Summary

We developed a rapid detection method for *Legionella pneumophila* (**Lp**) by filtration, immunomagnetic separation, double fluorescent staining, and flow cytometry (**IMS-FCM method**). The method requires 120 min and can discriminate ‘viable’ and ‘membrane-damaged’ cells. The recovery is over 85% of spiked **Lp** SG 1 cells in 1 l of tap water and detection limits are around 50 and 15 cells per litre for total and viable **Lp**, respectively. The method was compared using water samples from house installations in a blind study with three environmental laboratories performing the ISO 11731 plating method. In 53% of the water samples from different taps and showers significantly higher concentrations of **Lp** were detected by flow cytometry. No correlation to the plate culture method was found. Since also ‘viable but not culturable’ (VNBC) cells are detected by our method, this result was expected. The IMS-FCM method is limited by the specificity of the used antibodies; in the presented case they target **Lp** serogroups 1–12. This and the fact that no **Lp**-containing amoebae are detected may explain why in 21% of all samples higher counts were observed using the plate culture method. Though the IMS-FCM method is not yet fit to completely displace the established plating method (ISO 11731) for routine **Lp** monitoring, it has major advantages to plating and can quickly provide important insights into the ecology of this pathogen in water distribution systems.

Introduction

Members of the bacterial genus *Legionella* are water-borne pathogens and parasites of aquatic protozoa (Fields, 1996), which can be found in soil (Fliermans *et al*., 1981) and ubiquitously in water (Dufour *et al*., 2003). *Legionella* spp. (**Ls**) consists of more than 50 species and 65 serogroups (Fields *et al*., 2002). **Ls** are able to infect pulmonary cells through inhalation of aerosols (Gao *et al*., 1998) and thus present a health threat. Since their favoured growth temperatures lie in the range of 20–45°C, man-made installation systems, such as showers, air conditioners, and cooling towers are of major concern (Fields *et al*., 2002). *Legionella pneumophila* (**Lp**) is the causative agent of 50–90% of all infections (Breiman and Butler, 1998; Yu *et al*., 2002; Yáñez *et al*., 2005; Pravinkumar *et al*., 2010), though most **Ls** are potentially human pathogens (Alli *et al*., 2003; Palusińska-Szyysz and Cendrowska-Pinkosz, 2009). In 2011 the incidence recorded by the Swiss mandatory surveillance system was 3.2 cases/100 000 inhabitants (BAG, 2012). The incidence shows an upward trend with an average lethality of 6.6% (BAG, 2009).

The gold standard for the detection of **Ls** are presently plate culture methods, in Europe most prominently ISO 11731 (ISO, 2004), which take up to 10 days for a result. Repeatedly, ring trials revealed high inter-laboratory volatility for the plating methods (Boulanger and Edelstein, 1995; Bentham, 2000; Napoli *et al*., 2009; Lucas *et al*., 2011). One of the reasons for this might be that **Lp** can enter the ‘viable-but-not-cultivable’ (VNBC) state (Allegra, *et al*., 2008), which results in a major drawback for all cultivation-dependent methods. Furthermore, when plating **Ls** from water the number detected is not proportional to the sampling volume, since the distribution of **Ls** appears to be not homogeneous in water samples (Schafer, 2007). One reason for this may be amoeba carrying **Ls** (Oliver, 2010).
**Results**

**Spiking experiments**

Since we demonstrated previously that *Lp* quantification by FCM and IFM agree very well (Füchslin *et al.*, 2010), the spiking counts were determined by FCM. When applying our gating approach for spiked tap water samples it was possible to discriminate *Lp* cells very well from background signals in the main fluorescence dot plots, i.e., green versus blue fluorescence (Fig. 1), coupled to two different polyclonal antibodies and thus minimizing the risk for cross-reactions. Membrane-damaged and thus potentially dead cells are discriminated by an additional PI-staining and the time to result is only around two hours.

---

*Fig. 1.* Labelling concept for *Legionella pneumophila* (*Lp*) serogroups 1–12. *Lp* cells are labelled with two polyclonal antibodies targeting *Lp* serogroups 1–12 conjugated to two different dyes and excited by two different lasers (405 and 488 nm). For the capture of cells by magnetic separation, a super paramagnetic particle is bound to the FITC molecule through a FITC-specific antibody. Propidium iodide is employed for discrimination of membrane-damaged cells.

---

Ls detection using polymerase chain reaction (PCR) methods is frequently hampered by inhibitory compounds like humic acids, which are present in environmental samples (Palmer *et al.*, 1993). Such factors lead to reduced sensitivity, false negative results and higher limits of detection (LOD) (Tourn-Bodilis *et al.*, 2011). In most protocols not only cellular but also free and dead cell DNA is amplified, which leads to false-positive amplification (Fields *et al.*, 2002) and makes interpretation of data difficult (Krojgaard *et al.*, 2011).

Faster methods for *Lp*-detection based on immunofluorescent microscopy (IFM) were reported with variable recoveries of 25–75% (Edelstein, 1987; Palmer *et al.*, 1993), where also the successful application of viability stains was demonstrated (Delgado-Viscogliosi *et al.*, 2005). Also, several studies employing fluorescent in situ hybridization (FISH) to DNA, mRNA or rRNA (Buchbinder *et al.*, 2002; Declerck *et al.*, 2003; Dutil *et al.*, 2006; Dittommaso *et al.*, 2010; Whiley *et al.*, 2011) demonstrated the successful detection of total or viable *Lp* in environmental samples. However, low signal intensity, long overnight incubations (Hambsch *et al.*, 2010) and low photostability of the dyes were reported (Declerck *et al.*, 2003), leading to false negative results and, hence, only qualitative interpretation of results (Dittommaso *et al.*, 2010). Despite recent advances in instrumentation and image analysis tecnology, all microscopy-based methods are tedious, time-consuming (Hambsch *et al.*, 2010), require highly skilled laboratory personnel, and are known to generate variable results due to, e.g., viewer fatigue (Garcia and Shimizu, 1997). Consequently, the potential of these methods for routine use is considerably reduced.

Solid phase cytometry-based assays address these issues by automated counting of stained cells collected on membrane filters (Aurell *et al.*, 2004; Parthuisot *et al.*, 2011). However, this technique is hampered by low sensitivity (Hambsch *et al.*, 2010) and low throughput of a maximum of 15–20 samples per day (Aurell *et al.*, 2004) due to the time-consuming and often difficult manual validation of potentially identified targets (Aurell *et al.*, 2004; Vanhee *et al.*, 2009). Also the scanning procedure may fail completely due to low signal intensity (Hambsch *et al.*, 2010). Furthermore, it was shown that the obscuration of organisms on a filter by debris and other particles may lead to false negative results (Keserue *et al.*, 2011).

Flow cytometry (FCM) was already used 30 years ago for *Lp* detection. These first approaches, however, had very high LODs of 10^3 to 10^6 cells per litre (Tyndall *et al.*, 1985; Lebaron *et al.*, 1998). More recently, FCM-based approaches reached detection limits as low as 500 cells per litre, but high background signals, not well discriminated cell clusters, high counts of false-positives and lacking information about physiological state are some of the drawbacks of these methods (Füchslin *et al.*, 2010; Taguri *et al.*, 2011). Recently, the usefulness of propidium iodide (PI)-based discrimination of live and dead *Lp* cells was demonstrated in combination with FCM (Allegra *et al.*, 2008).

In this study, we developed an improved FCM-based method to detect and quantify total and viable *Lp* cells from tap water samples. It includes initial concentrating steps by filtration, re-suspension, followed by immuno-magnetic separation (IMS) of *Lp* cells to purify the samples. Detection by FCM is based on two fluorescent parameters, i.e. green and blue fluorescence (Fig. 1), coupled to two different polyclonal antibodies and thus minimizing the risk for cross-reactions. Membrane-damaged and thus potentially dead cells are discriminated by an additional PI-staining and the time to result is only around two hours.

The two-sided Pearson $r$ for both correlations is 0.9999. The method allowed to detect successfully cells at seeding levels of around 40 cells l$^{-1}$. A simple approach to estimate the limit of detection (LOD) was applied and consisted of adding three times the blank (background noise) standard deviation to the very same value (MacDougall and Crummett, 1980; McNaught and Wilkinson, 1997), leading to a LOD of 49.88 and 15.41 cells l$^{-1}$ for total and viable $Lp$ respectively ($P > 0.99$). By doubling these values the determination limits (statistically safe qualitative determination) can be estimated to be around 100 and 30 cells l$^{-1}$ and the quantification limits, calculated by tripling the LOD, were 150 and 45 cells l$^{-1}$ for total and viable $Lp$ (Deutsches Institut für Normung e.V., 2008).

For simplicity and added statistical confidence we considered 50, 100 and 150 cells l$^{-1}$ as detection, determination and quantification limit, respectively, for both viable and total $Lp$ quantification. The standard deviations for the method above the quantification limit are on average 5.9% and 5.1% for total and viable $Lp$, respectively (Table S1).
Detection of \( Lp \) in tap water samples

When detecting environmental \( Lp \) in water samples of contaminated distribution systems (Fig. 2C–F, Figs S3–S5), it was possible to discriminate well the \( Lp \) cluster from background signals. In contrast to the spiking experiments, strong background signals were often observed and environmental \( Lp \) cells sometimes appeared to be smaller than cultured ones, thus displaying less fluorescence intensity (Fig. 2D and E) than the latter.

When cells were heat-killed at 90°C for 1 min, a shift of the \( Lp \) cells over the threshold level for red fluorescence was observed (Fig. S4). This is due to the properties of the PI dye that can enter only cells with a damaged membrane resulting in an elevated red fluorescence signal.

Comparison of \( Lp \) detection by FCM versus plating

For comparison, a total of 85 drinking water samples from different taps and showers were analysed by both plating and FCM. Laboratories 1 and 2 provided 45 samples and applied the ISO 11731 method (ISO, 2004), whereas Laboratory 3 provided 40 samples and did plate 1 ml only. An overview of the results obtained is shown in Fig. 4.

As expected the FCM total \( Lp \) count was higher than that for viable \( Lp \) for each sample and usually both values were above the number of \( Lp \) colony-forming units. No correlation was observed between plating and FCM (Fig. S7).

Positive or negative agreement of FCM and plating results were defined to be below or above 1000 counts l\(^{-1}\), respectively, since this value is recommended in Switzerland and other countries as a threshold level for initiating measures against \( Lp \) (BAG, 2009). Using this threshold, an agreement of 62% and 60% was obtained for total and viable \( Lp \) cells, respectively (Table 1). The Cohen’s \( k \)-values were in the 0.2 range, indicating poor strength of agreement. Since both methods, FCM and plating, display false-negative results, and high deviations of results obtained by plating are known from interlaboratory comparisons (Lucas et al., 2011), it seems not appropriate to consider plating as the reference method. Thus using this value as the ‘real’ \( Lp \) result for calculating specificity and sensitivity for the FCM approach would not lead to a correct assessment of this method.

Quantification agreement

For comparing the quantification we took into consideration the FCM determination limit, the high plating de

\[
\text{Table 1. Comparison of positive and negative results for FCM and plating of } Lp.
\]

| Culture | FCM total \( Lp \) | | |
|---|---|---|
| Positive | 22 | 15 |
| Negative | 17 | 31 |

| Agreement | FCM viable \( Lp \) | | |
|---|---|---|
| Positive | 17 | 20 |
| Negative | 14 | 34 |

The threshold discriminating between positive and negative results is 1000 counts per litre. This is the level of contamination recommended for intervention in several countries.

D

0.5 log higher (18%) samples of these laboratories the plating result was significantly higher. For laboratory 3 this ratio was 23 (58%) for significantly higher FCM and 10 (25%) for higher plate count results, respectively. Since the results (FCM/Plating ratio) of the three laboratories did not significantly differ (tested was lab 1 + 2 versus 3, two-tailed; Mann–Whitney test: P = 0.31; independent samples Student’s test: P = 0.16), they were combined in Table 2.

Statistical comparison of the methods
An overview of the total cell count (TCC) and the viable cell count (VCC) obtained by FCM for all samples is shown in Fig. 5. They were statistically compared with results of plating and of the FCM detecting total and viable Lp (Table 3). As expected, viable and total cells in general, and total and viable Lp correlated very well. Furthermore, we encountered some correlation of TCC and VCC versus Lp plating (Pearson r = 0.425 and r = 0.357, respectively) (Table 3).

When comparing the values of Lp plating and FCM versus TCC and VCC, it appeared that most of the higher and alarming values (> 1000 Lp counts l-1) were found when TCC values were in the range from 10^6 to 10^9 cells l-1 (Fig. S8).

We compared the viable fraction of Lp and total bacteria and found the mean viable fraction of bacterial cells to be very similar, namely 57.3 ± 20.3% of the Lp and

56.8 ± 14.8% of the total bacteria were viable according to membrane integrity. The linearization function (y = −0.2255x + 69.699) displayed a poor fit and a negative slope (R^2 = 0.096, Fig. S9) indicating a slightly negative correlation of these two parameters.

Discussion
We recently reported the suitability and good performance of similar IMS approaches for separation of Giardia and Cryptosporidium from tap and surface waters (Keserue et al., 2011; 2012) and separation of Lp from buffer (Füchslin et al., 2010). In this study we could greatly enhance the performance of the detection compared with the latter study. Accordingly, the presented method performed excellently in spiking experiments with tap water. Since our FCM procedure involves the combination of different parameters, a positive signal has to fulfil many conditions and thus, many background signals are eliminated and a high noise reduction is achieved. For both, total and viable Lp counts, recoveries exceeded on average 80% with standard deviations of around 10% and a low number of false positives. This shows that only a very small fraction of Lp cells possibly became damaged at the membrane level during our procedure and, therefore, this effect can be neglected for interpreting the results.

For about half of the tap water samples the counts measured by the plate culture method were significantly lower (Δ > 0.5 log) than FCM quantification. There are a number of reasonable explanations why the plating is in most cases lower than the FCM measurement. The typical high plating volatilities mentioned above might be

Table 2. Agreement of quantification for Lp plating and FCM detection.

| Plating versus | FCM higher | Plate higher | Positive agreement | Negative agreement |
|----------------|------------|-------------|--------------------|--------------------|
| FCM total Lp   | 45%        | 16%         | 15%                | 9%                 |
| %              | 53%        | 19%         | 18%                | 11%                |
| FCM viable Lp  | 40%        | 18%         | 15%                | 12%                |
| %              | 47%        | 21%         | 18%                | 14%                |

Quantification with a difference of > 0.5 log and > 100 counts for laboratories 1 and 2 and > 0.5 log and > 1000 counts for laboratory 3 is considered to not agree. These conventions were chosen since the plating volatility is generally very high and for results from laboratory 3 the detection limit is 1000 cfu l-1.
one reason for this observation. In a proficiency testing scheme for US laboratories that culture *Ls* from tap water samples the cfu ml⁻¹ was underestimated by 1.25 ± 0.78 logs on average (Lucas *et al.*, 2011). Another important reason why cultivation methods may underestimate bacterial numbers is that ‘viable but not culturable’ (VNBC) state cells cannot be quantified by plating. It was shown that non-culturable *Ls* cells can be detected by FCM and resuscitated by co-culture with amoebae (Allegra *et al.*, 2008). Furthermore, Allegra and colleagues demonstrated the development of resistance of *Lp* to high temperatures and the persistence of VNBC cells to a 30 min heat treatment at 70°C (Allegra *et al.*, 2011). In addition, the used antibodies were not extensively tested against similar species and, therefore, cross-reactions cannot be excluded. It was also reported decades ago that only a limited number of polyclonal antibodies to *Lp* is available and that most of them have not been tested vigorously for their sensitivity and specificity (Orrison *et al.*, 1983); we are not aware that this has changed substantially since then. As we used two different antibodies and the binding of antibodies to a non-target cell would need to be similarly strong and the distribution would have to resemble that for *Lp* in order to be quantified by our gating regime, we doubt that cross-reactions did impair our overall measurement. Of course, this highly selective gating strategy bears the risk of missing some true positive cells; however, the spiking experiments revealed a high recovery, hence, this effect cannot be very pronounced.

A number of reasons can account for higher GVPC plate counts compared with FCM (~ 20% of cases); these include: (i) the used antibodies bind only to *Lp* Sg 1–12, thus, if *Lp* belonging to the remaining serogroups (*Lp* Sg 13–16) were present they would not have been quantified. Since the commercial serotyping agglutination kits discriminate only between *Lp* 1, *Lp* 2–15 and *Ls* it was not possible to check for the presence of these serogroups. In South Korea, these rare serogroups were identified from water samples in 1.4–2.6% of cases (Lee *et al.*, 2010). (ii) Similar colonies of other species may be quantified as *Lp* in the plating evaluation as not every colony is subjected to the agglutination tests. (iii) Also the before mentioned arithmetical inconsistency of plating different volumes may lead to overestimation, notably when plating only 1 ml (Schaefer, 2007). (iv) In samples with high iron oxide content, which is occasionally visible by a colouring of the filter membrane, an increased SCC signal of the target cells may result that might shift these signals outside the gating region and, thus, lead to false-negative results. An acid treatment or magnetic separation before filtration might help to avoid this. Alternatively, a simpler gating strategy without using the SCC signal could circumvent this difficulty. (v) Free-living amoebae (FLA) are abundant in drinking water systems and since *Lp* is an amoeba-resisting microorganism (ARM) (Thomas and Ashbolt, 2010), *Lp* can replicate within the FLA and subsequently return into the water. Hsu and colleagues found 26.6% of *Lp* positive samples to contain FLA-intracellular *Lp* in spring water (Hsu *et al.*, 2011). Thus, the presence of *Legionella*-containing amoebae, which will neither be destroyed nor quantified by the FCM assay, but may very well be detected by the plating approach, may lead to an underestimation of *Lp* cells by FCM.

We did not find a correlation of FCM *Lp* versus plating or TCC and VCC. Surprisingly though, we observed a weak correlation between TCC and VCC versus the *Lp* plating.

Only very rarely we found plating and FCM *Lp* numbers to be above 1000 counts l⁻¹ with TCC and VCC values up to 10⁹ cells l⁻¹. This may point to a need for future research to analyse correlation of these parameters and to estimate *Lp* growth potential relative to the total bacterial numbers (Fig. S8).

Furthermore, the results show that *Lp* viability does not correlate with total cell viability and thus *Lp* may profit from higher levels of other dead cells (Fig. S9). Results pointing towards necrotrophic growth were observed before (Temmerman *et al.*, 2006).

The few results presented here already illustrate the great potential of our method to investigate and understand the behaviour of this pathogen in its environmental and man-made habitats. A further optimization of the

described method could help to overcome some of its present weaknesses. An improved method should include the possibility to destroy FLA and release the \( Lp \) cells present in these protozoa; it also should be based upon specific antibodies targeting the appropriate species and serogroups and should not be dependent on the SSC. The limitations of the antibodies caused by the limited range of serogroups may be overcome by using a pool of antibodies, e.g., either covering all \( Lp \) serogroups, or even all \( Ls \). In the future antibody alternatives may provide improved binding properties and cost reduction (Stumpf and Amstutz, 2007; Chung et al., 2011).

The method developed and tested in the present study might not yet be fit to completely displace the plating methods used in laboratories for routine water analysis. However, it allows to quantify cultivable and VBNC state cells, thus offers the possibility to describe disinfection measures, to study physiological different viability states during disinfection processes, and to follow the survival and growth behaviour of \( Lp \) in water supply systems in more detail. This justifies studies for further improvement, which may finally lead to acceptance of this new approach to detecting and quantifying Legionella in water. When all the current drawbacks can be overcome, a fast, cost-effective, potentially automatable and high throughput method will be available for routine application.

**Experimental procedures**

ِLEGIONELLA PNEUMOPHILA CULTIVATION

*Legionella pneumophila* SG1 (ATCC 33152, Oxoid, Hampshire, UK) was cultivated on buffered charcoal yeast extract (BCYE) agar plates (obtained ready-poured from Oxoid, Pratteln, Switzerland) at 37°C. After at least 5 days of incubation, cells from one single colony were inoculated into 50 ml of a BCYE broth (10 g l\(^{-1}\) of yeast extract and 0.2 g l\(^{-1}\) activated charcoal (one tenth of the original concentration; Feeley et al., 1979; Edelstein, 1982) with one tenth of the original charcoal concentration of 0.2 g l\(^{-1}\) and BCYE growth supplement (Oxoid). The batch culture was incubated on a shaker at 150 r.p.m. for at least 3 days at 37°C. Then 100 \( \mu \)l of culture was transferred into 0.9 ml of sterile filtered phosphate-buffered saline (PBS, 9.0 g l\(^{-1}\) NaCl, 1.62 g l\(^{-1}\) \( \text{Na}_2\text{HPO}_4\cdot2\text{H}_2\text{O}, 0.36 \text{g l}\(^{-1}\) \( \text{K}_2\text{HPO}_4\), pH 7.2) and diluted as required for spiking experiments with the same buffer.

**Spiking experiments**

Tap water samples of 1 l used for spiking experiments were collected in 1 l screw-cap glass bottles from a well-frequented tap in the laboratory of the Federal Office of Public Health (FOPH, Bern, Liebefeld) having an outlet temperature above 55°C. Under these conditions, we found the samples to be virtually \( Ls \)-free with both the plating (< 10 \( Ls \) l\(^{-1}\) with GVPC; BCYE with glycine, vancomycin, polymyxin and cyclohexamide selective medium), and the FCM detection method. After the water temperature had dropped below 30°C, the water samples were spiked with 100 \( \mu \)l of PBS containing a defined amount of cells determined by FCM (see below).

**Pre-treatment of samples for method comparison experiments**

Samples for \( Ls \) detection were obtained from three different routine laboratories that are regularly testing water samples for clients maintaining large inhabited facilities. Samples were primarily obtained from buildings where \( Lp \) were recently found, in order to obtain a larger number of presumably positive results.

Laboratory 1 performed the standard ISO 11731 (ISO, 2004) method. Samples were collected in sterile 2 l screw-cap bottles and mixed after sampling. After the laboratory had withdrawn 1 l of the sample, the remaining litre was stored at 4°C and transported to the FOPH and FCM analysis was performed within 4–24 h after sampling.

Laboratory 2 performed the standard ISO 11731 method as well. Samples were collected in sterile 2 l screw-cap bottles and mixed after sampling. After the laboratory had withdrawn 1 l for the ISO method, the remaining litre was filtered through a hydrophilic 0.22 \( \mu \)m polycarbonate track-etch-membrane filter (PCTE, Sterilitech Corporation, Kent, WA, USA) and suspended in 15 ml centrifugation tubes in 4–5 ml of PBST (PBS + 0.05% Tween 20; Fluka). These tubes were then sent cooled to the FOPH. FCM analysis was thus performed 24–48 h after sampling.

Laboratory 3 performed a shortened adaptation of ISO 11731, where simply 1 ml of sample is split into two 0.5 ml aliquots and plated directly onto two GVPC plates. The detection limit of this approach is 1000 cfu l\(^{-1}\). Samples were collected in sterile 1 l screw-cap bottles and mixed after sampling. The remaining samples were transferred uncooled to the FOPH and further processed 6–12 h after sampling.

All laboratories confirmed up to 5 \( Lp \) colonies per plate by latex agglutination according to ISO 11731.

**Filtration**

After pre-filtration of the water samples through a 30 \( \mu \)m nylon mesh filter (Millipore AG, Zug, Switzerland), water samples were subsequently vacuum-filtered through a hydrophilic 0.22 \( \mu \)m pore size PCTE filter (Sterilitech). The filter was then carefully removed and re-suspended in a 50 ml centrifugation tube, containing 3 ml of sterile PBST and 10 \( \mu \)l 15% BSA (bovine serum albumin, Sigma, Steinheim, Germany) by strong vortexing.

**Bacterial cell staining**

The total flow cytometric bacterial cell concentration (TCC) and total number of \( Lp \) in pure cultures was determined as described by Hammes and colleagues (2008). Briefly, 1 ml of sample was stained with 10 \( \mu \)l SYBR Green I working solution (≈10 000 stock solution diluted 100-times in DMSO, Invitrogen, Zug, Switzerland) and incubated in the dark at 30°C for 15 min.

For the viable flow cytometric cell concentration (VCC) we added to 1 ml of sample 10 \( \mu \)l of PI solution (30 mM)
dissolved in DMSO (Invitrogen) together with the SYBR Green as for the TCC (Berney et al., 2008).

Specific Lp antibody-staining

To the re-suspended sample (3 ml; 4–5 ml for laboratory 2) we added 1.2 mg of fluorescein isothiocyanate (FITC) conjugated polyclonal IgG rabbit antibodies (Cat. No. ab20818, Abcam, Cambridge, UK). After incubation for 20 min at ambient temperature in the dark, 10 μl of superparamagnetic anti-fluorescein isothiocyanate (FITC) Microbeads (Miltenyi Biotech GmbH, Bergisch Gladbach, Germany) and 2 mg of anti-Legionella pneumophila rabbit polyclonal antibody (Cat. No. GTX40943, Genetex, Irvine, CA, USA) conjugated to Pacific Blue was added. The conjugation of the antibody was performed using a Pacific Blue protein labelling kit according to the recommendations of the manufacturer (Cat. No. P30012, Molecular Probes, Basel, Switzerland). The assay was then incubated for 40 min at 4°C.

For the positive controls, cells spiked into PBS were stained in the same way and then counted by FCM as described later. This approach has shown excellent correlation and agreement to IFM and is, therefore, appropriate for preparation of the seeding aliquots (Füchslin et al., 2010).

Immunomagnetic separation (IMS)

Immunomagnetic separation using MACS™ MS columns (Miltenyi Biotech) was conducted according to the recommendations of the manufacturer. The whole sample (3–5 ml) was run through the column after placing the column in the separator magnet. Subsequently, the column was rinsed in succession with 3 ml of PBS, 3 ml of PBST and 3 ml PBS. Recovery of the collected cells was conducted after removal of the column from the magnet by flushing 1 ml PBS through the column into a 15 ml Falcon tube by firmly applying the provided plunger.

FCM detection

Flow cytometric detection was performed with a Partec CyFlow ML flow cytometer (Partec GmbH, Münster, Germany) equipped with a 200 mW blue solid-state laser emitting light at 488 nm and a 110 mW violet diode-laser emitting at 405 nm. The volumetric counting properties of the flow cytometer measure the events in 200 μl of sample volume and extrapolate the results to 1 ml of sample volume. Optical filters were adjusted to measure green fluorescence at 520 nm, red fluorescence at 630 nm and the sideward scatter (SSC) at 488 nm emitted from spot one, i.e., excited by the blue laser. For the second spot, excited by the violet laser, the optical filters were set to measure the sideward scatter at 405 nm and the blue fluorescence at 460 nm. The trigger was set on green fluorescence. Events were defined based on sideward scatters (488 and 405 nm), fluorescence emitted at 455 nm and 520 nm. The 630 nm fluorescence signal was used to discriminate PI-positive and PI-negative cells.
A typical result obtained with environmental \textit{Lp} cells in tap water is shown in Fig. 2. Results were acquired by plotting green fluorescence against both sideward scatter (Fig. 6A and B), blue fluorescence against sideward scatter (Fig. 6D and E), blue versus red fluorescence (Fig. 6F), and green versus blue fluorescence (Fig. 6C). The \textit{Lp} clusters were gated in Fig. 6A, B, D and E by gates R1–4 and combined to a multigate G1, requiring a valid event to lie inside all 4 gates. In order to discriminate viable from dead cells the gate R5 was set in Fig. 6F as a red fluorescence threshold for PI-negative cells. A box plot and polygonal gate was chosen for better visualization as compared with a histogram with a range gate. Thus, for viable \textit{Lp} quantification, gate G1 and R5 were combined as Gate G2.

For counting, gate R6 was then set around the \textit{Lp} cluster on the main fluorescent parameters box plot, green versus blue fluorescence (Fig. 6C) and the gate G1, for total \textit{Lp} or the gate G2 for viable \textit{Lp} was applied.

The specific instrumental gain settings used for 520 nm, 455 nm, 630 nm, SSC 488 nm and SSC 405 nm channels were 300, 440, 500, 180 and 500, respectively. The speed rate was 3, implying a counting rate of less than 1000 events s$^{-1}$.

The TCC and VCC were measured and gated as described previously (Berney et al., 2008; Hammes et al., 2008).

Acknowledgements

This work was supported by research grants of the Federal Office of Public Health (grant number FOPH 08.000086) and EAWAG. Thanks go to Dr A. Auckenthaler for initiating this study. We thank the laboratories participating in this study for their effort. Especially, we want to thank Dr Ralf Maibusch (Stadtlab Bern), Dr Paul Svoboda and Dr Jill Engelmann (Kantonales Laboratorium Basel-Land, Liestal), Frau Matilde Mauerhofer (Bactlab AG, Bern-Liebefeld), and Dr Guido Vogel and Dr Valentin Pflüger (Mabritec AG, Riehen).
