Abstract

Metal ions play important biological roles e.g.: activation or deactivation of enzymatic reactions and signal transduction. Moreover, they can stabilize protein structure, or even be actively involved in the protein folding process. Therefore, accurate treatment of the ions is crucial to model and investigate biological phenomena properly. In this work the coarse-grained UNRES (UNited RESidue) force field was extended to include the interactions between proteins and four alkali or alkaline earth metal cations of biological significance, i.e. calcium, magnesium, sodium and potassium.Additionally, chloride anions were introduced as counter-ions. Parameters were derived from all-atom simulations and incorporate water in an implicit manner. The new force field was tested on the set of the proteins and was able to reproduce the ion-binding preferences.
Keywords
proteins, metal ions, UNRES force field, protein-ion binding

Introduction

Approximately 40% of the protein structures deposited in the Protein Data Bank (PDB) contain one or more ions. In some cases these ions were introduced artificially to enable structure determination, nevertheless most of them play important biological roles e.g.: structure stabilization, activation/deactivation of enzymatic reactions and signal transduction. Therefore, accurate treatment of the ions is crucial to model biological phenomena properly.

The most abundant ions in proteins structures from the PDB are $Zn^{2+}$, $Mg^{2+}$ and $Ca^{2+}$. They have significant effect on the protein folding, stabilize the structure and are an integral part of numerous enzymes. If the cell environment is taken into account $Na^{+}$ and $K^{+}$ are the metal ions with the highest concentration. They take part in signal transduction. Alkali and alkaline earth metal ions have a relatively straightforward pattern of interactions, in contrast to, for example, transition-metal cations, that form coordinate chemical bonds with protein side-chain atoms. Therefore $Mg^{2+}$, $Ca^{2+}$, $Na^{+}$ and $K^{+}$ are going to be the main subject of this work.

These ions have different interaction preferences for coordinating groups that can be summarized as follows: for $Ca^{2+}$ Asp, Glu, Asn, Gln and oxygen from the main chain, for $Mg^{2+}$ Asp, Glu and oxygen from the main chain, and for $K^{+}$ and $Na^{+}$ oxygen from the main chain. In case of the two last ions the interactions are almost entirely electrostatic but the coordination geometry is essential.

The average concentration of these ions in free state in blood plasma are: 145 mM, $4\text{ mM}$, $1.5\text{ mM}$ and $1.8\text{ mM}$ for $Na^{+}$, $K^{+}$, $Mg^{2+}$, $Ca^{2+}$ respectively. Disturbed homeostasis of these macroelements can lead to many disorders and diseases, such as: insomnia, anxiety,
urolithiasis or cardiac arrhythmia. Moreover, there is evidence that altered \( Mg^{2+} \) and \( Ca^{2+} \) homeostasis may be related to the progression of neurodegenerative diseases associated with intrinsically disordered proteins (IDP): Alzheimer’s disease and Parkinson’s disease.

While investigating the protein-ion interactions, especially when one aims to obtain information about the dynamics, the use of the methods based on the all-atom force fields seems to be appropriate. The extensive review about metal ion modeling has been published, it covers various strategies in quantum mechanics, classical and polarizable force field methods. Generally, three ion models are frequently used: nonbonded, bonded and with dummy atoms. Those representations are used in many common software like: AMBER, CHARMM, and GROMOS. Unfortunately, the use of all-atom (AA) methods require high computational power, especially because most ion-binding proteins are often large multichain subunits. In this regard, coarse-grained (CG) models can be a good alternative. However, introduction of metal ions is a challenging task and this issue is often dismissed in CG representations. In one of the most popular CG force field MARTINI ions are represented as a Q type particle (charged interaction site). In case of single-atom ions the first hydration shell is considered as a part of CG representation. The MARTINI ion model is only qualitatively accurate and the force field itself is unable to model protein folding events.

Another example is SIRAH force field developed to treat proteins with explicit representation of water (WT4) composed by four linked beads and represents 11 tetrahedrally-coordinated water molecules. Hydrated ions: \( Na^+, K^+, Ca^{2+} \) and \( Cl^- \) are also considered explicitly, each extended ion particle comprising the actual ion and 6 water molecules corresponding to the first hydration shell. It has been used in the simulations of natively unfolded proteins and protein aggregation and has the ability to capture ionic strength effects.

The coarse-grained UNited RESidue (UNRES) force field was already successfully extended to treat calcium-protein interactions by deriving the interactions of the ion
with Asp, Glu, Asn and Gln side-chains and the peptide group. For the side-chains that do not interact with calcium specifically, simple excluded-volume potentials were introduced. The parameters of the potentials were obtained from potential-energy surfaces of model system: \( \text{Ca}^{2+} \)-acetate, \( \text{Ca}^{2+} \)-propionate, \( \text{Ca}^{2+} \)-acetamide, \( \text{Ca}^{2+} \)-propionamide, and \( \text{Ca}^{2+} \)-N-methylacetamide systems calculated by using \textit{ab initio} molecular quantum mechanics at the Restricted Hartree-Fock (RHF) level with the 6-31G(d,p) basis set. It should be noted that those calculations were performed \textit{in vacuo} and obtained potentials of mean force (PMFs) were divided by water dielectric constant. Thus, these potentials do not incorporate interactions with solvent and cover only the interactions only with carbonyl groups.

In this article we extended the UNRES force field to investigate the interactions between proteins and four alkali and alkaline earth metals of biological significance, i.e. calcium, magnesium, sodium and potassium. Additionally the parameters for chloride ion were also included. The neutrality of the system is not necessary while performing simulations with the UNRES force field but in case when one wants to represent the environment more accurately, especially under high ionic strength, they can be required.

The method of deriving the potentials was modified with regards to the one previously used for the calcium ion.\textsuperscript{25} The following two modifications were introduced. First, the new potentials were derived to incorporate interactions with solvent in an implicit manner and therefore the AA force field was used. Second, we considered all amino-acid side-chains and peptide group. Hence the corresponding modifications of the calcium ion-protein interaction center potentials were also recalculated. Introduced potentials have been tested based on the known structures of proteins with bound metal ions.
Methods

UNRES force field

In the coarse-grained UNRES model \(^{22-24}\) a polypeptide chain is described by two geometry points per residue namely: \(C^\alpha\) atom and the geometrical center of each side-chain (SC). Moreover, there are two types of interaction sites: peptide group (p), which is positioned halfway between consecutive \(C^\alpha\) atoms and geometrical center of a side-chain. The peptide groups are modeled with spheres whereas side-chains are ellipsoids of revolution along the longer axis (Fig. 1). It should be noted that the \(C^\alpha\) atom is not a center of interaction and acts only as a geometric center. The effective energy function is represented by restricted free energy (RFE) or potential of mean force (PMF) of a given conformation ensemble restricted to coarse-grained conformation defined by \(C^\alpha\) and SC atoms and is expressed by (eq. 1): \(^{26}\)

\[
U = \sum_{i<j} U_{SCiSCj} + \sum_{i \neq j} U_{SCiSCp} + \sum_{i<j-1} U_{V^{WDW}_{p,p}} + \sum_{i<j-1} U_{\text{el}^2(T)} + \sum_{i} U_{\text{b}(\theta_i)} + \sum_{i} U_{\text{rot}(\theta_i, \alpha_{SC}, \beta_{SC})} + \sum_{i} U_{\text{bond}(d_i)} + \sum_{i} U_{\text{corr}^3(T)} + \sum_{i} U_{\text{turn}^3(T)} + U_{\text{ion-ion}} + U_{\text{ion-prot}}
\]

where the \(U_i\)'s are energy terms, \(\theta_i\) is the backbone virtual-bond angle between three consecutive \(C^\alpha\) atoms, \(\gamma_i\) is the backbone virtual-bond-dihedral angle between four consecutive \(C^\alpha\) atoms, \(\alpha_i\) and \(\beta_i\) are the angles defining the location of the center of the united side-chain of residue \(i\) (Fig. 1) with respect to \(C^\alpha_{i-1}\), \(C^\alpha_i\) and \(C^\alpha_{i+1}\) plane, \(d_i\) is the length of the \(i\)th virtual bond, which is either a \(C^\alpha \ldots C^\alpha\) virtual bond or \(C^\alpha \ldots \text{SC}\) virtual bond. \(^{24,25}\)

Each energy term is multiplied by an appropriate weight, \(w_x\), and the terms corresponding to factors of order higher than 1 are additionally multiplied by the respective
temperature factors that were introduced in paper\textsuperscript{22} and which reflect the dependence of the first generalized cumulant term in those factors on temperature, as discussed in refs \textsuperscript{22} and \textsuperscript{27}. The factors $f_n$ are defined by (eq \textsuperscript{2}).

$$f_n(T) = \frac{\ln [\exp(1) + \exp(-1)]}{\ln \{\exp \left[ (T/T_o)^{n-1} \right] + \exp \left[ -(T/T_o)^{n-1} \right] \}}$$  \hspace{1cm} \text{(2)}$$

where $T_o = 300$ K.

The term $U_{SC_iSC_j}$ represents the mean free energy of the hydrophobic (hydrophilic) interactions between the side chains, which implicitly contains the contributions from the interactions of the side chain with the solvent. The term $U_{SC_iP_j}$ denotes the excluded-volume potential of the side-chain – peptide-group interactions. The peptide-group interaction potential is split into two parts: the Lennard-Jones interaction energy between peptide-group centers ($U_{p_ip_j}^{VDW}$) and the average electrostatic energy between peptide-group dipoles ($U_{p_ip_j}^{el}$); the second of these terms accounts for the tendency to form backbone hydrogen bonds between peptide groups $p_i$ and $p_j$. The terms $U_{tor}$, $U_{b}$, $U_{rot}$, and $U_{bond}$ are the virtual-bond-dihedral angle torsional terms, virtual-bond angle bending terms, side-chain rotamer, and virtual-bond-deformation terms, respectively; these terms account for the local properties of the polypeptide chain. The term $U_{corr}^{(3)}$ represent correlation or multibody contributions from the coupling between backbone-local and backbone-electrostatic interactions, and the term $U_{\text{turn}}^{(3)}$ are correlation contributions involving 3 consecutive peptide groups; they are, therefore, termed turn contributions. The term $U_{\text{ion-ion}}$ represents the ion-ion interactions with parameters as in our previous work\textsuperscript{25} (charge of each ion was adjusted appropriately). The term $U_{\text{ion-prot}}$ represents the ion-polypeptide-chain interactions (details of obtaining and verifying this term are described in the next parts of this paper).
Determination of the Potentials of Mean Force for protein-ion interactions

To obtain the PMFs from which the effective energy terms accounting for protein-ion interactions ($U_{ion}$) were derived, simulations of the pairs consisting of the ion and the model of the UNRES interaction center (Tab. 1) were performed with the all-atom ff14SB force field from AMBER16 package. Each system was placed in a cuboid box containing TIP3P water molecules and counter-ions in order to maintain electroneutrality were added if needed. For $Ca^{2+}$ and $Mg^{2+}$ the multisite ion model, where the total charges are distributed into n-dummy centers that are placed in the direction of the coordinating atoms (n=7 for $Ca^{2+}$ and n=6 for $Mg^{2+}$), were used. The simulations of systems with $Na^+$, $K^+$ and $Cl^-$ were performed with the nonbonded-ions models available in AMBER package. The size of the box was set to ensure minimal distance of 12 Å between any atom in our system and the edge of the box. For each system Umbrella Sampling (US) simulations were performed with different harmonic-restraint potentials imposed on the distance between the centers of the mass of each particle. The distances varied from 2 Å to 12 Å, and were sampled every 1 Å.

The simulation procedure consisted of four steps: (1) minimization of the starting structure with restrain at 12 Å distance (for 4000 steps of steepest descent and 3500 steps of conjugate gradient); (2) heating of the system with restrain at 12 Å distance until it reached 300 K (NVT, 20 ps, dt=0.002); (3) equalibration of the system for each of the given harmonic restraints value (NPT, 1000 ps, dt=0.002); (4) molecular dynamic of the system at the given harmonic restraints value (NPT, 10000 ps, dt=0.002). To determine the PMFs of the systems studied, we processed the results of all restrained MD simulations by using the weighted histogram analysis method (WHAM) to remove the bias from restraints.
Analytical expressions for the energy of interaction of ions with polypeptide chain

The two types of the UNRES interaction sites cover the 19 amino-acids (as Gly has no side-chain) and the peptide group. They can be divided into three categories, taking into account their physicochemical properties that are responsible for the nature of interaction with the ions: charged interaction sites (Asp, Glu, Arg, Lys), polar interaction sites (peptide group, Ser, Thr, Asn, Gln, Cys, His, Tyr) and hydrophobic sites (Ala, Val, Ile, Leu, Met, Phe, Trp, Pro). Hereby, the following three combinations of analytical expressions for energy interaction of ions with polypeptide chain were used.

For the interactions of the ion with the charged sites, both negatively and positively, the following expression were used:

$$E_{\text{charged-ion}} = E_{\text{GB}} + \Delta F_{\text{cav}} + E_{\text{el}} + e_{\text{gb}} \quad (3)$$

where $E_{\text{GB}}$ is the van der Waals energy term for two ellipsoids expressed as the Gay-Berne-type potential, $\Delta F_{\text{cav}}$ is the cavity term which accounts for the difference between the free energy of hydration of the side-chain-ion pair and the sum of the free energies of the isolated components, $E_{\text{el}}$ is Coulombic term, and $e_{\text{gb}}$ is generalized Born potential.

The expression for the ion-polar sites interactions is defined by:

$$E_{\text{polar-ion}} = E_{\text{GB}} + \Delta F_{\text{cav}} + E_{\text{pol}} + E_{\text{cp}} \quad (4)$$

where $E_{\text{pol}}$ is the polarization energy, and $E_{\text{cp}}$ is charged-polar term.

For the hydrophobic group the expression is defined by:

$$E_{\text{hydrophobic-ion}} = E_{\text{GB}} + \Delta F_{\text{cav}} \quad (5)$$

The general analytical expressions with which the effective energy of the interactions
of the ions considered in this study are approximated are shown below.\textsuperscript{32-34} The variables describing the geometry of an UNRES interaction site and an ion are illustrated in Fig. 2.

The Gay-Berne potential\textsuperscript{35} is expressed by the equation:

\begin{equation}
E_{GB} = 4\varepsilon_{ij} \left[ \left( \frac{\sigma_{ij}^0}{r_{ij} - \sigma + \sigma_{ij}^0} \right)^{12} - \left( \frac{\sigma_{ij}^0}{r_{ij} - \sigma + \sigma_{ij}^0} \right)^{6} \right]
\end{equation}

where $r_{ij}$ is the distance between the center of mass of united side-chain or peptide-group model and ion, $\varepsilon_{ij}$ is the van der Waals well-depth for a given orientation of the two interaction sites, $\sigma_{ij}$ is the distance corresponding to the zero value of $E_{GB}$ for arbitrary orientation of the particles, and $\sigma_{ij}^0$ is the distance corresponding to the zero value of $E_{GB}$ for the orientation where $\theta_{ij} = 90^\circ$. The dependence of the $\varepsilon_{ij}$ and $\sigma_{ij}$ on the orientation of the interacting sites is given by eqs. (7-9)

\begin{equation}
\varepsilon_{ij} = \varepsilon_{ij}^0 \left[ 1 - \chi_{ij}^{(1)} \omega_{ij}^{(1)2} \right]^2
\end{equation}

\begin{equation}
\sigma_{ij} = \sigma_{ij}^0 \left[ 1 - \chi_{ij}^{(1)} \omega_{ij}^{(1)2} \right]^{-1/2}
\end{equation}

\begin{equation}
\omega_{ij}^{(1)} = \cos \theta_{ij}^{(1)}
\end{equation}

where $\chi_{ij}$ is the van der Waals interaction anisotropy, $\chi_{ij}'$ is the anisotropy of the van der Waals depth, and $\varepsilon_{ij}^0$ is the van der Waals depth of the potential energy minimum for the orientation where $\theta_{ij} = 90^\circ$. The fitting parameters are: $\sigma_{ij}^0, \varepsilon_{ij}^0, \chi_{ij}, \chi_{ij}'$.

To account for the interactions with solvent, a cavity term was introduced:\textsuperscript{32,33}

\begin{equation}
\Delta F_{cav} = \frac{\alpha_{ij}^{(1)} \left[ (x \cdot \lambda)^{1/2} + \alpha_{ij}^{(2)} x \cdot \lambda - \alpha_{ij}^{(3)} \right]}{1 + \alpha_{ij}^{(4)} (x \cdot \lambda)^{12}}
\end{equation}

with
\[ x = \frac{r_{ij}}{\sqrt{\sigma_i^2 + \sigma_j^2}} \]  

(11)

\[ \lambda = \left[ 1 - \chi''_{ij}(1) \omega_{ij}^{(1)2} \right]^{1/2} \]  

(12)

where \( \alpha_{ij}^{(1)} \), \( \alpha_{ij}^{(2)} \), \( \alpha_{ij}^{(3)} \), and \( \alpha_{ij}^{(4)} \) are coefficients, \( \sigma_i^2 \) and \( \sigma_j^2 \) are the deviation of the Gaussian distribution of the solute density for particles \( i \) and \( j \), respectively, and \( \chi''_{ij}(1) \) is the anisotropy pertaining to the cavity term. The fitting parameters are: \( \alpha_{ij}^{(1)} \), \( \alpha_{ij}^{(2)} \), \( \alpha_{ij}^{(3)} \), \( \alpha_{ij}^{(4)} \), \( \chi''_{ij}(1) \) and \( \sigma = \sqrt{\sigma_i^2 + \sigma_j^2} \).

The polarization energy originated in the deformation of the charge distribution of the side-chain or peptide group by the ion is expressed by the equation:

\[ E_{pol} = 332 \left( \frac{1}{\varepsilon_{in}} - \frac{1}{\varepsilon_{out}} \right) \left( \frac{\alpha_{ji}^{pol}}{f_{GB}(r_{ji}')} \right)^4 \]  

(13)

with \( f_{GB} \) being the generalized Born function:\(^{36}\)

\[ f_{GB}(r_{ji}') = \sqrt{r_{ji}'^2 + a_ia_j \exp \left(-\frac{r_{ji}'^2}{4a_ia_j} \right)} \]  

(14)

where the coefficient 322 is there to express the energies in kcal/mol, \( \varepsilon_{in} \) and \( \varepsilon_{out} \) are the effective dielectric constant of the "inside" of the interacting particles and the solvent (equal to 80 for water), respectively, \( \alpha_{ji}^{pol} \) is the polarizability of the nonpolar part of the particle \( i \), \( a_i \) and \( a_j \) are the Born radii of particles \( i \) and \( j \), and \( r_{ji}' \) is the distance between the interacting "head" of a side chain or peptide group and ion. The fitting parameters are: \( a_i, \varepsilon_{in}, \alpha_{ji}^{pol} \) and \( d_{\text{head}} \).

The generalized Born term is expressed by equation:

\[ e_{gb} = 332 q_i q_j \frac{D}{f_{GB}(r_{ji}')} \]  

(15)
with

\[ D = \frac{1}{\epsilon_{in}} - \frac{exp(-\kappa f_{GB}(r'_{ij}))}{\epsilon_{out}} \]  

(16)

where \( \kappa \) is Debye screening length. The fitting parameters are: \( \kappa \) and \( a_i, \epsilon_{in} \) and \( d_{head} \).

The Coulombic term is expressed by the equation:

\[ E_{el} = 332 \left( \frac{q_1 q_2}{\epsilon_{in} r'_{ij}} \right) \]  

(17)

where \( q_1 \) and \( q_2 \) are the charges of particles \( i \) and \( j \), respectively. The fitting parameters are: \( \epsilon_{in} \) and \( d_{head} \).

The charged-polar term is expressed by equation:\textsuperscript{34}

\[ E_{cp} = w_\perp \cdot \frac{q \cdot \cos \theta_{ij}}{r'_{ij}^2} - w_\parallel \cdot \frac{q^2 \cdot \sin \theta_{ij}^2}{r'_{ij}^4} \]  

(18)

where \( w_\perp \) and \( w_\parallel \) are fitting parameters, and \( r'_{ij} \) is a distance between the ion and the center of the amphiphilic head group of side-chain or peptide-group. The fitting parameters are: \( w_\perp, w_\parallel \) and \( d_{head} \).

The approximate analytical expressions for ion-interaction-site energy functions were fitted to the PMF calculated numerically for each ion-interaction-site system by means of a nonlinear least-squares Marquardt method. The similar procedure was used before in introducing the potentials for protein-DNA interaction into UNRES force field\textsuperscript{34} Subsequently, the obtained expressions were compatibly added to the already existing UNRES energy function.
Verification of the protein-ion potentials

Simulation procedures

The developed coarse-grained model of polypeptide-ion interaction was tested to predict the ion-binding sites on five proteins listed in Tab. 2.

A set of multiplexed replica exchange simulations (MREMD) were performed in temperatures 260 K, 272 K, 279 K, 284 K, 288 K, 291 K, 294 K, 298 K, 308 K, 322 K, 341 K, 370 K. The temperature set was adjusted with the algorithm developed by Trebst et al. which maximizes the walk of replicas in temperature. For each temperature 4 replicas were calculated. Every simulation took 10 mln steps with a time step equal to 4.89 fs. The periodic boundary conditions were used with the cubic boxes edges length equal to 150 Å. The simulations were started from the experimental structures from the Protein Data Base (PDB) - including the position of ions. This starting point is sufficient because the MREMD allows to enhance probing of the conformation space and ions are able to dissociate and bound again to the protein. For analysis, only the second half of trajectories were considered. During the simulation temperatures were exchanged between trajectories every 10000 steps, therefore to obtain the correct ensemble properties reweighing was performed with the bin-less Weighted Histogram Analysis Method (WHAM), which was implemented in UNRES and described in earlier work. Subsequently, the five most populated clusters were obtained with the use of Ward’s minimum variance method in the temperature 280 K.

The simulations in higher ion concentrations were performed for the systems where ions dissociate permanently after starting from the PDB structure. It was the case for two proteins: 2Z2K and 5E56, and used concentrations were 55 mM and 70 mM respectively. For this test counter-ions were used but the rest of the procedure was the same as the one described above.

In the last test association binding constants of $\text{Ca}^{2+}$, $\text{Mg}^{2+}$, $\text{Na}^{+}$ and $\text{K}^{+}$ to the $\alpha$-
lactalbumin were computed and compared to experimental values. For this purpose the molecular dynamic simulations were performed for the 1F6S\textsuperscript{41} protein with the ion ($Ca^{2+}$, $Mg^{2+}$, $Na^+$ or $K^+$) bound in the native position. The 200 independent trajectories were run at 293 K, each last for 5 mln steps with time step equal to 4.89 fs. The periodic boundary conditions were the same as in two other tests.

**Analysis**

For simulations starting from the experimental structure the following analysis was performed. First, the representative structure for each cluster (the conformation with the lowest RMSD to cluster average structure) was determined and the TM-score was calculated in order to check its quality.

Subsequently, the distances averaged over all structures for ion from its starting placement for every cluster were calculated. Normalized histograms of those distances were also prepared.

Moreover, the contact maps for ions and particular amino acid side-chains averaged over all structures were prepared for each cluster and compared with the corresponding experimental structure. The scoring function ($S_{i,j}$) for the contact between any C$^\alpha$ atoms and ion ($d_{i,j}$) is defined as follows:\textsuperscript{42}

$$S_{i,j} = \begin{cases} 
0 & \text{for } d_{i,j} > 12 \\
\frac{12-d_{i,j}}{4} & \text{for } 8 \leq d_{i,j} \leq 12 \\
1 & \text{for } d_{i,j} < 8
\end{cases}$$ (19)

Root-mean square fluctuation (RMSF) was used to analyze the fluctuation of C$^\alpha$ atoms in each cluster. As a reference structure the cluster representative was taken.

For simulations with higher ion concentration the cluster representatives were also verified by TM-score. Then the radial distribution function (RDF) for the distances between
ions and protein were calculated.

In order to calculate the binding constants the concentration of unbound states as a function of time averaged over all 200 trajectories were calculated for each system. An unbound state was defined as a structure where ions were further than 8 Å from any C\(^\alpha\) atom of the protein. Subsequently, function expressed by eq. 20 was fitted with the use of the nonlinear least-squares (NLLS) Marquardt-Levenberg algorithm\(^\text{43}\) implemented in the GNUPLOT program (http://www.gnuplot.info).

\[
[E](t) = 2[E]_0 k_{-1} \left( \frac{1 - \exp(-tW)}{k_{-1}(1 - \exp(-tW)) + W(1 + \exp(-tW))} \right) \tag{20}
\]

where \(E[t]\) is the concentration of unbound ion and \(W\) is expressed by:

\[
W = \sqrt{k_{-1}^2 + 4k_1k_{-1}[E]_0} \tag{21}
\]

The eq. 20 is derived based on the method used in.\(^\text{44}\)

Results and discussion

Obtained Potentials of Mean Force and fitted functions

The PMFs, fitted analytical energy functions and parameters are presented in SI (Fig. SI 1-15 and Tab SI 1-3). The strongest interactions appeared for the systems containing ions: Ca\(^{2+}\) and Mg\(^{2+}\), and side-chain models for: Asp, Glu (Fig. SI 3A-D and Fig. SI 6A-D). This is reasonable as there is the strongest Coulombic interaction for oppositely charged molecules. Those two ions strongly interact also with Asn, Gln and the peptide-group models (Fig. SI 2 G-J,O-P and Fig. SI 5 G-J,O-P). For K\(^+\) and Na\(^+\) the strongest interaction is observed for Asp and Glu side-chain models (Fig. SI 9 A-D and Fig. SI 12 A-D). As in case of Ca\(^{2+}\) and Mg\(^{2+}\) the strongest interactions are observed for oppositely charged
molecules. The next strongest interactions are for the peptide-group model (Fig. SI 8 O-P and Fig. SI 11 O-P), Asn and Gln models (Fig. SI 8 G-J and Fig. SI 11 G-J) and weaker for His model (Fig. SI 8 K-L and Fig. SI 11 K-L). For all metal ions also weak interactions for Ser model (Fig. SI 2 A-B, Fig. SI 5 A-B, Fig. SI 8 A-B, Fig. SI 11 A-B) and Thr model (Fig. SI 2 C-D, Fig. SI 5 C-D, Fig. SI 8 C-D, and Fig. SI 11 C-D) were observed. Those patterns are mostly in agreement with the information collected from the PDB analysis. As for Cl$^-$ the interactions are observed for Arg and Ser models only (Fig. SI G-H and Fig. SI 14 A-B) but because of their weak character they are represented by even weaker CG potentials.

**Simulations on the test proteins set**

Probabilities and population sizes of each cluster, TM-score for cluster representative and average ion displacement are presented in Tab. 3. The probabilities and population sizes of each cluster represent satisfactory distribution of obtained structures. The TM-score shows that at least one cluster in each system has in about the same fold (the value is greater than $\sim 0.5$).

Normalized histograms of distances between the predicted ion placement and the one in the native structure are in Fig. 3. As assumed, even for the metal ions that strongly interact with the protein, the ion was able to dissociate from the molecule during the simulation (panels A and B). Whereas for the rest of the ions the broader distances are represented (panels C, D and E) indicating weaker interactions.

The contact maps for ion-protein interactions (Fig. 4) and structures (Fig. 5) are presented for proteins 6EKG, 4AQO and 4RJ9 because only for those systems contacts occur (Fig. 3).

The best prediction of ion placement was determined for 4AQO protein with Ca$^{2+}$, especially for the third and fifth clusters with average ion displacements 6.52 Å and 2.99 Å, respectively (Tab. 3). The quality of predicted binding sites can be verified based on contact maps (Fig. 4) where the prediction of the amino-acid side-chains that interact with
$Ca^{2+}$ is in very good agreement with the experimental data. Moreover, the structure of the representative of the cluster with the best prediction (cluster III, based on contact maps) compared with the experimental structure is presented in Fig. 5.

$Mg^{2+}$-binding protein (6EKG) strongly interacts with ion (Fig. 3) but based on average ion displacements (Tab. 3) and contact maps (Fig. 4) the predicted binding sites are different from the experimental one. The best prediction is the structure form cluster IV and is presented in Fig. 5.

High-quality prediction was also obtained for $K^+$ (4RJ9) but only in the least populated cluster. For this protein the maps for two $K^+$ were shown in Fig. 4 where weak but correct contacts can be observed. The best prediction (the structure form cluster V) is presented in Fig. 5.

The worst predictions were obtained for the interactions with $Na^+$ and $Cl^-$ (proteins 5E56 and 2Z2K, respectively), where ion dissociate from the protein and do not bind to the protein again (Fig. 3 D and E).

RMSF plots are presented in SI (Fig. SI 16). Shaded areas indicate the amino acid residues that are in contact with the ion in the native structure. The lowest fluctuations are observed for 5E56 protein (Fig SI 16 D) meaning the structures in each cluster are the most similar to each other. For the rest of the systems fluctuations are higher but still showing the similarities in each cluster. Only for 4AQO protein the highest fluctuations can be observed for the region where ion bounds.

The results from simulations in high ion concentration are presented in Fig 6 A. It can be seen that neither $Cl^-$ nor $Na^+$ interact with protein. For comparison RDF for the simulations that were started from the experimental structures (low ion concentrations) were calculated for $Ca^{2+}$ and $K^+$ (Fig 6 B). The strong interactions with both ions can be observed.

The plots of concentration of unbound states of bovine $\alpha$-lactalbumin as a function of time and curves (eq. 20) fitted to those data are in Fig SI 16. The calculated and
experimental equilibrium binding constant are in Tab 4. Despite the fact that qualitatively binding affinities are not reproduced the tendency of binding affinity is in agreement for the simulations and experiment with the strongest binding for \( Ca^{2+} \) then \( Mg^{2+} \), \( Na^+ \) and \( K^+ \), respectively.

Conclusions

The new approach to simulate the protein-ion interactions in a CG representation was reported in this work. We implemented \( Ca^{2+} \), \( Mg^{2+} \), \( Na^+ \), \( K^+ \) and \( Cl^- \) within the formalism of the physics-based UNRES model. Parameters were derived from AA simulations and incorporate water in an implicit manner. It is important to remember that the results can be at best of the same quality as the ones obtained by the method used to derive the new potentials.

We were able to predict the binding site of \( Ca^{2+} \), \( Mg^{2+} \) and \( K^+ \) and the strongest interaction were observed for \( Ca^{2+} \) and \( Mg^{2+} \). As for the simulations of \( Na^+ \) and \( Cl^- \) no interactions with protein were observed. Based on the PDB analysis\(^1\) \( Na^+ \) (and to some extent \( K^+ \)) with water molecules around often appear in the bulk solvent in the crystal structure, or with a small number of protein oxygen atoms around them. The interactions are likely to be very labile and would not be expected to persist in the solution,\(^1\) and our simulations reflect that.

Moreover, we were able to reproduce the experimental tendency of binding of the metal ions to bovine \( \alpha \)-lactalbumin that again verified the strongest affinity for \( Ca^{2+} \) and \( Mg^{2+} \).

Therefore, the new potentials allow to represent approximate interaction sites for \( Ca^{2+} \), \( Mg^{2+} \) and \( K^+ \). They also can be applied to reproduce the labile interaction pattern for \( Na^+ \) and \( K^+ \).
Supplementary information

The supplementary information contains the PMFs, fitted analytical energy function, parameters, plots of RMSF of $C^\alpha$ atoms in each cluster for protein test set and plots of concentration of unbound structures of 1F6S and metal ions over time with fitted kinetic curves.

Declarations

Competing Interests:

The authors declare no competing interests

Funding

The funding for this work was obtained from the National Science Centre (Poland): UMO-2016/21/N/ST4/03154 (to AGL).

Availability of data and material

The datasets generated during and analysed during the current study are available from the corresponding author on reasonable request.

Code availability

The code is available through GIT: git://mmka.chem.univ.gda.pl/unres4 as UCGM branch

Authors’ contributions

AGL gave the main idea, performed the AA simulation, fitted the analytical expressions for $K^+$, performed and analyzed the test of the method, and prepared the manuscript. AMA
fitted the analytical expressions for $Cl^-$ and $Na^+$. PW fitted the analytical expressions for $Ca^{2+}$ and helped with the Introduction section of the manuscript. AW fitted the analytical expressions for $Mg^{2+}$. SAS helped with the AA simulations. AKS helped with implantation into UNRES software, performed the analysis for kinetic constants and helped with the rest of data analysis. All authors read and revised the final version of the manuscript.

Acknowledgement

The funding for this work was obtained from the National Science Centre (Poland): UMO-2016/21/N/ST4/03154 (AGL). Computational resources were provided by (a) the Informatics Center of the Metropolitan Academic Network (IC MAN) in Gdańsk, and (b) the Interdisciplinary Center for Mathematical and Computer Modeling in Warsaw (ICM), grant GA76-18 (c) our 682-processor Beowulf cluster at the Faculty of Chemistry, University of Gdańsk.
