rates observed for planar $C_u$ and $O$. Whereas $\frac{1}{T} \gamma(T) C_u$ increases with decreasing temperature between $T_N > T > T_c$, $\frac{1}{T} \gamma(T) O$ reduces monotonically below $T_N$.

Let us now discuss these interesting phenomena from the point of view of the ASL physics described in the previous part. As has been suggested by Kim and Lee the enhancement of $C_u$ over $O$ relaxations is expected to depend on the inclusion of the gauge fluctuations. The rational for this suggestion arises from the fact that $C_u - NMR$ probes $q \sim Q_{AF}$-fluctuations which are strongly affected by the gauge fluctuations whereas $O - NMR$ derives its main contributions from $q \sim 0$ which is protected from gauge fluctuations by current conservation. We have shown above that this enhancement indeed takes place with $\text{Im} \chi_{q_{AF}}$ (see Fig.[3]) being strongly increased over the mean-field behavior which determines the spin fluctuations at $q = 0$. Given the different $T$-dependence for the spin lattice relaxation rates for temperatures $T_N > T > T_c$, it is thus natural to identify this regime with the ASL physics.

Sternlieb et al. have performed temperature dependent neutron-scattering experiments on $YBa_2Cu_3O_{6.6}(T_c = 53K)$ and found a universal dependence of

$$\text{Im} \chi(\omega) = \int \text{Im} \chi(q, \omega) dq \propto \text{Im} \chi(Q_{AF}, \omega)$$

on the ratio $\omega/T$ above a temperature $T \sim 100K$. Their data (see Fig.8) suggests that the temperature at which this universal scaling appears increases with decreasing energy. In particular for $\omega = 5 \text{meV}$ the onset temperature is $T \sim 100K$. Below this characteristic temperature (which again is well above $T_c$) their data shows a decrease in spectrum which they associate with the open-
sF-singlet correlations as low as this temperature scale both the scale which we associate with a temperature \( T/\omega \) and the characteristic frequency \( \omega \) decreases with decreasing probe-frequency are consistent with the anomalous behavior of \( 1/T_1(T)_{Cu} \) which probes \( \omega \sim 0 \) and increases down to \( T = T_{T_1} \sim 150K \).

As we argued above it is exactly the regime for \( \omega > m \) at \( T \approx 0 \) or \( T > T_m \) at \( \omega \sim 0 \) that we associate with the ASL physics. Under the assumption of perfect scaling we can thus account for the difference in \( 1/T_1(T) \) between \( C_u \) and \( O \) quite naturally. From

\[
\frac{1}{T_1T} \propto \sum q \frac{\text{Im} \chi(q,\omega)}{\omega} \bigg|_{\omega \rightarrow 0}
\]

(29)

where for \( C_u \): \( \sum q \sim Q_{AF} \) due to the form factor whereas \( O \) probes the uniform spin fluctuations. In the ASL we can for \( C_u \) approximate \( \sum q \frac{\text{Im} \chi(q,\omega)}{\omega} \bigg|_{\omega \rightarrow 0} \sim \text{Im} \chi(Q_{AF},\omega) \bigg|_{\omega \rightarrow 0} \) which via scaling results in

\[
\frac{1}{T_1T}(C_u) \propto \frac{1}{T^{2\nu-1}} \quad 2\nu = \frac{32}{3\pi^2}
\]

(30)

whereas \( \frac{1}{T_1T}(T)_{O} \) falls monotonically as \( T \) is reduced following the uniform susceptibility (see Fig.3). As \( 2\nu - 1 \sim 0 \) this is consistent with the weak temperature dependence seen by Sternlieb et al Fig.8 at large \( T/\omega \).

The ASL gets destroyed below the massgap energy scale which we associate with a temperature \( T_m \). Below this temperature scale both the \( C_u \) and the \( O \) spin lattice relaxation rates fall monotonically following the sF-singlet correlations as \( T \) is reduced. This is seen in experiments (see Fig.3).

Thus we associate the temperature \( T_{T_1} \sim 150K \) where \( \frac{1}{T_1T}(T)_{Cu} \) shows the peak with \( T_m \) the temperature below which the massless \( U(1) \) gauge structure (and thus the underlying quantum order) becomes unstable and undergoes a “transition” (see discussion at the end of this section)

To summarize the above comparison between the ASL and NMR experiments, we present the phase diagram Fig.10. Below the pseudo-gap scale \( T_{pg} \), which we associate with \( T_N \), the oxygen \( 1/T_1T \) starts to decrease due to the opening of the pseudo-gap associated with the spin singlet formation. However, the copper \( 1/T_1T \) keeps increasing as temperature decreases, despite the small single particle density of states in the pseudo-gap regime. This strange behavior can be explained very well by the ASL due to the diverging AF spin fluctuations at low energies even in the presence of the pseudo-gap. Below the temperature \( T_m \), the \( U(1) \) gauge field starts to gain a gap and the enhancement in the AF spin fluctuations ceases to exist. This causes the copper \( 1/T_1T \) to decrease with decreasing temperature following the expected mean-field behavior. Thus the ASL described by the sF state (or the U1Cn01n state) appears between \( T_m \) (associated with the experimental temperature scale \( T_{T_1} \)) and \( T_{pg} \) (associated with the experimental scale \( T_N \)). Below \( T_m \), the ASL will change into another state whose nature will be discussed later.

Let us now discuss the INS results which in their own right paint a very interesting picture of the spin fluctuations in the cuprates. First we consider the spectra at the antiferromagnetic ordering wavevector as a function of temperature and energy. Already well above the superconducting transition in the normal state, INS data show a marked increase in spectral weight at a finite characteristic frequency \( E_{spg} \) and a reduced spectral weight for \( \omega < E_{spg} \) (the spin-pseudo-gap see Fig.1) bottom curve and compare Fig.3). On cooling below \( T_c \) this gap increases in size and the corresponding peak shifts to higher energies as depicted in Fig.1 where we have added the two dashed lines to the data taken by Fong et al to guide the readers eye. From the perspective of the ASL liquid the “normal state” above \( T_c \) corresponds to

FIG. 9: Temperature dependence of \( 1/T_1(T)_{Cu} \) and \( 1/T_1(T)_{O} \) in \( YBa_2Cu_3O_{6.63} \). The dotted-dashed line shows the temperature dependence of the static susceptibility. The data is taken from [1] who quotes Takigawa’s results

FIG. 10: Phase diagram implied by NMR experiments.
FIG. 11: Energy dependence of peak intensity at $Q_{AF}$ as a function of temperature taken from Fong et al. Note the shift in the peak position on decreasing the temperature below $T_c = 67\,K$ (the dashed lines were added by the current authors as a guide to the eye - see main text).

FIG. 12: The energy of the peak in the superconducting state - also called the resonance energy $E_{\text{resonance}}$ as a function of $T_c$ in underdoped $YBCO$. Data taken from Dai et al. By extrapolating the linear relationship down to $T_c = 0$ (dashed line added as a guide) we extract an estimate for the mass scale related to topological gauge fluctuations.

FIG. 13: Contour plot of $\text{Im} \chi$ - notice the “spin-pseudo-gap” at $(q) = 0 \equiv Q_{AF} = (\pi/a, \pi/a)$ for energies below $m = 20\,meV$ and the dispersion above $m$.

FIG. 14: Spin excitation spectrum for odd (open symbols) and even (closed circles) excitations at 5K. The open square indicates the energy of the maximum of the odd susceptibility. The dotted lines correspond to the spin-wave dispersion relation in the insulating antiferromagnetic state with $J_{||} = 120\,meV$. This Fig is taken from Bourges et al.

FIG. 15: for underdoped $YBCO$. Furthermore we can account for the very different doping dependence of the normal state maximum (determined by the instanton scale with weak doping dependence) versus the doping dependence of $E_{\text{resonance}}$ (determined by the condensed bosons $\propto x$) as was stressed in a recent article by Ph. Bourges.

From this understanding of the ASL, we can conclude immediately that, $T_m$ the temperature of the spin-pseudo-gap formation (and hence $T_{T_1}$) should be rather insensitive to changes in doping. Contrast this with the doping dependence of $T_{pg}$ the formation of the pseudo-
gap in the single particle spectrum which as \( x \to 0 \) will get as large as the spin-wave band width, since in that limit the ASL will be described by the \( \pi \)-flux phase.

Another interesting point to discuss about the INS data is their momentum dependence. In Fig. 14 we show the data by Bourges et al taken on \( Y'\text{Ba}_2\text{Cu}_3\text{O}_{5.5}(T_c = 52) \) which shows the spin excitation spectrum for odd (acoustic) and even (optical) excitations at high energies. The dotted lines correspond to the spin-wave dispersion relation in the insulating antiferromagnetic state. The dispersive behavior compares nicely with Fig. 13 the correlations in the ASL liquid above the mass scale \( m \sim 20\text{meV} \).

So far we have argued for the strange phenomenology of the pseudo-gap phase to be tied to the physics embodied in the ASL. It is however clear that the ASL physics has to give way to the superconducting state at low temperatures. An important question is how this transition happens. Let us then briefly mention three plausible scenarios for how the ASL goes over to the superconducting state. In other words, we would like to understand how the \( U(1) \) gauge field gains a mass term which leads to the destruction of the ASL state.

In the first picture the mass of the \( U(1) \) gauge field is generated via confinement due to instantons. After the opening of the energy gap, there is no residual unbroken gauge structure left at low energies. Thus the confinement can also be referred to as \( U(1) \) gauge structure breaking down to \( Z_1 \). \( (Z_1 \) gauge structure means no gauge structure.) In the confinement phase (i.e. after the \( U(1) \) gauge field is gapped), the spinons and holons recombine into electrons which appear as the relevant degrees of freedom at low energies. Thus we also call the first picture spin-charge recombination. This in particular would suggest the existence of well defined quasiparticles at low energies (as probed by ARPES) even above the superconducting transition temperature \( T_c \). (This should also be accompanied by \( T^2 \) resistance in dc conductivity.) Furthermore the binding of spinons and holons will give rise to Fermi arcs.

In the second picture, the \( U(1) \) gauge structure also breaks down to the \( Z_1 \) gauge structure, but now via holon condensation. In this case, \( T_m = T_c \) and the ASL directly transforms into the \( d \)-wave superconducting state. There are no well defined quasi particles above \( T_c \).

A third scenario might be the breaking of the \( U(1) \) gauge structure down to a \( Z_2 \) gauge structure via the condensation of spinon bi-linear terms which do not break any symmetries (\( \alpha Z_2 \) gauge structure was also found in a slave-fermion description of spin systems via the condensation of boson bi-linear terms which break 90° rotation symmetry). The \( Z_2 \) gauge structure can also be obtained via the condensation of bound states of double vortices. The breaking from \( U(1) \) to \( Z_2 \) also results in a mass for the \( U(1) \) gauge field and leads to a new \( Z_2 \) spin liquid. The transition to this new topological/quantum ordered phase implies the appearance of \textit{true} spin charge separation since the \( Z_2 \) gauge interaction is only short ranged (Senthil experiment).

To determine which scenario actually applies to real high \( T_c \) samples, we need to rely on experiments. In the following we would like to argue that experiments suggest the first scenario as most plausible in the high \( T_c \) samples. The appearance of Fermi arcs in the first scenario implies a small energy scale \( \Delta_{\text{SCspin}} \) for the spin excitations associated with the superconducting state. (See Fig. 13) Such a small energy scale was observed in the experiment of Ref. 45 (see Fig. 16), where it was found that the spin susceptibility \( \chi(\omega) \) decreases below \( T_c \) only when \( \omega < 4\text{meV} \). This indicates that \( \Delta_{\text{SCspin}} \) is as small as a few meV. Direct evidence for Fermi arcs comes from their observation in a recent photoemission experiment 44. The expected well defined electron-like quasiparticles near the Fermi arcs were also observed.

VII. CONCLUSION AND OPEN QUESTIONS

In this paper we have given an account of the spin correlations in the ASL phase through the calculation of \( O(1/N) \) contributions depicted in Fig. 1. It was shown how the gauge fluctuations strongly enhance the staggered spin correlations leaving the uniform spin corre-
tion unaffected. This result is very natural within this gauge fluctuation picture where the uniform spin correlation is protected by current conservation and cannot have any anomalous dimension. From this perspective it is also easy to account for the qualitative different behaviors of planar $C_u$ and $O$ spin lattice relaxation rates seen in NMR experiments where $C_u$ probes the enhanced staggered correlations of the ASL down to a temperature scale $T_m \sim T_1$, where the $C_u = 1/(T_1(T))$ peaks, which we associate with the appearance of an energy gap in the gauge spectrum. What is really remarkable in the ASL picture is that enhanced staggered spin correlations are obtained while at the same time having a small single particle density of states within the pseudo-gap phase without any fine tuning. As the doping $x$ decreases, the pseudo-gap increases and, surprisingly, the staggered spin correlations also increase. This strange experimental behavior is explained naturally by the ASL picture.

It should be noted here that our ASL shows qualitative similarities with the quantum critical point scenario of Refs. 47. However as was stressed in the paper, the appearance of the pseudo-gap which they associate with the suppression of the spectral weight of spin waves characteristic of the quantum disordered (QD) regime should affect the low frequency dynamics for both $\mathbf{q} = 0$ and $\mathbf{q} = (\pi, \pi)$. Within this framework it then seems hard to account for the qualitative different behaviors seen at the $C_u$ and $O$ sites in NMR experiments. As we have stressed many times within the ASL this difference is protected by the $U(1)$ gauge structure. Also, in our ASL approach, we do not assume, in contrast to the quantum-critical-point approach, any nearby symmetry breaking phase and we do not require any strongly fluctuating order parameters to give us critical behavior. The ASL can by itself appear as a stable quantum phase, or as a phase transition point between two states with new kinds of order - quantum order. The two states can have the same symmetry and no order parameters. Hence the ASL associated with the transition between quantum orders can show scaling properties divorced from any critical point studied so far.

From this perspective the ASL is just one of a whole slew of possible quantum orders characterized by a massless $U(1)$ gauge field coupled to massless Dirac fermions. It is also clear that the destruction of the ASL via the transition into a phase with a massive $U(1)$ gauge field (phenomenologically described above via the introduction of the mass-scale $m$) demands a much more careful analysis and highlights the main difficulty with the slave boson approach to the $tJ$-model. Within this scheme it currently seems to be impossible or at least very challenging to describe this energy/temperature regime around $m/T_m$ theoretically. The reason for that is related to the need of introducing a scale which is not tied to boson condensation and hence divorced from the mean-field energies and the corresponding degrees of freedom.

Through our examination of the experimental data, we find that the ASL, plus spin-charge recombination at lower energies, provides a consistent and natural (with no fine tuning) description of underdoped cuprate superconductors. This is the main result and the bottom line of this paper.

We would like to thank P. A. Lee and M. Kastner for many helpful discussions. W.R. would particularly like to thank A. Seidel, for his mathematical insights. This work is supported by NSF Grant No. DMR–01–3156 and by NSF-MRSEC Grant No. DMR–98–08941.

**APPENDIX A: SPIN OPERATORS IN THE CONTINUUM LIMIT**

In this appendix we derive the expression for the spin operators near $\mathbf{q} = (0,0), (\pi, \pi)$ and $(\pi, 0)$ in terms of the spinon field $\Psi$ defined near the four nodes in momentum space.

Let us look at the staggered correlation in detail.

$$\tilde{S}(\mathbf{Q} + \mathbf{q}) = \frac{1}{2} \sum_{\mathbf{p}} f^\dagger(\mathbf{p} - \mathbf{q}) \tilde{\sigma} f(\mathbf{p} + \mathbf{Q}) \quad (A1)$$

where $\mathbf{Q} = (\pi/a, \pi/a)$ and we have suppressed the frequency index. After introducing

$$f_e \equiv \frac{1}{\sqrt{2}} (f(\mathbf{q}) + f(\mathbf{q} + \mathbf{Q}))$$

$$f_o \equiv \frac{1}{\sqrt{2}} (f(\mathbf{q}) - f(\mathbf{q} + \mathbf{Q})) \quad (A2)$$

the expression for the staggered spin operator can be rewritten

$$\tilde{S}(\mathbf{Q} + \mathbf{q}) = \frac{1}{4} \sum_{\mathbf{p}} [f^\dagger_e(\mathbf{p} - \mathbf{q}), f^\dagger_o(\mathbf{p} - \mathbf{q})] \tilde{\sigma}(\sigma_1 - i\sigma_2) \left( f_e(\mathbf{p}) \right) \quad (A3)$$
Splitting the sum $\sum_p = \sum_Q + \sum_{\tilde{Q}}$, where $\bar{Q} = (\pi/2, \pi/2)$ $\tilde{Q} = (-\pi/2, -\pi/2)$ yields

\[
\tilde{S}(Q + q) = \frac{1}{\tilde{\mathcal{Q}}} \sum_k \left[ f^\dagger_k (k - q + \bar{Q}), f^\dagger_o (k - q + \tilde{Q}) \right] \sigma_3 + \frac{1}{\tilde{\mathcal{Q}}} \sum_{k'} \left[ f^\dagger_o (k' - q + \tilde{Q}), f^\dagger_o (k' - q + \bar{Q}) \right] \sigma_3 \tag{A4}
\]

Noting $\tilde{Q} = \tilde{Q} + Q$ and using $f_e (p + Q) = f_e (p)$ $f_o (p + Q) = -f_o (p)$ we arrive at

\[
\tilde{S}(Q + q) = \frac{1}{2} \sum_k \left[ f^\dagger_k (k - q + \bar{Q}), f^\dagger_o (k - q + \tilde{Q}) \right] \sigma_3 \left( f_e (k + \tilde{Q}) \right) \tag{A5}
\]

where $\bar{\Psi}_1 (k - q) = \left( f^\dagger_k (k - q + \bar{Q}), -f^\dagger_o (k - q + \bar{Q}) \right)$ and $k$ is measured away from the node of type $1 \equiv \bar{Q} = \pm (\pi/2, \pi/2)$. The remaining contribution arises from the other two nodes in the spectrum at $\pm (\pi/2, -\pi/2)$.

Following the same calculation for the uniform correlation function

\[
\tilde{S}(Q_1 + q) = \frac{1}{2} \sum_p f^\dagger (p - q) f (p) \tag{A6}
\]

we find

\[
\tilde{S}(Q + q) = \frac{1}{2} \sum_k \bar{\Psi}_1 (k - q) \sigma_3 \tilde{\Psi}_1 (k) \tag{A7}
\]

with $\bar{\Psi}_1 (k - q) = \left( f^\dagger_k (k - q + \bar{Q}), -f^\dagger_o (k - q + \bar{Q}) \right)$ and $k$ is measured away from the node of type $1 \equiv \bar{Q} = \pm (\pi/2, \pi/2)$. As before the remaining contribution arises from the other two nodes.

The correlation near $Q = (\pi, 0)$ is obtained in a similar fashion the only difference here is that for this momentum transfer the two types of nodes get mixed and hence when we split up the sum over momentum space we need to consider all four nodes simultaneously. Under this proviso the calculation goes through as above and we end up with

\[
\tilde{S}(Q + q) = \frac{1}{2} \sum_k \bar{\Psi}_1 (k - q) \left( \begin{array}{c} 0 \\ \sigma_1 \\ 0 \end{array} \right) \tilde{\Psi}_1 (k) \tag{A8}
\]

where

\[
\bar{\Psi}_1 (k - q) = \left[ f^\dagger_k (k - q + Q_1), -f^\dagger_o (k - q + Q_1), -f^\dagger_o (k - q + Q_2), f^\dagger_o (k - q + Q_2) \right]
\]

with $Q_1 = (\pi/2, \pi/2)$ and $Q_2 = (\pi/2, -\pi/2)$

**APPENDIX B: TWO-LOOP CALCULATION OF SPIN CORRELATION**

We employ a four dimensional representation of the Dirac algebra $\{ \gamma_\mu, \gamma_\nu \} = 2 \delta_{\mu\nu}$ $(\mu, \nu = 0, 1, 2)$ in the main body of the paper ie $Tr 1 = 4$. To perform the $Tr$ over the spinor indices we need the following identity

\[
Tr \left[ \gamma^\epsilon \gamma^\delta \gamma^\mu \gamma^\nu \gamma^\alpha \right] = \delta^{\epsilon\mu} Tr \left[ \gamma^\delta \gamma^\alpha \right] - \delta^{\alpha\mu} Tr \left[ \gamma^\delta \gamma^\nu \right] + \delta^{\alpha\nu} \left[ \gamma^\delta \gamma^\mu \gamma^\nu \right] - \delta^{\alpha\delta} \left[ \gamma^\gamma \gamma^\mu \gamma^\nu \right] + \delta^{\alpha\gamma} \left[ \gamma^\delta \gamma^\mu \gamma^\gamma \right]
\]

which can be simply derived from the Dirac algebra by commuting $\gamma$-matrices through and using the cyclic property of the trace $Tr$. Using the above identity we can simplify

\[
[1(A)] = \int \frac{d^d k}{(2\pi)^d} \int \frac{d^d q}{(2\pi)^d} Tr \left[ \frac{8 \left( p + k + q \right) \gamma^\epsilon \gamma^\delta \gamma^\mu \gamma^\nu \gamma^\alpha k \left( \delta_{\mu\rho} q^\rho - q_{\mu q} \right) \left( p^2 + k^2 \right) \left( k^2 + q^2 \right) \left( q^2 \right) \right] \left( \delta_{\rho\mu} q^\rho - q_{\rho q} \right) \right] \tag{B1}
\]
Therefore we set via a momentum cut-off (such divergences do not appear in Lorentz invariant regularization schemes). Thus after the \( \vec{p} \), \( \vec{k} \), \( \vec{q} \), \( \vec{p} \cdot \vec{k} - \vec{q} \cdot \vec{q} \)

\[
\begin{align*}
[1(A)] &= \frac{64}{N} \int \frac{d^d k}{(2\pi)^d} \int \frac{d^d q}{(2\pi)^d} \left[ \frac{\vec{k}^2 (\vec{p} + \vec{k}) \cdot \vec{q} (\vec{k} + \vec{q}) \cdot \vec{q} - 2 (\vec{p} + \vec{k}) \cdot \vec{k} (\vec{k} + \vec{q}) \cdot \vec{q} \cdot \vec{q}}{(\vec{p} + \vec{k})^2 (\vec{p} + \vec{q})^2 |\vec{q}|^4} \right] \\
[1(C)] &= \int \frac{d^d k}{(2\pi)^d} \int \frac{d^d q}{(2\pi)^d} \text{Tr} \left[ \frac{8 (\vec{p} + \vec{k}) \cdot \vec{q} \cdot \vec{q} - 2 (\vec{p} + \vec{k}) \cdot \vec{k} (\vec{k} + \vec{q}) \cdot \vec{q} \cdot \vec{q}}{(\vec{p} + \vec{k})^2 (\vec{p} + \vec{q})^2 (\vec{k} + \vec{q})^2 |\vec{q}|^3} \right].
\end{align*}
\]

where

\[
F(\vec{q}, \vec{k}, \vec{p}) = \left[ \frac{\vec{k}^2 (\vec{q}^2 \vec{k}^2 - \frac{1}{2} \vec{k} \cdot \vec{q} \vec{q} + 2 \vec{k} \cdot \vec{q} \vec{q}^2 + \vec{k} \cdot \vec{p} \vec{q} \cdot \vec{p} - \frac{1}{4} \vec{q}^2 \vec{p}^2 + \vec{q}^2 + (\vec{q} \cdot \vec{p})^2)}{(\vec{p} + \vec{k})^2 (\vec{p} + \vec{q})^2 (\vec{k} + \vec{q})^2 |\vec{q}|^3} \right]
\]

In both expressions the integration over \( \vec{k} \) is convergent in \( d = 3 \) and can be performed noting that

\[
\begin{align*}
\int \frac{d^d k}{(2\pi)^d} \frac{1}{\vec{k}^2 (\vec{k} + \vec{p})^2 (\vec{k} + \vec{q})^2} &= \frac{1}{8|\vec{p}||\vec{q}| |\vec{q} - \vec{p}|} \\
\int \frac{d^d k}{(2\pi)^d} \frac{1}{\vec{k}^2 (\vec{k} + \vec{p})^2 (\vec{k} + \vec{q})^2 (\vec{k} + \vec{q})^2} &= \frac{1}{8|\vec{p}||\vec{q}| |\vec{p} + \vec{q}|} \left[ \frac{1}{|\vec{p} - \vec{q}|} - \frac{1}{|\vec{q} + \vec{p}|} \right].
\end{align*}
\]

Thus after the \( \vec{k} \) integration we arrive at

\[
\begin{align*}
[1(A)] &= \frac{2}{N} \int \frac{d^d q}{(2\pi)^d} \left[ \frac{2 \vec{p} \cdot \vec{q} + \vec{p}^2}{|\vec{q}|^3 |\vec{p} + \vec{q}|} - \frac{\vec{p} \cdot \vec{q} - |\vec{p}|}{|\vec{q}|^3} \right] \\
[1(C)] &= \frac{4}{N} \int \frac{d^d q}{(2\pi)^d} \left[ \frac{2 |\vec{p}|}{|\vec{q}|^2} + \frac{4 |\vec{p}|}{|\vec{q}|^3 |\vec{p} + \vec{q}|} - \frac{\vec{p} \cdot \vec{q} - |\vec{p}|}{|\vec{q}|^3} - \frac{2 \vec{p} \cdot \vec{q} + \vec{p}^3}{|\vec{q}|^3 |\vec{p} + \vec{q}|} \right].
\end{align*}
\]

Adding the contributions

\[
2 \times [1(A)] + [1(C)] = \frac{4}{N} \int \frac{d^d q}{(2\pi)^d} \left[ \frac{2 |\vec{p}|}{|\vec{q}|^2} - \frac{4 |\vec{p}|}{|\vec{q}|^3 |\vec{p} + \vec{q}|} - \frac{\vec{p} \cdot \vec{q} - |\vec{p}|}{|\vec{q}|^3} - \frac{2 \vec{p} \cdot \vec{q} + \vec{p}^3}{|\vec{q}|^3 |\vec{p} + \vec{q}|} \right].
\]

As noted previously because of the \( \vec{p} \cdot \vec{q} \) term in the denominator of the last term above we won't use dimensional regularization. Therefore we set \( d = 3 \) and introduce an upper cut-off \( \Lambda \) to regularize the above integrals. Also note that we will neglect the first term in \( [B8] \) which is linearly divergent whose appearance is tight to the regularization via a momentum cut-off (such divergences do not appear in Lorentz invariant regularization schemes).

Under this proviso we obtain the following result for the last three terms in \( [B8] \)

\[
\begin{align*}
\frac{4}{N} \left[ -\frac{8 |\vec{p}|}{4\pi^2} - \frac{4 |\vec{p}|}{4\pi^2} ln \frac{\Lambda^2}{\vec{p}^2} + \frac{2 |\vec{p}|}{36\pi^2} + \frac{|\vec{p}|}{12\pi^2} ln \frac{\Lambda^2}{\vec{p}^2} + \frac{|\vec{p}|}{8\pi^2} (C_1 + C_2) + \frac{2 |\vec{p}|}{8\pi^2} ln \frac{\Lambda^2}{\vec{p}^2} \right]
\end{align*}
\]

where the last term \( [B9] \) is given by

\[
\begin{align*}
\int \frac{d^3 q}{(2\pi)^d} \frac{\vec{q} \cdot \vec{q}^2 + \vec{p} \cdot \vec{q}^2 + 2 \vec{p} \cdot \vec{q}^2}{|\vec{p} + \vec{q}|^2} &= \frac{|\vec{p}|}{8\pi^2} \left[ \int_0^1 dy \frac{2 + y}{y(1 + y)} ln \frac{\sqrt{1 + y}}{\sqrt{1 + y} - \sqrt{y}} + \int_1^{\frac{\Lambda^2}{\vec{p}^2}} dy \frac{2 + y}{y(1 + y)} ln \frac{\sqrt{1 + y} - 1}{\sqrt{1 + y} + 1} \right] \\
&= -\frac{|\vec{p}|}{8\pi^2} \left( C_1 + C_2 + 2 ln \frac{\Lambda^2}{\vec{p}^2} \right)
\end{align*}
\]
and
\[ C_1 = -\int_0^1 dy \frac{2 + y}{y\sqrt{1 + y}} \ln\frac{\sqrt{1 + y} - \sqrt{y}}{\sqrt{1 + y} + \sqrt{y}} = 7.748128723 \]
\[ C_2 = 4\ln(\sqrt{2} - 1) + 4 + \ln(3 - 2\sqrt{2})^2 - 2\ln(3 - 2\sqrt{2}) + 2\ln(3 - 2\sqrt{2})\sqrt{2} = 2.121475665 \]

Finally extracting the logarithmically divergent terms we arrive at the result stated in the body of the text.

**APPENDIX C: ANALYTIC CONTINUATION OF 1/N CORRECTION**

Having obtained the $1/N$ correction we would now like to reexponentiate our result in the form
\[ \langle S_x^+(\vec{q})S_x^-(\vec{q}) \rangle_0 = -\frac{\sqrt{q^2}}{16} - \frac{8}{12\pi^2 N \sqrt{q^2}} \ln \left( \frac{\Lambda^2}{q^2} \right) \sim -\frac{\Lambda^{2\nu}}{16} (q^2)^{1/2-\nu} \quad \nu = \frac{32}{3\pi^2 N} \]

This however immediately confronts us with the problem that after analytically continuing $C_1$ the susceptibility has the wrong sign for $2\nu > 1$. It is however hard to understand why the spin operator cannot have an anomalous dimension bigger than $\frac{1}{2}$. In order to analyze this issue it is helpful to look at the corresponding Euclidean real space correlations. Let’s take the case of a general staggered spin correlation of the form
\[ \langle S_x^+(\vec{x})S_x^-(0) \rangle = \frac{1}{16\pi^2} (-1)^x \frac{C}{|\vec{x}|^{4-2\nu}} \]

where the spin operator has anomalous dimension $\nu$. We now Fourier transform this to obtain
\[ \frac{1}{4\pi} |q|^{1-2\nu} \int_0^\infty \frac{du}{u^{3-2\nu}} \sin(u) \]

For $0 < |Re(2\nu - 2)| < 1$ this can be evaluated to give
\[ \frac{1}{4\pi} \Gamma(2\nu - 2) \sin((\nu - 1)\pi)|q|^{1-2\nu} \]

This leads after analytic continuation to the result equation (16). From here it is easy to see how the $\Gamma$-function and the $\sin$ which are missed in the naive exponentiation of the Euclidean momentum space result conspire to give the correct sign for the spin correlation no matter what the size of the anomalous dimension. In particular we can continue the above for the case $\nu \to 0$ to give the correct mean-field result.

**APPENDIX D: TWO-LOOP CALCULATION IN THE MASSIVE PHASE OF THE U(1) GAUGE FIELD**

This appendix gives some details of the calculation leading to the $O(1/N)$ corrections to the staggered spin correlation in the case when the gauge field is in the massive phase with propagator
\[ D_{\mu\nu}(\vec{q}) = \frac{8}{N\sqrt{q^2 + m^2}} (\delta_{\mu\nu} - \frac{q_\mu q_\nu}{q^2}) \]

We can use the results derived in Appendix A for the integrals over $\vec{k}$ (B8) since they are unaffected by the change in the gauge propagator.

\[ 2[1(A)] + \boxed{C} = \frac{4}{N} \int \frac{d^d q}{(2\pi)^d} \left[ -\frac{4|\vec{p}|}{|\vec{q}|}\frac{1}{\sqrt{q^2 + m^2}} - \frac{\vec{p} \cdot \vec{q}}{|\vec{q}|\sqrt{q^2 + m^2}} - \frac{\vec{q}^2 \vec{p}^2}{|\vec{q}|^2} - \frac{1}{9\pi^2 p^2} \left( \frac{p^2 + m^2)^3}{2} - m^3 \right) \right] \]

where we have neglected the linearly divergent term as discussed above. After integration over $\vec{q}$ in $d = 3$ we arrive at
\[ \frac{4}{N} - \frac{2}{\pi^2} \left( \sqrt{p^2 + m^2^2} - m \right) - \frac{2|\vec{p}|^2}{\pi^2} \ln \left( \frac{\Lambda}{|\vec{p}|} \right) \frac{2}{\pi^2} + \frac{2\Lambda}{\pi^2} \frac{2}{6\pi^2} - \frac{2}{9\pi^2 p^2} \left[ (p^2 + m^2)^3/2 - m^3 \right] \]

\[ + \frac{|\vec{p}|}{6\pi^2} \ln \left( \frac{2\Lambda}{|\vec{p}| + \sqrt{p^2 + m^2}} \right) - \frac{|\vec{p}|}{8\pi^2} \int_0^1 dy \frac{1}{\sqrt{y}} \sqrt{y + (\frac{m}{|\vec{p}|})^2} \ln \frac{1 + y - \sqrt{y}}{1 + y + \sqrt{y}} - \frac{|\vec{p}|}{8\pi^2} \int_0^1 dy \frac{1}{\sqrt{y}} \sqrt{y + (\frac{m}{|\vec{p}|})^2} \ln \frac{1 + y - 1}{1 + y + 1} \]
It is not hard to check that in the limit $|\vec{p}| / m \to 0$ the terms proportional to $m$ cancel. In extracting the logarithmic term we have to take a closer look at the last term which can’t be evaluated in a closed form. In Fig.(17) we compare two different functional forms with the numeric evaluation of

$$f_1 = -2|\vec{p}|ln\frac{\Lambda^2}{|\vec{p}|^2 + m^2}, f_2 = -4|\vec{p}|ln\frac{2\Lambda}{|\vec{p}| + \sqrt{\vec{p}^2 + m^2}}$$

and the numeric evaluation of $f_1$, $f_2$ and the numeric evaluation of (D3) after analytic continuation ($m = 30$).

Note that there is virtually no difference between $f_1 = -2|\vec{p}|ln\frac{\Lambda^2}{|\vec{p}|^2 + m^2}$ and $f_2 = -4|\vec{p}|ln\frac{2\Lambda}{|\vec{p}| + \sqrt{\vec{p}^2 + m^2}}$. However this comparison has to be taken with a grain of salt as we are still in Euclidean space but are interested in the analytically continued forms. In Fig.(18) we plot the analytically continued ($ip_0 \rightarrow \omega + i\epsilon$) forms of the above functions. From this comparison it is now obvious that $f_1$ which has developed a pole at $m$ is unsuitable as an approximation and we take $f_2$ which fits the numerically integrated form quite well. Collecting the $ln$-terms in (D2) we obtain

$$2 \times [1(A)]_m + [\Pi(C)]_m = -\frac{16|q|}{3\pi^2 N}ln\frac{2\Lambda}{|q| + \sqrt{q^2 + m^2}}$$

Analytically continuing and combining with the mean-field result (10) gives (22).
APPENDIX E: LOW ENERGY EFFECTIVE THEORY FOR THE SUPERCONDUCTING STATE

Starting from the mean-field Hamiltonian for the spinons

\[ H = \frac{1}{2} \sum_{i,j,\sigma} \psi^\dagger_{\sigma i} J U_{ij} \psi_{\sigma j} + \sum_{i} \frac{1}{2} a_0^i \psi^\dagger_{\sigma i} \tau^\dagger \psi_{\sigma i} \]  

(E1)

in the d-wave paired state

\[ U_{i,i+k} = -\tau^3 \chi + \tau^\dagger \Delta \]
\[ U_{i,i+\hat{y}} = -\tau^3 \chi - \tau^\dagger \Delta \]
\[ a_0^i \neq 0 \]  

(E2)

we obtain after Fourier transformation the following Lagrangian

\[ L = \sum_{\mathbf{q},\omega} \left[ f^\dagger_{\mathbf{q}}(\mathbf{q},\omega), f_{\mathbf{q}}(-\mathbf{q},-\omega) \right] \left( -i\omega - \epsilon(\mathbf{q}) + a_0^3 \right) \left( \eta(\mathbf{q}) \right) \left( f^\dagger_{\mathbf{q}}(-\mathbf{q},-\omega) \right) \]

(E3)

\[ \epsilon(\mathbf{q}) = -2J \chi (\cos(q_x a) + \cos(q_y a)) \]
\[ \eta(\mathbf{q}) = -2J \Delta (\cos(q_x a) - \cos(q_y a)) \]  

(E4)

which results with

\[ S^+(\mathbf{q},\omega) = \frac{1}{\sqrt{2}} \sum_{\mathbf{k},\omega_k} f^\dagger_{\mathbf{k}}(\mathbf{k},\omega_k) f_{\mathbf{q}}(\mathbf{k} + \mathbf{q}, \omega_k) \]
\[ S^-(\mathbf{q},\omega) = \frac{1}{\sqrt{2}} \sum_{\mathbf{k},\omega_k} f^\dagger_{\mathbf{k}}(\mathbf{k},\omega_k) f_{\mathbf{q}}(\mathbf{k} + \mathbf{q}, \omega_k) \]  

(E5)

in

\[ \langle S^+(\mathbf{q},\omega) S^-(-\mathbf{q},-\omega) \rangle = \frac{1}{4} \sum_{\mathbf{k},\omega_k} \left[ \frac{(-i\omega_k - \epsilon(\mathbf{k}) - a_0^3)}{\omega_k^2 + (\epsilon(\mathbf{k}) + a_0^3)^2 + \eta(\mathbf{k})^2} \right] \left[ \frac{\eta(\mathbf{k})^2}{\omega_k^2 + (\epsilon(\mathbf{k}) + a_0^3)^2 + \eta(\mathbf{k})^2} \right] \]  

(E6)

next we split \( \sum_{\mathbf{k}} = \sum_{\mathbf{Q}_i + \mathbf{p}} \) where \( \mathbf{Q}_i \) with \( i = 1 \ldots 4 \) corresponds to \( (\pi/2, \pi/2), (-\pi/2, -\pi/2), (\pi/2, -\pi/2), (-\pi/2, \pi/2) \) in this order. To extract the correlations near \( \mathbf{Q}_AF = (\pi, \pi) \) we write \( \mathbf{q} = \mathbf{Q}_AF + \mathbf{k} \)

Concentrating on one of the terms in the sum - e.g. about \( \mathbf{Q}_1 = (\pi/2, \pi/2) \) we can expand

\[ \epsilon(\mathbf{Q}_1 + \mathbf{p}) \sim v_f p_1 \]
\[ \eta(\mathbf{Q}_1 + \mathbf{p}) \sim -v_{2p_2} \]
\[ v_f \equiv 2 \sqrt{2} \chi J \]
\[ v_{2p_2} \equiv 2 \sqrt{2} \delta J \]
\[ p_1 \equiv \frac{\hat{p}_x + \hat{p}_y}{\sqrt{2}} \]
\[ p_2 \equiv \frac{-\hat{p}_x + \hat{p}_y}{\sqrt{2}} \]  

(E7)

to obtain

\[ \langle S^+(\mathbf{Q}_AF + \mathbf{k},\omega) S^-(-\mathbf{Q}_AF - \mathbf{k},-\omega) \rangle \]
\[ = \frac{1}{4} \sum_{\mathbf{Q}_1,\omega_{p}} \left[ \frac{(-i\omega_p - v_f p_1 - a_0^3) (i\omega_p - i\omega_k - v_f (p_1 + k_1) + a_0^3) + v_{2p_2} v_{2p_2}}{\omega_p^2 + (v_f + a_0^3)^2 + v_{2p_2}^2} \right] \left[ (v_f - \omega_k)^2 + (v_f (p_1 + k_1) + a_0^3)^2 + v_{2p_2}^2 (p_2 - k_2)^2 \right] \]
\[ + \frac{1}{4} \sum_{\mathbf{Q}_1,\omega_{p},i=2,4} \ldots \]  

(E8)

Note \( k_1 \equiv \frac{k_x + k_y}{\sqrt{2}} \)
\( k_2 \equiv \frac{k_x + k_y}{\sqrt{2}} \)

Now we approximate the sums by integrals and define

\[ \bar{p}_1 \equiv v_f p_1 + a_0^3 \]
\[ \bar{p}_2 \equiv v_{2p_2} \]
\[ k_1 \equiv v_f k_1 + 2a_0^3 \]
\[ k_2 \equiv v_{2p_2} k_2 \]

which allows us to rewrite the first term in \( \text{[E8]} \)

\[ \frac{1}{4} \int \frac{d^3 \bar{p}}{(2\pi)^3 v_f v_{2p_2}} \left[ \bar{p} \cdot (\bar{p} - \bar{k}) + i\bar{p}_1 \omega_k - i\omega_p k_1 \right] \left( \bar{p} (\bar{p} - \bar{k})^2 \right) \]  

(E9)
Using the Feynman trick or otherwise it is not hard to convince oneself that the last two terms cancel each other and the final result is
\[-\frac{1}{64v_f v_2} \sqrt{\omega_k^2 + \tilde{k}_x^2 + \tilde{k}_y^2} \]

(E10)

Combining all four contributions from the four nodes in this way and translating the \(\tilde{k}\)'s back to the \(\tilde{k}'\)'s which measure momentum along the ab axis away from \(Q_{AF}\) we obtain after analytic continuation

\[
\text{Im}(S^+(\omega, Q_{AF} + \tilde{k}) S^-(\omega, -Q_{AF} - \tilde{k})) = \frac{1}{64v_f v_2} \left\{ \theta [\omega^2 - (v_f k_1 + 2a_0^3)^2 - v_2^2 k_2^2] \sqrt{\omega^2 - (v_f k_1 + 2a_0^3)^2 - v_2^2 k_2^2} + \right.
\]
\[
\theta [\omega^2 - (v_f k_1 - 2a_0^3)^2 - v_2^2 k_2^2] \sqrt{\omega^2 - (v_f k_1 - 2a_0^3)^2 - v_2^2 k_2^2} + \theta [\omega^2 - (v_f k_2 + 2a_0^3)^2 - v_2^2 k_1^2] \sqrt{\omega^2 - (v_f k_2 + 2a_0^3)^2 - v_2^2 k_1^2} + \right.
\]
\[
\theta [\omega^2 - (v_f k_2 - 2a_0^3)^2 - v_2^2 k_1^2] \sqrt{\omega^2 - (v_f k_2 - 2a_0^3)^2 - v_2^2 k_1^2} \}
\]

(E11)

\[
k_1 \equiv \frac{\tilde{k}_x + \tilde{k}_y}{\sqrt{2}} \quad k_2 \equiv \frac{-\tilde{k}_x + \tilde{k}_y}{\sqrt{2}} \quad v_f \equiv 2\sqrt{2}aJ \chi \quad v_2 \equiv 2\sqrt{2}aJ \Delta
\]

the result stated in the main body of the paper.
