I. INTRODUCTION

Measurements of the nuclear composition and of the antimatter fraction of cosmic rays (CR) are one of the main tools to understand their origin. Because the propagation of charged CRs in the turbulent component of the Galactic magnetic field is diffusive up to energies \( E/Z < 10^{17} \text{eV} \), properties as the average injection spectrum of CRs or the diffusion tensor and its energy dependence have to be determined indirectly. The quality of these measurements has been improved in the last years considerably, for instance by the determinations of the intensity of CR protons and He performed by the PAMELA collaboration \cite{2}. In particular, the PAMELA collaboration found a slope change of the CR spectrum, which is difficult to explain in the simplest models \cite{3}. Similar deviations from a pure power-law even below the knee region were found using gamma-ray observations of selected molecular clouds in the Gould belt \cite{4, 5}.

Previously, the PAMELA collaboration measured the positron fraction together with a “standard” antiproton fraction in Ref. \cite{10}: Secondaries created by hadronic interactions in the shock vicinity participate in the acceleration process and therefore it was suggested that they have a flatter energy spectrum than primary CRs. In Ref. \cite{10}, it was estimated that the resulting positron fraction can explain the PAMELA excess and increases up to 50\%, while subsequently this mechanism was applied to antiprotons in Ref. \cite{11} and to the B/C and Ti/Fe ratios in Refs. \cite{12}.

The present work examines the acceleration and production of nuclei in SNRs. Following closely in spirit our previous studies \cite{13, 14}, we use a Monte Carlo (MC) approach calculating the trajectory of each particle individually in a random walk picture. This makes it easy to include interactions and the production of secondaries. As our main result, we predict a flat B/C ratio in the source vicinity, without a rise at high energies. At Earth, the additional contribution from SNRs to the secondary fluxes only flattens the B/C ratio but does not lead to a rise in the high energy limit. Consequently, an increase in the antiproton-proton ratio cannot be explained by astrophysical models and could be used as a signature of DM. This prediction can be tested soon by the AMS-2 collaboration \cite{15}, which aims at a 1\% accurate measurement of the flux of different nuclei up to energies of \( \text{TeV/nucleon} \) \cite{16}.

II. SIMULATION PROCEDURE

As we are following closely the approach presented already in Refs. \cite{13, 14}, we recall only briefly our methodology. We model trajectories by a random walk in three dimensions with step size \( l_0(E) \) determined by an energy-dependent, isotropic diffusion coefficient \( D \). We assume as usual in the test particle approach that the diffusion of a nucleus with charge \( Z \) and momentum \( p \) proceeds in the Bohm regime,

\[
D = \frac{c l_0}{3} = \frac{c R_L}{3} = \frac{c^2 p}{3 Z e B},
\]

where \( B \) denotes the turbulent magnetic field. Then the mean free path \( l_0 \) is given by the Larmor radius \( R_L \), which in turn is determined by \( R_L = p/(ZeB) \). Thus the step-size \( l_0 \) and the time step \( \Delta t = l_0/c \) is controlled by \( p/Z \).

As a draw-back of our Monte Carlo approach, the step-size in the random walk decreases therefore as \( l_0 \propto 1/Z \),
reducing larger computing time for nuclei with higher charges Ze. Therefore we restrict our analysis to relatively light nuclei, concentrating on the B/C ratio.

We do not consider any feedback of CRs on the shock or the magnetic field. As the strength of the magnetic field is assumed to change from a phase of amplification to damping, we use two models for the time evolution of the magnetic field B: In the first case, we use a constant turbulent magnetic field with B = 1 μG during all the evolution of the SNR. As the second choice, we assume strong field amplification in the early phase, with B = 100 μG before the transition to the Sedov-Taylor phase at t = 240 yr, and subsequent damping to B = 1/20 μG at t > t∗.

For the position rsh and the velocity vsh of the SNR shock we use the n = 0 case of the analytical solutions derived in Ref. [17]. These solutions connect smoothly the ejecta-dominated phase with free expansion rsh ∝ t and the Sedov-Taylor stage rsh ∝ t2/5. The acceleration of CRs is assumed to cease after the transition to the radiative phase at the time tmax. We use an age-limited scenario for the CR escape where most CRs are accumulated downstream and are released at tmax. The SNR is modeled by the following parameters: We choose the injected mass as Mej = 4M⊙, the mechanical explosion energy as Eexp = 5 × 1051 erg, and the density of the ISM as nISM = 2 cm−3. The end of the Sedov-Taylor phase follows then as tmax = 13,000 yr. We model the injection rate proportional to the CR pressure [18].

\[
\dot{N} \propto R_s^2 v_{sh}^\alpha \delta(E - E_0)\delta(r - r_{sh}) \tag{2}
\]

with α = 3. We choose the isotopes according to the source abundances of Ref. [1] and inject isotopes up to A = 20. Lifetimes for radioactive isotopes are taken from the database [19]. We use for the simulation of nuclear reactions the cross sections and decay tables extracted from GALPROP which in turn are based on Refs. [20, 21].

We describe the propagation of cosmic rays in the Galaxy with the help of the Galprop code [1][22]. More specifically, we consider plain diffusion, neglecting re-acceleration process and fixing all relevant parameters, like the normalization and the energy-slope of the diffusion coefficient, from a fit to HEAO data [23] to both primary and secondary nuclei in the 1 ÷ 30 GeV range.

### III. NUMERICAL RESULTS

In Fig. 1, we show the energy dependence of the B (10B + 1H) and C (12C + 13C) spectra E^2 dN/dE at tmax for the two cases of magnetic field evolution. For a constant magnetic field, the spectra dN/dE of both primary and secondary CRs are well approximated by an E^−2 shape\(^1\). The corresponding B/C ratio shown in Fig. 2 by the solid line remains constant up to the acceleration cutoff: Because the energy per nucleon E/A in a spallation reaction is approximately conserved and the simple relation E/Z ≃ 2E/A holds, the rigidity E/Z of the reaction products stays approximately unchanged. Hence, the acceleration process is not influenced by the conversion of, say, a 12C into a 10B nuclei. The secondary nucleus follows the same trajectory in a given magnetic field configuration as its parent would do, if no conversion took place. As a consequence, the boron and carbon spectra as function of energy per nucleon have practically identical shapes, with their relative normalization determined.

\(^1\) The small “bump” near the acceleration cutoff E_{max} \sim \text{few} \times 10^{13} \text{GeV} is formed by the small overdensity of the most energetic CRs in the acceleration zone, as discussed in more detail in [14].
FIG. 3: Diffuse intensity of Boron (red dashed) and Carbon (red solid) at the position of the Earth for the constant (left panel) and time-dependent (right panel) magnetic field case. Additionally, in the left panel the B and C intensity including only secondary production in the ISM are shown by black dot-dashed and black dotted lines respectively. Experimental data: HEAO [23] - filled circles, CREAM [24] - open squares, TRACER [25] - filled squares.

FIG. 4: The B/C ratio as a function of energy per nucleon at the position of the Earth for the constant (red solid) and time-dependent (blue dashed) magnetic field case; the green dot-dashed line shows the B/C ratio including only secondary production in the ISM. Experimental data: HEAO [23] - filled circles, ATIC [26] - open stars, CREAM [27] - open squares, and TRACER [25] - filled squares.

approximately by the interaction depth in the SNR: The latter is given by \( \tau = c t_{\text{max}} R_{\text{ISM}} \sigma_C \approx 0.01 \) assuming \( \sigma_{C \rightarrow B} \approx 50 \text{ mbarn} \) as typical value for the fragmentation cross section of a carbon nuclei into boron.

In the second model for the magnetic field evolution, the spectral shape is more complicated: Nuclei that were injected early are accelerated up to few \( \times 10^{15} \text{ ZEV} \), while the bulk of CRs injected when the turbulent magnetic field is damped has a cutoff around \( 10^{12} \text{ ZEV} \). However, due to the conservation of the rigidity by the spallation process, the energy spectra of B and C are remarkably similar: The B/C ratio is again energy-independent and coincides with the one obtained for the case of a constant magnetic field—as it should, since the interaction depth is the same in the two cases. Thus, our conclusion on the energy-independence of the primary to secondary CR ratios is of general character, being independent of a particular scenario for the source magnetic field.

As the next step, we calculate the CR propagation in the Galaxy using the Galprop code, and compare in Fig. 3 the resulting B and C intensity at Earth with experimental data. For the spatial diffusion coefficient in the Galaxy, we used \( D_{xx}(E) = D_0(E/10 \text{ GeV})^{0.65} \), with \( D_0 = 4.8 \times 10^{28} \text{ cm}^2/\text{s} \). In the left panel of Fig. 3, we show additionally the B and C intensity including only secondary production in the interstellar medium (ISM), i.e. neglecting the SNR contribution to the B intensity. The SNR contribution to the Boron intensity remains small in the whole energy range considered, independent of the models used for the magnetic field evolution in the SNR. At Earth, the obtained B/C ratio shown in Fig. 4 coincide with the pure propagation results up to \( \sim \) few \( \times \) 100 GeV/nucleon; at higher energies the ratios slowly flatten to the per cent level, i.e. to the respective source value.

IV. CONCLUSIONS

We calculated the energy spectra of nuclei in the B-C group and their secondaries produced in a supernova remnant (SNR) using a simple random walk picture. In contrast to a previous prediction [12] that the B/C ratio rises sharply above energies \( \sim \) TeV/nucleon, we found that the...
ratio remains approximately constant in the vicinity of a source. Our results suggest that the contribution of SNRs to the intensity of secondary CRs is subdominant up to very high energies.

In our simulations we used an age-limited escape of CRs. Implementing a free-escape boundary may change our results, except if the boundary is placed at the distance $\propto E$. In particular, assuming the same position of the free-escape boundary for all energies will lead to a softening of the secondary spectra [28], lowering further the B/C ratio.

This prediction can be soon tested by the AMS-2 collaboration [15]. The absence of a rise in the B/C ratio would support the arguments of Refs. [13, 14] that reacceleration close to shock fronts in SNRs does not lead to a change in the secondary to primary ratios.

Acknowledgments

We are grateful to Ricard Tomàs for collaboration in the early stage of this project, and to Igor Moskalenko for advice on Galprop and comments on the text.
