Abstract

Idiopathic pulmonary hemosiderosis (IPH) is an unusual cause of pediatric iron deficiency anemia (IDA) characterized by alveolar hemorrhage leading to hemosiderin deposition and fibrosis in the lungs. Though the typical triad of presentation is hemoptysis, IDA, and lung opacities on thoracic radiographs, often the sole manifestation of IPH may be severe IDA in children.

Keywords

► hemoptysis
► pulmonary hemorrhage
► hemosiderosis

Case Report

An 8-year-old female child presented to us with complaints of cough and acute exacerbation of dyspnea for 4 months. Her mother recalled that the child had easy fatiguability, poor weight gain, and lethargy since 2 years of age. The child had also found it difficult to actively engage in outdoor games with her peer group due to recurrent episodes of dyspnea. There was no history of hemoptysis, fever, contact with tuberculosis/pets, or exposure to factory smoke. The child had been diagnosed with iron deficiency anemia (IDA) in 2014 based on peripheral smear, blood profile, serum iron studies, and bone marrow biopsy done from another institute. Her hemoglobin at that time was only 4 mg/dL and over 5 years she had had six episodes of blood transfusion and treatment with oral iron and antihelminthics.

Clinical examination revealed grade III clubbing, right parasternal heave, and loud P2 on auscultation. Her blood examination currently showed normal peripheral smear and no evidence of IDA with red blood cell count of 4.9 million/mm³, hemoglobin 14mg/dL, hematocrit 46.3%, mean corpuscular volume (MCV) 94.5 fL, mean corpuscular hemoglobin (MCH) 30.4 pg, MCH concentration (MCHC) 32.2%, serum ferritin 506.46 ng/mL, serum iron 44 µg/dL, and total iron-binding capacity 378 µg/dl. Sputum was negative for tubercular bacilli; however, her Mantoux test was positive. The serum human immunodeficiency virus screen turned out to be negative.

A routine chest radiograph of the child revealed reticular opacities in bilateral middle and lower zones with patchy opacities in the left lower zone, based on which interstitial lung pathology was suspected (►Fig. 1). Further, a high-resolution computed tomography (HRCT) was done, which showed diffuse bilateral ground-glass opacity (GGO) with a mild apicobasal gradient (►Fig. 2A). Few thin-walled small cysts were seen in peribronchovascular distribution (►Fig. 2B) in upper lobes along with crazy paving appearance due to superimposed interlobular septal thickening over areas of GGO in upper and lower lobes (►Fig. 2C). Peripheral and basilar, confluent nodules, and interlobular septal thickening with mild tractional bronchiectasis were observed in the left lower lobe, suggestive of fibrotic changes (►Fig. 2D).
HRCT was followed by contrast-enhanced CT (CECT) due to clinical suspicion of pulmonary artery hypertension (PAH) on the mediastinal window of the scan and also to rule out any necrotic lymphadenopathy. CECT depicted PAH (►Fig. 3) and homogenously enhancing mediastinal lymph nodes.

Based on the imaging findings and history of IDA, the possibility of pulmonary hemosiderosis was considered. A detailed vasculitic work-up including serum antineutrophil cytoplasmic antibody (ANCA), antinuclear antibody profile, antiphospholipid antibody (immunoglobulin [Ig] M and IgG), antilglomerular basement membrane antibody, anti-human tissue transglutaminase antibody, anti-endomyosial antibody, infection: sputum culture & sensitivity, coagulation disorders: coagulation profile, drug & toxin exposure, miscellaneous: pulmonary veno-occlusive disease, pulmonary capillary hemangiomatosis, confirmed on BAL or lung biopsy, idiopathic pulmonary hemosiderosis, and HRCT thorax in a patient with IDA, features of pulmonary hemorrhage with/without fibrosis, ruled out causes of pulmonary hemorrhage, exclusion of other pathologies were performed.

Fig. 3 Contrast-enhanced computed tomography (CT) in mediastinal window demonstrates dilated main pulmonary artery (asterisk).

Fig. 4 (A,B) Cytopathological examination of bronchoalveolar lavage fluid with Perl’s Prussian blue stain revealing presence of hemosiderin-laden macrophages (green arrow) (A). On evaluation with May-Grunwald-Giemsa stain, the hemosiderin engulfed by siderophages stain brown (black arrow) (B), confirming the diagnosis of pulmonary hemosiderosis.

Fig. 5 Algorithm for approach to pulmonary hemosiderosis.
Further, a bronchoscopic alveolar lavage (BAL) was performed and cytopathological analysis of BAL fluid with Perl’s Prussian blue stain (►Fig. 4A) and May-Grunwald-Giemsa stain (►Fig. 4B) depicted the classical hemosiderin-laden macrophages (siderophages), confirming the diagnosis of idiopathic pulmonary hemosiderosis (IPH). BAL fluid culture and sensitivity tested negative for tuberculosis. The child was started on oral prednisolone and currently has shown marked clinical improvement after 2 weeks of therapy.

Discussion
Pulmonary hemosiderosis is characterized by deposition and aggregation of hemosiderin in the lungs due to recurrent alveolar capillary hemorrhage and can be primary or secondary. Primary pulmonary hemosiderosis or IPH is a diagnosis of exclusion after ruling out secondary causes of pulmonary hemorrhage like vasculitis, autoimmune disorders, coagulation disorders, or mitral stenosis. IPH is a rare disease with an incidence of 0.24 to 1.23 cases/million. Its pathogenesis is unclear, with autoimmune, environmental, allergic, and genetic etiologies being hypothesized for the same. Association of IPH with celiac disease has been described, which is called as “Lane-Hamilton syndrome.”

IPH is typically diagnosed within 10 years of age with around 20% being detected late in adulthood. The classic triad described for this entity is hemoptysis, IDA, and pulmonary fibrosis, confirming the diagnosis of idiopathic pulmonary hemosiderosis (IPH). BAL fluid culture and sensitivity tested negative for tuberculosis. The child was started on oral prednisolone and currently has shown marked clinical improvement after 2 weeks of therapy.

Table 1 Imaging features of idiopathic pulmonary hemosiderosis on chest radiograph and high-resolution computed tomography (HRCT) in acute and chronic phases of the disease

| Table 1 Imaging features of idiopathic pulmonary hemosiderosis on chest radiograph and high-resolution computed tomography (HRCT) in acute and chronic phases of the disease |
|--------------------------------------------------------|
| **Acute phase** | **Chronic phase** |
| **Chest radiograph** | Airspace opacities/consolidation in perihilar and lower lobe | Reticular opacities in areas of consolidation especially basilar and subpleural location |
| **HRCT** | Ground-glass opacity (GGO) and consolidation in diffuse pattern or hilar, perihilar, and lower lobe distribution. | Pulmonary fibrosis and honeycombing. Intra- and interlobular septal thickening with traction bronchiectasis and bronchiolectasis. Progression of fibrosis (PMF) with high attenuation consolidation and centriflobular nodules due to intra-alveolar macrophages |

Thoracic imaging is a useful pointer to this lung pathology and sometimes a routine chest radiograph could prevent an unnecessary delay in diagnosis. Plain radiograph and HRCT of thorax efficiently detect IPH and the imaging features correspond to pulmonary hemorrhage with or without fibrosis, depending on the phase of the disease and episodic acute exacerbation (►Table 1). Magnetic resonance imaging is not necessary for diagnosis, though affected lung regions have been reported to show hyperintense signal on T1-weighted and hypointense signal on T2-weighted images, respectively. Lymphadenopathy, hemothorax, and fibrothorax have also been described in this condition.

However, imaging features are not pathognomonic for IPH as these may be seen in any case of diffuse alveolar hemorrhage (DAH). The radiological differential diagnosis for DAH would primarily include congenital heart disease, especially mitral stenosis and vasculitis like Goodpasture’s syndrome, granulomatosis with polyangiitis, systemic lupus erythematosus, rheumatoid arthritis, celiac disease, etc. Gomez-Roman had classified DAH syndrome in three groups: (1) pulmonary capillaritis with positive ANCA; (2) bleeding caused by immune deposits; and (3) drug reactions, infections, and idiopathic conditions. Pulmonary tuberculosis is a major differential diagnosis in endemic countries. Other additional conditions to be ruled out would be coagulation disorders, neoplasms, and rarer disorders such as pulmonary veno-occlusive disease and pulmonary capillary hemangiomatosis. Exposure to toxins like cocaine, pesticides, and insecticides may also present with similar radiological picture. Hence, adequate workup to rule out vasculitis, collagen vascular diseases, infections, and congenital heart diseases is warranted before diagnosing IPH. A clinicoradiological approach to pulmonary hemosiderosis has been outlined in ►Fig. 5.
Table 2 Laboratory findings on blood examination in iron deficiency anemia

| Test                        | Reference Range               |
|-----------------------------|-------------------------------|
| RBC count                   | Low (< 4 million/mm³)         |
| Hemoglobin                  | Low for age and gender (< 12 mg/dL for females, < 13 mg/dL for males) |
| Hematocrit                  | Low for age and gender (< 36% for females and 41% for males) |
| MCV                         | < 72 fL                       |
| MCH                         | < 27 pg                       |
| MCHC                        | < 30%                         |
| Peripheral smear            | Hypochromia, microcytosis, anisocytosis |
| Serum ferritin              | < 12 ng/mL                    |
| Serum iron                  | < 30 µg/dL                    |
| Total iron binding capacity | > 480 µg/dL                   |
| Transferrin saturation      | < 16%                         |
| RDW                         | > 14                          |

Abbreviations: MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell; RDW, red cell distribution width.

Systemic glucocorticoid is the drug of choice in the acute phase and has been found to limit the progression of fibrosis. Oral prednisolone 0.5 to 0.75 mg/kg/day is given for induction of treatment until pulmonary opacities on chest radiograph regress. The dose is then tapered accordingly and discontinued after around 18 to 24 months. Nonresponsive cases may be treated with immunosuppressive medication like azathioprine and hydroxychloroquine. A gluten-free diet is proposed in Lane-Hamilton syndrome. Trials of lung transplants have been unsuccessful due to the recurrence of bleed into the transplanted tissue. Overall, the prognosis is poor in children with mortality rate > 50% due to delay in diagnosis from lack of awareness of the entity and absence of classical triad. The most common cause of death is an acute or chronic respiratory failure due to massive alveolar hemorrhage or cor pulmonale, respectively.

IDA is the most prevalent nutritional deficiency globally with children in developing countries bearing most of the brunt. It is characterized by hypochromic microcytopenic blood picture and low hemoglobin count, MCV, MCH and MCHC, serum ferritin, serum iron, and transferrin saturation (~Table 2). Though the most common cause of IDA is nutritional, blood loss as an underlying cause should be considered in older children, especially when there is a poor response to oral iron treatment and the requirement of blood transfusion. A detailed clinical history may give clue to etiologies like the passage of worms in stool in parasitosis or menorrhagia in adolescent girls with von Willebrand factor deficiency. Occult gastrointestinal bleeding and bleeding disorders have to be ruled out primarily. Occult stool blood may be positive in cases of Meckel’s diverticulum, gastrointestinal polyp, peptic ulcer, inflammatory bowel disease, intestinal hemangioma or vascular malformations. Other rare but significant causes to be assessed are pulmonary hemosiderosis and malabsorption from celiac disease or chronic diarrhea. A simplified approach to pediatric IDA has been outlined in ~Fig. 6.

Conclusion

IPH in children often has a severe disease course with a poor prognosis due to irreversible fibrosis and PAH that sets in. Early diagnosis of the condition with the institution of corticosteroid therapy alone or in combination with immunosuppressants, however, has shown a promising role during acute exacerbations and maintenance therapy of IPH. Treatment of anemia is only supportive and detection of the underlying cause of blood loss is the key to accurate management of pediatric IDA. Hence, awareness of the condition, systematic approach to IDA, and high clinical suspicion with early referral for thoracic imaging is essential for prompt detection of pediatric IPH, as hemoptysis is not a consistent feature in children.

Funding

This study has not received funding/sponsorship of any sort, including study design, collection, analysis, and interpretation of data, writing of the report, decision to submit the paper for publication.

Conflict of Interest

There are no conflicts of interests, real or perceived, among authors.
