ABSTRACT

We report the discovery by the HATSouth network of HATS-7b, a transiting Super-Neptune with a mass of 0.120 ± 0.012 M jov, a radius of 0.563+0.048−0.034 R jov, and an orbital period of 3.1853 days. The host star is a moderately bright (V = 13.340 ± 0.010 mag, Ks = 10.976 ± 0.026 mag) K dwarf star with a mass of 0.849 ± 0.027 M jov, a radius of 0.815+0.049−0.035 R jov, and a metallicity of [Fe/H] = +0.250 ± 0.080. The star is photometrically quiet to within the precision of the HATSouth measurements, has low RV jitter, and shows no evidence for chromospheric activity in its spectrum. HATS-7b is the second smallest radius planet discovered by a wide-field ground-based transit survey, and one of only a handful of Neptune-size planets with mass and radius determined to 10% precision. Theoretical modeling of HATS-7b yields a hydrogen–helium fraction of 18 ± 4% (rock-iron core and H2–He envelope), or 9 ± 4% (ice core and H2–He envelope), i.e., it has a composition broadly similar to that of Uranus and Neptune, and very different from that of Saturn, which has 75% of its mass in H2–He. Based on a sample of transiting exoplanets with accurately (<20%) determined parameters, we establish approximate power-law relations for the envelopes of the mass–density distribution of exoplanets. HATS-7b, which, together with the recently discovered HATS-8b, is one of the first two transiting super-Neptunes discovered in the Southern sky, is a prime target for additional follow-up observations with Southern hemisphere facilities to characterize the atmospheres of Super-Neptunes (which we define as objects with mass greater than that of Neptune, and smaller than halfway between that of Neptune and Saturn, i.e., 0.054 M jov < M jov < 0.18 M jov).

Key words: stars: individual (HATS-7) – techniques: photometric – techniques: radial velocities – techniques: spectroscopic

1. INTRODUCTION

The HATSouth project (Bakos et al. 2013) is the first global network of homogeneous, fully automated telescopes, capable of round-the-clock monitoring of a wide field of view (FOV) on the sky.

The key scientific goal of HATSouth is to search for transiting extrasolar planets, especially ones that are smaller and/or have longer periods than hot Jupiters and Satsums, which have been the primary type of planet found by ground-based surveys to date. By covering a wider total FOV than the NASA Kepler mission (Borucki et al. 2010), HATSouth monitors more bright stars per unit time than this mission, promising a greater yield of planets amenable to detailed characterization.

The HATSouth telescopes are installed at Las Campanas Observatory (LCO) in Chile, at the H.E.S.S. site in Namibia, and at Siding Spring Observatory (SSO) in Australia. HATSouth was commissioned in late 2009, with regular operations beginning in 2011 after a ∼1 year shakedown period, and has since collected 2.9 million science images at 4 minute cadence for some 9.5 million stars with r < 16 mag (2% per-point precision) in the Southern sky. As of 2015 May 1, the HATSouth telescopes have opened on 1788, 1528, and 1324 nights from LCO, HESS, and SSO, respectively. Based on weather statistics through 2015, the sites have averaged 8.24 hr, 7.54 hr, and 5.24 hr of useful dark hours per 24 hr time period, respectively. The longitudinal distribution of the three

* The HATSouth network is operated by a collaboration consisting of Princeton University (PU), the Max Planck Institute für Astronomie (MPIA), the Australian National University (ANU), and the Pontificia Universidad Católica de Chile (PUC). The station at Las Campanas Observatory (LCO) of the Carnegie Institute is operated by PU in conjunction with PUC, the station at the High Energy Spectroscopic Survey (H.E.S.S.) site is operated in conjunction with MPIA, and the station at Siding Spring Observatory (SSO) is operated jointly with ANU. This paper includes data gathered with the 10 m Keck-I telescope at Mauna Kea, the MPG 2.2 m and ESO 3.6 m telescopes at the ESO Observatory in La Silla. This paper uses observations obtained with facilities of the Las Cumbres Observatory Global Telescope.

sites means that selected regions of the sky may be observed for long contiguous stretches of time, occasionally reaching 130 hr with interruptions shorter than 30 minutes.

Here we present the discovery of HATS-7b, which together with the recently announced HATS-8b (Bayliss et al. 2015), is one of the first two transiting Super-Neptunes found by the HATSouth network, and one of only four such planets discovered by a ground-based wide-field survey (the other two being HAT-P-11b, Bakos et al. 2010, and HAT-P-26b, Hartman et al. 2011a). By combining photometric observations with high-resolution, high velocity-precision spectroscopy, we determine the mass and radius of HATS-7b to better than 10% accuracy. HATS-7b is one of only nine planets with $M < 0.18 M_J$ for which both the mass and radius have been determined to this level of accuracy. $^{15}$ With $V = 13.340 \pm 0.010$ mag, HATS-7 is the 7th brightest star known to host a transiting planet with $M < 0.18 M_J$, and for which the mass has been accurately (with 10% accuracy) determined. And of these planets, only GJ 436 (Gillon et al. 2007), GJ 3470 (Bonfils et al. 2012), and HAT-P-26 (Hartman et al. 2011a) have deeper transits, making HATS-7b one of the best known low-mass transiting planets for detailed follow-up studies, e.g., transmission spectroscopy for probing its atmospheric composition.

In the following section we describe the observations utilized to discover and characterize HATS-7b. In Section 3 we discuss our analysis of the data to rule out blend scenarios and determine the system parameters. We discuss the results in Section 4.

2. OBSERVATIONS

2.1. Photometry

2.1.1. Photometric Detection

The star HATS-7 (2MASS 13552567-2112276) was observed by the HATSouth wide-field telescope network between UT 2011 March 24 and UT 2011 August 19. These observations are summarized in Table 1. Observations were made from LCO in Chile, the H.E.S.S. site in Namibia, and SSO in Australia. The data were reduced to trend-filtered light curves following Penev et al. (2013) and making use of the Trend Filtering Algorithm (TFA; Kovács et al. 2005). We searched the light curves extracted from the images for periodic box-shaped transits using the Box Least Squares (Kovács et al. 2002) algorithm, and identified a $P = 3.1853150$ days resulting from the global fit described in Section 3. The solid line shows the best-fit transit model (see Section 3). In the lower panel we zoom-in on the transit; the dark filled points here show the light curve binned in phase using a bin size of 0.002.

2.2. Spectroscopy

Spectroscopic follow-up observations of HATS-7 were carried out with WiFeS on the ANU 2.3 m telescope at SSO (Dopita et al. 2007), FEROS on the MPG 2.2 m (Kaufer & Pasquini 1998), CORALIE on the Euler 1.2 m at LSO (Queloz et al. 2001), and HIRES on the Keck-I 10 m telescope at Mauna Kea Observatory in Hawaii (Vogt et al. 1994).

The WiFeS observations were carried out as part of our reconnaissance to rule out false positives, and reduced and analyzed following Bayliss et al. (2013) and Zhou et al. (2014). We obtained three observations at a resolution of \( R = 3000 \) was obtained to provide an initial spectral classification and estimate of the surface gravity. Based on this observation we found that HATS-7 is a K dwarf star with an estimated effective temperature of \( T_{\text{eff}} = 4700 \pm 300 \) K and a surface gravity of \( \log g_s = 4.4 \pm 0.3 \).

We obtained three \( R = 48,000 \) resolution FEROS spectra and five \( R = 60,000 \) resolution CORALIE spectra, which were reduced and analyzed following Jordán et al. (2014). The RVs measured from these spectra had a rms scatter of 20 m s\(^{-1}\) and were consistent with no variation. Based on these observations we concluded that HATS-7b is a probable Neptune-mass planet, and continued observing it with the larger aperture Keck-I telescope. The stellar atmospheric parameters estimated from the FEROS and CORALIE spectra are consistent with those measured from WiFeS. We also determined that the star is slowly rotating (with \( v \sin i < 5 \text{ km s}^{-1} \)), and, based on inspecting the cross-correlation functions (CCFs), found no evidence for additional stellar components in the spectra.

We observed HATS-7 with the HIRES spectrometer (Vogt et al. 1994) on the 10 m Keck-I telescope using standard practices of the California Planet Survey (Howard et al. 2010). Our 10 observations through a gas cell of molecular iodine (I\(_2\)) lasted 25 minutes each using the “C2” decker (14 times 0.86 arcsec slit). In addition, we observed HATS-7 without the I\(_2\) cell using the “B3” decker (14 times 0.57 arcsec slit) to record a template spectrum for the RV analysis and for measuring high-precision stellar atmospheric parameters. We computed relative RVs using the Butler et al. (1996) method to model the I\(_2\) × star spectrum. RV errors were estimated from the uncertainty on the mean of 700 spectral segments (each spanning ~2 Å) that were separately analyzed for each observation. We also measured spectral line bisector spans (BSs) from these data following Torres et al. (2007). The final RVs and BSs are provided in Table 3 and are displayed in Figure 3. The RVs vary in phase with the photometric ephemeris and with a semi-amplitude of \( K = 18.4 \pm 1.9 \text{ m s}^{-1} \), while the BSs are consistent with no variation and have an rms scatter of 8.4 m s\(^{-1}\).

Based on the Keck/HIRES spectra, HATS-7 is a quiet K dwarf, with barely detectable Calcium HK activity \( \langle \delta S \rangle = 0.27, \log R'_{\text{HK}} = -4.800; \) Table 4). Also, HATS-7 has no significant RV jitter (Table 5). It is similar to other very low activity K dwarfs, like HAT-P-26 (Hartman et al. 2011a).

3. ANALYSIS

We analyzed the photometric and spectroscopic observations of HATS-7 to determine the parameters of the system using the
standard procedures developed for HATNet and HATSouth (see Bakos et al. 2010, with modifications described by Hartman et al. 2012).

High-precision stellar atmospheric parameters were measured from the Keck/HIRES template spectrum using the Spectral Parameter Classification program (SPC; Buchhave

Notes.

ᵃ SPC—“Stellar Parameter Classification” method based on cross-correlating high-resolution spectra against synthetic templates (Buchhave et al. 2012). These parameters rely primarily on SPC, but have a small dependence also on the iterative analysis incorporating the isochrone search and global modeling of the data, as described in the text.

ᵇ Isochrones +γ₁+SPC = Based on the Y² isochrones (Yi et al. 2001), the stellar density used as a luminosity indicator, and the SPC results.

c Total V band extinction to the star determined by comparing the catalog broad-band photometry listed in the table to the expected magnitudes from the isochrones +γ₁+SPC model for the star. We use the Cardelli et al. (1989) extinction law.

d The resulting Tₑff, and [Fe/H] measurements were combined with the stellar density ρ₁ determined through our joint light curve and RV curve analysis, to determine the stellar mass, radius, age, luminosity, and other physical parameters, by comparison with the Yonsei-Yale (Y²; Yi et al. 2001) stellar evolution models (see Figure 4). This provided a revised estimate of log g₁, which was fixed in a second iteration of SPC. Our final adopted stellar parameters are listed in Table 4. We find that the star HATS-7 has a mass of 0.849 ± 0.027 Mₒ, a radius of 0.815±0.005 Rₒ, and is at a reddening-corrected distance of 261±16 pc. Note that the error on the distance does not include the errors on the individual parameters.

Notes.  

ᵃ The adopted parameters assume a circular orbit. Based on the Bayesian evidence ratio we find that this model is strongly preferred over a model in which the eccentricity is allowed to vary in the fit. For each parameter we give the median value and 68.3% (1σ) confidence intervals from the posterior distribution.

ᵇ Reported times are in Barycentric Julian Date calculated directly from UTC, without correction for leap seconds. Tₑ: reference epoch of mid transit that minimizes the correlation with the orbital period. Tₑ₂₃: total transit duration, time between first to last contact; Tₑ₂₃ = Tₑ₁₄: ingress/egress time, time between first and second, or third and fourth contact.

ᶜ Reciprocal of the half duration of the transit used as a jump parameter in our MCMC analysis in place of a/Rₒ. It is related to a/Rₒ by the expression c(Rₒ) = a/Rₒ(2π(1 + e sin ω))/(b(Rₒ(1 - b²)1/2 - 1 - e²)) (Bakos et al. 2010).

ᵈ Values for a quadratic law, adopted from the tabulations by Claret (2004) according to the spectroscopic (SPC) parameters listed in Table 4.

ᵉ The 95% confidence upper-limit on the eccentricity from a model in which the eccentricity is allowed to vary in the fit.

ᶠ Error term, either astrophysical or instrumental in origin, added in quadrature to the formal RV errors for the listed instrument. This term is varied in the fit assuming a prior inversely proportional to the jitter.

ᵍ Correlation coefficient between the planetary mass Mₑ₂₃ and radius Rₑ₂₃ determined from the parameter posterior distribution via C(Mₑ₂₃, Rₑ₂₃) = (∆Mₑ₂₃ ∆Rₑ₂₃)(σMₑ₂₃ σRₑ₂₃), where (∆) is the expectation value operator, and σᵢ is the standard deviation of parameter i.

ʰ Planet equilibrium temperature averaged over the orbit, calculated assuming a Bond albedo of zero, and that flux is re-radiated from the full planet surface.

¹ The Safronov number is given by Θ = 1/2(Vₑ₂₃/Vₑ₂₃)² = (a/Rₒ)(Mₑ₂₃/Mₒ) (see Hansen & Barman 2007).

² Incoming flux per unit surface area, averaged over the orbit.
not take into account the systematic errors due to uncertainties in the stellar isochrones. HATS-7 is a main-sequence star, and has a poorly constrained age due to the limited stellar evolution expected within the age of the universe at this stellar mass.

We also carried out a joint analysis of the HIRES RVs (fit using a Keplerian orbit) and the HATSouth, LCOGT 1 m, and GROND light curves (fit using a Mandel & Agol 2002 transit model with fixed quadratic limb darkening coefficients taken from Claret 2004) to measure the stellar density, as well as the orbital and planetary parameters. This analysis makes use of a differential evolution Markov Chain Monte Carlo procedure (ter Braak 2006) to estimate the posterior parameter distributions, which we use to determine the median parameter values and their 1σ uncertainties. We also varied the jitter as a free parameter in the fit following Hartman et al. (2014), where we use the empirical distribution of the Keck/HIRES RV jitter values for low-activity cool main sequence stars from Wright (2005) to place a prior on the jitter. The results are listed in Table 5. We find that the planet HATS-7b has a mass of 0.120 ± 0.012 M_J, and a radius of 0.563±0.046 R_J. We also find that the observations are consistent with a circular orbit. When the eccentricity is allowed to vary in the fit, we find $e = 0.065 \pm 0.053$ and a 95% confidence upper-limit of $e < 0.170$. The parameters listed in Table 5 were determined assuming a fixed circular orbit.

In order to rule out the possibility that HATS-7 is a blended stellar eclipsing binary system, we carried out a blend analysis of the photometric data following Hartman et al. (2012). We find that a model consisting of single star with a transiting planet fits the data better than any of the blended stellar eclipsing binary models that we tested, but there are some blend models which cannot be rejected with greater than 5σ confidence based on the photometry alone. In these models the primary star in the background eclipsing binary has a distance modulus that is no more than 2.1 mag greater than that of a brighter foreground star. We simulated the CCFs, RVs, and BSs that would be measured with HIRES/Keck-1 for these blend scenarios and found that in almost all cases the object would be easily identified as a composite stellar system (the CCFs would be double-peaked, or the BSs and/or RVs would vary by greater than 100 m s⁻¹). We searched the spectrum for the spectral signature of a secondary star as described in Kolbl et al. (2015), and found no companions down to 1% of the brightness of the primary at separations in RV greater than ±10 km s⁻¹. There is a small region of parameter space where the BS and RV scatter for the blended system would be comparable to the measured scatters. These are blends where the background binary has a distance modulus that is between 1.95 and 2.1 mag greater than that of the foreground star, and where the RV of the foreground star differs by at least 50 km s⁻¹ from the systemic RV of the binary. Considering, however, that these blends can still be rejected with 4σ confidence based on the photometry, and that the simulated RVs do not show the sinusoidal variation in orbital phase that is observed, we conclude that these blend scenarios do not provide a good description of the observations, and that HATS-7 is a transiting planet system.

While we can rule out the possibility that HATS-7 is a blended stellar eclipsing binary system, we cannot rule out the possibility that HATS-7 is a transiting planet system with a fainter unresolved stellar companion. We note that this is often the case for many known transiting exoplanet systems. We simulated this scenario as well, and find that companions with masses up to that of the planet host cannot be ruled out. The highest spatial resolution images we have available are from the HIRES guide camera based on which we can rule out companions with ΔV < 4 at a separation greater than 1.5″. High mass companions would also need to have been observed near conjunction for the system not to have been detected as a spectroscopic binary. Higher spatial resolution imaging and/or additional RV monitoring would be needed to put tighter constraints on any stellar companions. If HATS-7 does have a stellar companion, the radius and mass of the planet HATS-7b would be somewhat larger than what we infer here.

4. DISCUSSION

With its mass of $M_p = 0.120 \pm 0.012 M_J$, HATS-7b is one of the very few transiting and well characterized super-Neptunes known to date. We adopt a nomenclature, whereby planets with $0.18 M_J < M_p \leq 0.3 M_J$, i.e., those more massive than halfway between Neptune and Saturn, are referred to as sub-Saturns (especially those toward the lower end of this mass range), whereas planets with $0.054 M_J < M_p \leq 0.18 M_J$ as super-Neptunes (especially those toward the higher mass end). This nomenclature is more or less consistent with previous literature, e.g., HAT-P-18b (Hartman et al. 2011b) is a called a sub-Saturn ($M_p = 0.197 M_J$), while Kepler-101b (Bonomo et al. 2014) is called a super-Neptune ($M_p = 0.16 M_J$). The mass versus radius of low mass ($M_p < 0.2 M_J$) transiting planets with accurately determined masses (here we use <20% uncertainty) is shown in Figure 5. It is noteworthy that only a handful of super-Neptunes are known (with accurate parameters), and the regime between 0.1 M_J and 0.18 M_J is occupied by only five such objects. These are Kepler-9c (K = 12.34 mag; Torres et al. 2011), Kepler-101b (K = 12.0; Bonomo et al. 2014), the recently discovered HATS-8b (K = 12.6; Bayliss et al. 2015), Kepler-35b (K = 13.9; Welsh et al. 2012), and HATS-7b (K = 10.97), the subject of this paper. Among these planet hosting stars, HATS-7 is by far the brightest, which will greatly facilitate detailed studies. All low-
mass transiting planets shown in Figure 5 were found by either Kepler and Corot (space-born surveys), HATNet and HAT-South (ground-based wide-field surveys), the pointed ground-based survey MEarth (GJ 1214b; Charbonneau et al. 2009; Irwin et al. 2009), or they were found by the photometric follow-up of planetary systems that were first discovered by RVs.

Well characterized planets and host stars in this regime are important in exploring the correlations between various system parameters. One example is the host star metallicity–planet occurrence rate correlation, which has been known for a long time (Fischer & Valenti 2005) to exist for Jupiter size planets, and which correlation was found to be weakened for small, <4R⊕ planets by Buchhave et al. (2012). However, recent analysis by Wang & Fischer (2015) shows that the planet occurrence rate–metallicity correlation is universal, including for terrestrial planets. Using an increased sample and new analysis, Buchhave et al. (2014) find a correlation between host star metallicity and planet radius, in the sense that the average metallicity of the host star increases with planet size. These authors also find three populations of exoplanets (rocky, gas-dwarf, giant), as based on the metallicity of the stars. The discovery of HATS-7b around a metal-rich ([Fe/H] = +0.250 ± 0.080) star, and the apparent lack of a hot Jupiter in this system will help in refining such future analyses.

The mass regime of super Neptunes is important in studying the transition from ice giants to gas giants, where, in the core accretion scenario (e.g., Mordasini et al. 2015), rapid accumulation of a gaseous envelope is expected to start. This transition is well demonstrated in Figure 6, which plots the bulk density of transiting exoplanets as a function of their masses (again, only for those with reliable parameters determined to better than 20% precision). Mean density first decreases with increasing planetary mass, as the planetary mass increases from super-earths (~0.01 M⊕) to Neptunes (~0.1 M⊕). Then, in the super-Neptune/sub-Saturn regime, the trend reverses, as matter becomes increasingly degenerate under high pressure, and density starts to increase.

With the increasing number of well characterized transiting exoplanets, we are gradually mapping out the parameter space these planets occupy. While it is customary to explore the relations between various parameters (e.g., mass, radius, equilibrium temperature), here we examine the boundaries spanned in the planetary mass–density domain. The approximate envelopes of the distribution are:

\[
M_p \lesssim 0.02 M_J:\begin{cases}
\rho_p \gtrsim 14 \left( \frac{M_p}{M_J} \right)^{0.178} \\
\rho_p \lesssim 25 \left( \frac{M_p}{M_J} \right)^{0.178},
\end{cases}
\]

e.g., for rocky planets without significant amount of volatiles, 

\[
M_p \lesssim 0.4 M_J:\begin{cases}
\rho_p \gtrsim 3/4 \times 10^{-4} \left( \frac{M_p}{M_J} \right)^{-2} \\
\rho_p \lesssim 3/5 \left( \frac{M_p}{M_J} \right)^{-3/4},
\end{cases}
\]

e.g., for Neptunes and Saturns, and

\[
M_p \gtrsim 0.4 M_J:\begin{cases}
\rho_p \gtrsim 1/5 \left( \frac{M_p}{M_J} \right)^{3/2} \\
\rho_p \lesssim 5/2 \left( \frac{M_p}{M_J} \right)^{1/1},
\end{cases}
\]

for ice and gas giants (ρₚ measured in g cm⁻³ for all). Here the ρₚ ∝ (M_p/M_J)^0.178 relation for the smallest planets is taken from Sotin et al. (2007), and is based on models. The other relations are approximate, and are not physically motivated, though it is possible that physical explanations for them do exist. Between earths and super-earths, the mean density only increases slightly. Once \( M_p \gtrsim 0.02 M_J \) (6 M⊕) is reached, the bulk

---

**Figure 5.** Mass–radius diagram of super-Neptunes \((M_p \leq 0.18 M_J)\) and super-Earths with accurately measured masses and radii (<20% uncertainties). Color indicates equilibrium temperature (with the palette of \( R, G, B = 2000, 1500, 1000 \) K), while size is inversely proportional to surface gravity. HATS-7b is also marked with a large box. Isodensity lines for \( \rho = 0.2, 0.5, 1.27 \) (Uranus), 1.64 (Neptune), 5.5 (Earth) g cm⁻³ are shown with dashed lines. Neptune is marked with a blue triangle. Abbreviations are: K: Kepler, H: HAT, HS: HATSouth, C: Corot.
density decreases as a result of retaining more volatiles, and the ability to form a more extended atmosphere. Finally, at around \( M_p \gtrsim 0.2 M_J \) (\( \sim 60 M_\oplus \)), the compression of matter gets significant to result in an increasing mean density.

The lower limit for the density of gaseous planets (dashed line in Figure 6, \( \propto M_p^{3/2} \)) is related to the inflation mechanism of planets, which has not been fully solved. It is noteworthy that this relation holds over two orders of magnitude in mass, from \( M_p \approx 0.5 M_J \) to 50 \( M_J \). The upper limit for the density of rocky planets (dotted line, \( \propto M_p^{-3/4} \)) is likely to suffer from the bias against discovering compact rocky/iron planets, due to their smaller transit signatures. Also, while there are close to 250 well characterized transiting exoplanets, considering the dimensionality of the parameter space (e.g., \( M_p \), \( R_p \), \( M_* \), \( P \), [Fe/H], \( T_{\text{eff}} \), age), this is still a very small number to understand their distribution. Consequently, significant biases in the observed distribution exist. Probably the most important such bias is that the majority of the planets plotted in Figure 6 have short periods. The confirmation and characterization of long period planets takes much more time, and these systems are primarily discovered by Kepler, so the host stars are typically faint, further hindering follow-up studies.

The bulk composition of HATS-7b may be estimated by fitting theoretical structural and evolutionary models to the observed mass and radius of \( 38.0 \pm 3.9 M_\oplus \) (0.120 \( \pm \) 0.012 \( M_J \)) and \( 6.31^{+0.52}_{-0.33} R_\oplus \) (0.563 \( \pm \) 0.046 \( R_J \)). We compute a range of models for planets of HATS-7b’s mass for various possible parameters using the methodology of Howe & Burrows (2015). If a two-layer partitioning with a rock-iron core and a hydrogen–helium envelope is assumed, the best fit models suggest a core mass of 31 \( \pm 4 M_\oplus \) and an envelope mass of 7 \( \pm 1.5 M_\oplus \), that is, a hydrogen–helium fraction of 18 \( \pm \) 4\%. This result is consistent within uncertainty across a range of metallicity and whether or not evaporative mass loss is incorporated in the model. More quantitatively, increasing the metallicity from 1× solar to 10× solar increases the radius at 7.8 Gyr by about 0.2 \( R_\oplus \) (0.018 \( R_J \)), approximately the same amount as decreasing the core mass by 1\( M_\oplus \). This is also of the same order as the uncertainty introduced by the uncertainty in age. Models with significantly smaller cores, \( \lesssim 25 M_\oplus \), are ruled out because they under no circumstances shrink to the observed radius of the planet over the age of the system. For comparison, final radii for the 10× solar models with core
masses of 0, 5, 10, 15, and 20 $M_⊕$ are 0.95, 0.87, 0.79, 0.71, and 0.65 $R_⊕$, respectively (all larger than the observed radius of 0.56 $R_⊕$), while a bare core of 38 $M_⊕$ has a radius of 0.202 $R_⊕$ if composed of rock-iron and 0.296 $R_⊕$ if composed of ice. In the case of a pure ice core, the best fit is a core mass of $34.5 \pm 4 M_⊕$, and an envelope mass of $3.5 \pm 1.5 M_⊕$, that is, a hydrogen–helium fraction of $9 \pm 4\%$, similar to the composition of Uranus and Neptune (Heil et al. 2011). Figure 7 shows radius versus time for representative evolutionary models with core masses of 28–34 $M_⊕$, encompassing the full range of core masses consistent with observations.

While the mean density of exoplanets is an important constraint on their bulk composition, detailed studies of the planetary atmospheres can provide a direct measurement of the composition of the planet. One important way to detect such compositions is via transmission spectroscopy. In Figure 8 we show super-Neptunes to super-Earths, including the sub-Saturn HAT-P-18b, with the expected transmission signatures plotted against the planetary masses. To derive an approximate measure of the transmission signatures, we approximated the $H$ scale height as $H = k_B T_{eq}/(\mu g_p)$, where $k_B$ is the Boltzmann constant, $T_{eq}$ is the equilibrium temperature of the planets (assuming black bodies, and full redistribution of heat), $\mu$ is the mean molecular weight, and $g_p$ is the planetary surface gravity. To make the comparison simpler (and because of lacking further information on their atmospheric composition), we used $\mu = 2$ (i.e., H$_2$) for all planets, even though the mean molecular weight of the atmospheres will be larger, and thus our estimates are somewhat optimistic. We then approximated the fractional contribution of transmission through the planet’s atmosphere to the total stellar flux as $\delta = 5 \times 2 R_p H/R_p^2$ (Perryman 2014), and multiplied this with the total estimated $K$-band flux of the star. Atmospheric transmission analysis has been carried out for five of these planets, typically those in the top left side of Figure 8 (those with low mass and high expected transmission signal). These are, in order of increasing planetary mass, GJ-1214b (Kreidberg et al. 2014), HD 97658b (Knutson et al. 2014b), GJ 3470b (Ehrenreich et al. 2014), GJ 436b (Knutson et al. 2014a), and HAT-P-11b (Fraile et al. 2014). With the exception of HAT-P-11b, all showed essentially featureless transmission spectra, indicating hazes, clouds, or atmospheres with high molecular weight. The only Neptune mass planet with features in its transmission spectrum is HAT-P-11b, where the signature of water was detected (Fraile et al. 2014). Among the super Neptunes, HATS-7b is the most promising target for detecting its atmosphere. Also, such measurements will be facilitated by the quiet host star; high-resolution spectroscopy of HATS-7 shows very low RV jitter, low $v \sin \iota$, and no chromospheric activity. Altogether, it is scientifically compelling to pursue transmission spectroscopy for the recently discovered super Neptunes HATS-7b and HATS-8b, and the sub-Saturn HAT-P-18b, where relatively large signals are expected. Perhaps a trend from featureless spectra to feature-rich transmission (observed for certain hot Jupiters) will be observed with increasing planetary mass through the super-Neptune regime.

Development of the HATSouth project was funded by NSF MRI grant NSF/AST-0723074, operations have been supported by NASA grants NNX09AB29G and NNX12AH91H, and follow-up observations received partial support from grant NSF/AST-1108686. Figure 8. Approximate detectability of a planet’s atmosphere in transmission as a function of planetary mass for super-Neptunes ($M_P \leq 0.18M_J$) and super-Earths. In calculating the scale height of the planet atmosphere we assume the molecular weight of pure molecular hydrogen, and the equilibrium temperature and surface gravity of the planet determined as from our analysis (Table 5). The fractional contribution of the transmission signal to the star light is approximated as $\delta = 5 \times 2 R_p H/R_p^2$ (Perryman 2014). We then calculate the $K$-band flux of the star, and multiply with $\delta$, to come up with an approximate measure of the transmission signal. We stress that this quantity does not take into account the detailed estimate of the signature. The size of the filled circles scales with the radius of the planet (arbitrary scale), and the radius of the open circles scales with the scale height of the atmosphere. Small plus symbols denote planets with uncertain mass or radius measurements (error >20%). Abbreviations are: K: Kepler, H: HAT, HS: HATSouth, C: Corot.
